Inpatients¹⁵⁰¹: AWOL; improvement clinically in absence of change in situational factors; partial alleviation¹⁵⁰² (may be seen as manipulative or complaining and so lose support); Qin ea (2005) found that hospitalised Danish suicides were associated with the periods just after admission¹⁵⁰³ and discharge, affective disorder, and brief hospital stay; Hunt ea (2009), apart from finding that the early post-discharge period was one of high risk for CS (43% occurred within 1 month and 47% of these died before first follow-up appointment), found risk (history of self-harm, primary diagnosis of affective disorder, a recent last contact with services and expressing symptoms at last staff contact, discharge AMA, and missing last appointment) and protective (involuntary status [for treatment] at last admission, enhanced aftercare) factors for CS

Insulin sensitivity¹⁵⁰⁴ (see Lawlor ea, 2003)

Intercountry adoption?

Internet advice¹⁵⁰⁵ on suicide and how to do it (cybersuicide)!(Biddle ea, 2008b; Coombes, 2008) A suicide video is available in Oregon.

¹⁵⁰⁰ The American Second Amendment in its Constitution preserves the right to bear arms but this dates from the early days of independence and the need for 'a well regulated Militia'. (Tushnet, 2008; Miller & Hemenway, 2008) Brady *Handgun Violence Prevention Act* (1994) in USA requires licensed firearms dealers to initiate check on background of people seeking to buy a handgun and to observe a waiting period between application and handgun delivery. However, as the 2007 Blacksburg (virginia) shootings amply demonstrated, it is easy to get a gun in the USA. (Anonymous, 2007) Firearms killed 30,143 people in the USA in 2005 (17,002 suicides, 12,352 homicides, 789 accidents) and wounded nearly 70,000. (Curfman ea, 2008)

¹⁵⁰¹ CS in psychiatric inpatients may have fallen during 1997-2003. (Kapur ea, 2006)

¹⁵⁰² Partial improvement as a factor in CS has been challenged by those who point out that suicidal tendencies wax and wane throughout a depressive episode.

¹⁵⁰³ Being off the ward with staff permission is a strong predictor of CS. (Hunt ea, 2007)

¹⁵⁰⁴ Possibly by lowering 5-HT and inducing depression.

¹⁵⁰⁵ E.g. *Alt Suicide* (ASH), *Satan Service*, and *Suicide methods.net*.

Location, e.g. high in deprived areas of Scotland/Scottish Highlands (highest alcohol consumption in Britain), (Boyle ea, 2005) Irish in Britain, Japan (school failure; Akita Prefecture has highest rate in Japan: Fushimi ea, 2006), New Zealand (failure to live up to 'macho' image and excel at rugby), some pockets in Hungary (possibly alcohol again¹⁵⁰⁶ – CS rate declined from 45.9/100,000 in 1984 to 31.7 in 1997 the decline being faster after 1990 when political changes began), and being Black or Native American in USA (alcohol and substance abuse, psychosis, depression and social loneliness in Native American Indians: Gaw, 2001, p. 33) – sex difference reversed in China (mainly young rural women according to Phillips R ea [2002] but older rural Chinese women also have an increased rate [Pritchard & Baldwin, 2002]); marriage was not protective against suicide among young rural Chinese women and being single but in a relationship is a risk factor for CS, religion/religiosity was not protective, and cultural conflicts (communism v Confucianism) and impulsivity were risk factors (Zhang ea, 2010); however, Tong and Philips (2010) found that suicide risk among urban residents with any mental disorder was more than double that of rural residents

Loneliness/social isolation/lack of social integration (Duberstein ea, 2004; Harriss ea, 2005); the effects of social fragmentation on CS rates are most marked in younger people (Whitley ea, 1999)

Low CSF 5-HIAA¹⁵⁰⁷ (probably relates more to impulsivity than CS per se; similar deduction from study of serotonin receptors in CS; low 5-HIAA (in impulsive violent criminals, arsonists and some violent alcoholics) and **HVA**; retrospectively, violent CS may be associated with lifetime history of aggression, impulsivity, substance abuse/dependence, and psychotic disorder (Dumais ea, 2005b)

Increased levels of 5-HT2A receptors, especially in prefrontal cortex¹⁵⁰⁸; other work suggests increase in 5-HT2A receptors in platelets, a reduction in 5-HT uptake, and less 5-HT transporter sites

Low cAMP binding to regulatory subunits of protein kinase A, as well as **reduced catalytic activity of protein kinase A**, in prefrontal cortex of CS victims who had suffered from major depression during life (needs to be replicated)

Low IQ (in Swedish males) (Gunnell ea, 2005) It has been stated that higher IQ may be a risk factor in people with schizophrenia. However, lower IQ may be a marker for liability to becoming a psychiatric patient in general and possibly having a personality disorder in particular (Urfer-Parnas ea, 2010)

Male sex (the classic case is the depressed older divorced male who does not practice his religion, drinks alcohol excessively, has no social supports, and suffers from a chronic painful immobilising physical illness; impulsivity in young males), despite the fact that females have a higher prevalence of depression. A Finnish prospective birth cohort study (Sourander ea, 2009) found that most males (but not females) who CS or made serious AS by adolescence/early adulthood had psychiatric problems by age 8 years (especially conduct disorder and internalising disorders)

Mania/bipolar affective disorder (BP) – BP at risk especially if young male, early phase of illness, abusing alcohol, and recently discharged from hospital¹⁵⁰⁹; suicide risk also increased in BP if in depressed phase, mixed state, or psychotic mania; absolute risk of CS for BP is about 193/100,000 (18 times the relative risk, i.e. compared to the general population), but 99,807 cases out of each 100,000 with BP will not kill themselves (Simon, 2008, p. 1638)

Media coverage of (a) suicides and (b) deaths of famous people (increased CS, especially female, in month following funeral of Princess Diana in UK – also increased parasuicide in females during same month); clustering of CS among mentally ill people may account for 10% of such cases (McKenzie ea, 2005)

Mefloquine (Lariam): antimalarial – rare reports of possibly-related suicidal ideation/CS - avoid/stop if history/emergence (depression, mood changes/instability, anxiety/panic attacks, confusion/restlessness-aggression-agitation/hallucinations/delusions), of psychiatric disorder (Irish Medicines Board, 2003)

¹⁵⁰⁶ Referring to the late 1980s, the historians Csorba ea (2003, p. 234) blame overwork and 'widespread alcoholism' as contributing to a low life expectancy in Hungary. Other writers refer to excess CS in both Finland and Hungary and, because these two populations share a single ethnic background, they suggest that this should be interpreted as a genetically determined phenomenon.

¹⁵⁰⁷ The 779C allele for tryptophan hydroxylase (TPH) gene (11p15-14) is associated with lower CSF 5-HIAA levels, again a finding that appears to correlate with impulsivity. (Nielsen ea, 1998)

¹⁵⁰⁸ There is evidence that recovered unipolar depression cases have increased 5-HT2A receptors (PET) and that this correlates with dysfunctional attitudes. (Bhagwagar ea, 2006) Individuals with TT/T or T/C genotype of the T102C polymorphism of the 5-HT2A receptor gene are more responsive to protective maternal nurturing than are those with the C/C genotype. (Jokela ea, 2007)

¹⁵⁰⁹ A study in Taiwan of CS among severely depressed patients (Lin ea, 2008) found that the mean number of days following discharge for CS was 29.9. Patients discharging themselves AMA were 2.85 times more likely to commit suicide than were those leaving hospital with the doctors' approval.

Miscarriage

Modern living, e.g. crime, illegitimacy, or low social cohesion with low marriage rates and increased marital separation rates (youth suicides)

Natural disasters (literature suggests some disasters such as hurricanes but not others such as storms – artifactual? – most people exposed to disaster do not develop PTSD or other mental disorder[Bromet & Havenaar, 2002])

Occupation, e.g. farmer (in ROI and UK), caring professions (doctors and nurses: Agerbo ea, 2007), low job status (Agerbo ea, 2007), taxi driver, chef, tradesman, unemployed; farmers may take too low a dose of antidepressant, have insomnia treated and depression missed, not be treated at all, lack a close confidant, have work/financial problems, and have firearms which they know how to use¹⁵¹⁰; job classification changes and Meltzer ea (2008) found in England & Wales that in 2001-5 male CS numbers were highest in construction workers and plant/machinery operatives but rates were highest in professionals and agricultural workers whereas in females administrative/secretarial had the highest numbers with the highest rates in health/sport and fitness

Pain, especially chronic (Fishbain ea, 1991)

Panic/anxiety – Brendel ea (2008, p. 734) suggest that up to 20% of people with anxiety disorders kill themselves and hold that anxiety disordered people have almost the same suicide risk as do people with major depression, but some of this increase is accounted for by co-morbid alcohol/substance abuse and depression

Perinatal circumstances – higher maternal parity, mother < 20 years old, non-professional parents, low birth weight (< 2500 g) (Riordan ea, 2006)

Personality disorder - perhaps half or more of cases; especially dissocial, of whom 5% commit suicide; 3-8% in borderline personality disorder; history of adolescent emotional instability and conduct problems in an adult; McGirr ea (2009) suggest that familial transmission of CS and major depression, while partially overlapping, are distinct, and that cluster B traits and impulsive-aggressive behaviour represent intermediate phenotypes of CS

Physician-assisted suicide/euthanasia (O'Shea, 2000d)

Positive DST (Coryell & Schlessner, 2001): survival analysis showed estimated risk for eventual CS was 26.8% if DST abnormal v 2.9% if DST normal

Primary affective disorders (PAD): CS rate 30 times general population rate; ultimate CS risk of 15% in PAD seems high (Inskip ea [1998] put it as low as 6%)¹⁵¹¹; very high in psychotic depression; depression is diagnosed in over half of elderly CS in psychological autopsy studies (Harwood, 2008, p. 559); no difference in CS between depressives with/without melancholic features (Kessing, 2003)

Prisoners (especially if on remand, first week in prison, in receipt of a long sentence, high violence index offence/convicted of serious offence, history of psychiatric contact or suicidality, on psychotropic medication, drug dependence, 30 years of age and older¹⁵¹², single-cell accommodation, availability of ligature points in cells; 54 attempts at suicide in Irish prisons in 1999 resulting in 6 deaths)¹⁵¹³ It should be noted that release (especially if recent) from prison is associated with an increase in CS (Pratt ea, 2006, 2010; Frater, 2008) although certain groups may be at particular risk, e.g. history of self harm or alcohol abuse or having a psychiatric diagnosis.

Puerperium (associated with psychiatric illness; less common than previously – in fact the rate may have fallen below general population!)

¹⁵¹⁰ To kill sick stock.

¹⁵¹¹ The exact figure is debatable, e.g. van Praag (2005) states that 15-19% of people who were ever hospitalised for depression commit suicide and lower figures are reported for depressed outpatients. Gelder ea (2006, p. 410) accept the 6% figure. According to Nierenberg ea (2001) the lifetime CS rate for severe major depression is 3-8%.

¹⁵¹² However, Fazel ea (2005) reported a real increase in English prison suicides, esp. in males aged 15-17. According to Frater (2008) the self-inflicted death rate in English prisons rose to 14.8 in 2002-3/100,000 prisoners, falling slightly to 11.1 in 2007-8. Prison suicides in England & Wales April 2002-March 2003 totalled 105 with 92 males and 13 females. Deaths from natural causes are also increased in prisoners. (Frater, 2008)

¹⁵¹³ Mullen and Lindqvist (2000) list certain factors likely to increase suicidal behaviour in prisoners: personality factors (hopeless, suspicious, non-trusting), history of self-damage, substances (intoxication/withdrawal), long sentence, guilt/self-blame, chronic painful or fatal disorders, and the environment (fear due to victimisation/intimidation, social isolation, lack of power to influence events, a spartan milieu, lack of meaningful activities/boredom, and humiliation). See also Fruehwald ea. (2004)

Religion (private faith more protective than external observance, and church attendance is more protective than denomination; differences between Catholic and Protestant countries might relate to gross domestic product; Muslim countries are said to have low rates (not all data support this and violent deaths may have an element of suicide attached: Pritchard & Amanullah, 2007), but countries with religious sanctions are less likely to return rates to WHO)(Koenig, 1999; Dervic ea, 2004); Buddhist teachings are not clear on morality of suicide and suicide as part of samurai code are among factors that may operate in Japan (McCurry, 2008)

Retired status

Risk-taking behaviour in adolescence, including sexual activity

Schizophrenia¹⁵¹⁴ Perhaps 10% kill themselves, but Inskip ea (1998) put it at 4%; low CSF 5-HIAA may be a factor

Severe mental illness, e.g. non-affective psychosis in the older male

Shorter hospital stays

Socio-economic groups I & V - In Denmark, with no private service, a history of mental illness plus affluence increases CS risk); European men of low socioeconomic status at greater risk for CS – this appeared less relevant for women (Lorant ea, 2005); Rehkopf and Buka (2006), in a systematic review, found inverse relationship between CS rates and area socio-economic position

Spinal cord injury (depression important; lack of social contact and unemployment; less severe injury: Geisler ea, 1983; De Vivo ea, 1999)

Stigma (reduces help-seeking)

Stillbirth

Substance abuse (complex association, e.g. with cannabis [Lynskey ea, 2004])

Suicide among close relatives (Qin ea, 2002) including spouse (Agerbo, 2003)

Teenage pregnancy/offspring of teenage mothers (Olausson ea, 2004; Ekéus ea, 2006)

Terminal illness

Unmarried motherhood (also increased mortality from violence and alcohol)

Veteran (military) status – white, more educated, activities limited by illness, normal weight (> overweight) (Kaplan ea, 2007)¹⁵¹⁵

Visual impairment, neurological disorders, and malignancy in elderly Swedes (Waern ea, 2002)

Women employed outside the home

Possibly decreasing

Antidepressants (Olfson ea, 2003; Gunnell & Ashby, 2004), especially in older adults (Stone ea, 2009)

Antipsychotic treatment (Tiihonen ea, 2006b)

Apathy/avolition, e.g. in some cases of schizophrenia (Kutcher & Chehil, 2007, p. 19)

Certain dates, e.g. Christmas Day; a general reduction before and during all holidays in USA

Children (independent of social class and education), e.g. Norwegian mothers less likely to kill themselves the more children they have – but loss of a child, especially during first month after loss, can increase risk Church support

Clozapine (not all sources agree – compare Sernyak ea, 2001; Meltzer, 2002; Meltzer ea, 2003; Duggan ea, 2003)

¹⁵¹⁴ The highest risk for suicide is soon after diagnosis and so CS rates may vary depending on when they are measured.

¹⁵¹⁵ Prospective population-based study in US – veterans twice as likely to kill themselves as non-veterans but just as likely to die from illness or ‘external’ causes (no increase in chances of being murdered or dying in an accident).

Collaborative therapeutic relationship and symptom improvement in BP (Ilgen ea, 2009)

Community psychiatric services (Pirkola ea, 2009)

ECT

Female sex

HAART for AIDS (Keiser ea, 2010)

Higher socioeconomic status (see O'Reilly ea, 2008)

Limiting pack sizes of paracetamol, salicylates and other **OTC drugs** following 1998 legislation in UK (Hawton ea, 2001a) and 2001 legislation in Ireland (Donohoe ea, 2006)

Lithium prophylaxis (even when affective disorder not controlled; possible anti-aggressive effect)(Kessing ea, 2005; Cipriani ea, 2005); suicidal behaviour occurs 2-3 times less often in patients on lithium compared to those on divalproex(Goodwin ea, 2003)

Lithium in drinking water (Ohgami ea, 2009)

Married/cohabitating, Married woman with children

Methadone (also use in overdoses)

Natural gas (replacing coal gas)

Parental support

Pregnancy

Student status

SSRIs?(Hall ea, 2003)

TCAs (higher prescribed doses have correlated with reduced suicidal behaviour)

Twins – this may reflect strong family ties(Tomassini ea, 2003)

War¹⁵¹⁶

Work

Neutral

TCAs

Increased antidepressant prescribing in Iceland 1975-2000.(Brugha ea, 2004;Helgason ea, 2004)

¹⁵¹⁶ **War and suicide:** Exceptions abound, e.g. police in Northern Ireland (New York City police do not have an increased suicide rate according to Marzuk ea, 2002), frontline soldiers at Stalingrad (the commanding general [Paulus] had to issue an order forbidding suicide as dishonourable: Roberts, 2009, p. 341), whole families in East Prussia during the Soviet advances e.g. see Hastings, 2004, p. 337; Davies, 2006, p. 342), diners in Dresden restaurant who were trapped after Allied bombing of February 1945.(Taylor, 2004, p. 352) and prisoners of war who seek death whilst trying to escape (suicide-by-escape: Roberts, 2009, p. 162). Suicide risk is increased among civilians exposed to 'friendly' bombardment (Beavor, 2009, p. 314) and inexperienced replacements in a combat zone (Beavor, 2009, p. 258). Jews who realised their role in organising fellow Jews for 'resettlement', civilians in France in 1940, (Vinen, 2006, p. 14) facing prosecution for war crimes (Stafford, 2007), monks burning themselves during the Vietnam War to make a politico-religious statement. However, the rate also fell during both world wars in non-belligerent countries like Switzerland. High rate of suicide in Sri Lanka during civil war where pesticides were readily available. Suicide declined briefly in Britain immediately following the crashing of 'planes into the Twin Towers in New York (Salib, 2003b) and following 7 July 2005 terrorist attacks in London.(Salib & Cortina-Borja, 2009) Suicide less likely among motivated paramilitaries.

Properly conducted trials in schizophrenia that use placebo (Storosum ea, 2003)

No urban/rural difference in Corcoran ea (2003)

Gestational age at birth¹⁵¹⁷ (Riordan ea, 2006)

Intellectual disability is not associated with an increase in CS (Simon, 2008, p. 1640)

Ovenstone and Kreitman (1974) divided suicides into a 'P' group comprised of sociopaths, drug addicts and alcoholics, were known to psychiatrists, were largely refractory to treatment, had long and unstable histories with chronic personal and social disorganisation, were in debt, had a criminal record, used drugs to kill themselves, told others what they were going to do before they did it, and committed suicide in the presence of other people, and a 'NP' group consisting of more stable personalities with shorter periods of instability who killed themselves because they could not adapt to acute stress, especially following loss of a loved person, were alone at the time, used lethal methods such as carbon monoxide and self-injury, and warned no one of the act. The P group had a history of parasuicide, whereas the NP group had no such history.

People under 35 years of age may be less likely to visit their GP in the months before suicide. They may not see talking about emotional issues to their doctor as appropriate. Also, suicide in this age group may be impulsive. Based on British coroners' inquisitions, many elderly CS may not be in contact with primary care, may receive inadequate treatment (e.g. antidepressant), and may infrequently be referred for psychiatric care. As many suicides in northern England were found to see a police officer in the last 3 months of their lives as had seen a mental health professional in the last 12 months. (Linsley ea, 2007) Emile Durkheim described four categories of suicide in 1897: egoistic (lacks significant interpersonal relationships), anomic (anarchy leads to a loss of social restraint), altruistic (dies for a common cause) and fatalistic (excessive restraints on liberty, e.g. POW camp). Suicide in Japan is now seen as being less honourable than it was in the 1940s.

Very high rates of CS have been reported in China.¹⁵¹⁸ Rates of depression were said to be low. Women commit suicide more often than men in China. (Phillips R ea, 2002) Yip and Liu (2006) argue that male Chinese CS rates are increasing and will surpass female rates eventually due, they believe, to increasing urbanisation.

Among 15-19 year olds globally, the countries reporting higher CS rates for females than males are China, Cuba, Ecuador, El Salvador and Sri Lanka. (Wasserman ea, 2005)

The *Werther effect*, called after one of Goethe's characters, refers to the influence of media coverage on the suicide rate. Whilst research shows some positive associations, the contribution is only part of a multifactorial aetiology, and the effect may be transient in some cases. Concern over the influence of media reporting of suicides has led to strong suggestions for more responsible reporting, the avoidance of dramatic portrayal and oversimplification of causes (e.g. leaving out mental health issues), and the need for a clear policy on internet 'suicide sites'. (Hawton & Williams, 2002)

The incidence of suicide in the medical profession is high. Females, as medical students and doctors, are disproportionately affected. (Schernhammer & Colditz, 2004) Various factors may affect female rates, e.g. single childless status and sexual harassment. (Schernhammer, 2005)

At-risk patients who seek seclusion should be carefully observed. Doctors who are being investigated or who have been suspended from the professional register have been noted to be at increased risk of CS in the US, UK and Ireland. (e.g. Ganly, 2004)

¹⁵¹⁷ Räikkönen ea (2007) found increased susceptibility to depressive symptoms at age 60 years in people with shorter length of gestation.

¹⁵¹⁸ Kleinman (2000) has suggested that family conflict, failure to give birth to a son, and 'loss of face' are important reasons for CS in China. Phillips and co-workers (Phillips MR ea, 2002b) interviewed the families and close associates of 519 CS's in China and used persons who died from other injuries as controls. The risk of CS increased as the number of risk factors increased. In order of importance these risk factors were high depression symptom scores, past personal AS, acute stress, low quality of life, high chronic stress, severe interpersonal conflict during the 48 hours before death, and previous suicidal behaviour in a blood relative or a friend. Females outnumbered males, rural villagers were over-represented, and victims were older than controls (mean in years: 48 v 43). Methods of CS included agricultural chemicals/rat poison (62% - often stored at home), hanging (20%), other poisons (7%), drowning (5%), jumping (2%), and other (4%). Negative life events such as economic problems and serious illness or injury did not differentiate the two groups (although both groups had an excess) and other events (childbirth, pregnancy [incl. unwanted], fines for exceeding birth quota, abortion, and sterilisation) were only somewhat more common in the female CS group (16% v 11% in female controls).

Children's ability to grasp the finality of death is usually developed sometime after their seventh birthday, the concept continuing to develop thereafter. Nevertheless, even younger children can have suicidal thoughts or even harm themselves deliberately.

About 20% of suicides leave a suicide note, the percentage perhaps being higher in the elderly. (Harwood, 2008, p. 558)

Most psychiatrists will experience CS among their patients. (Landers et al., 2010) At least a minority will experience depressed mood, insomnia and irritability as a result of such an experience. Nearly half will change the way they practice in various ways such as becoming more structured in their approach to patients or admitting more involuntary patients. A few will consider early retirement. Shock, fear of blame, grief, guilt, self-doubt, shame, anger, and a sense of betrayal are common. Colleagues, family and friends offer the best support. Other useful measures are team and critical incident reviews. These allow to learn and to improve our clinical management skills of such cases and to handle the aftermath better. The relatives of the deceased ('suicide survivors' in US) should be offered an early appointment wherein the tragic event can be discussed in an open, honest, uninterrupted and sympathetic manner.

Help needed by surviving relatives of CS (American Foundation for Suicide Prevention¹⁵¹⁹, 2007)

Acceptance and understanding of their troublesome feelings

Help to learn to accept guilt/anger

Help to work out self-blame for not preventing the death

Channelling intense, painful feelings into activities that help others, including suicide prevention

Epidemiology of CS

The Central Statistics Office for Ireland gets its information on CS from the investigating Garda (police) who gives his/her opinion on the cause of death on the confidential Garda Síochána (police force) Form 104 after a coroner's inquest has taken place. The coroner produces a Record of Verdict¹⁵²⁰ at the end of his/her deliberations.

Official suicide figures in Ireland may have underestimated the problem in the past (underreporting may still apply in India: Joseph et al., 2003). Reasons for missing CS include stigma and the need for criminal rather than civil standards of proof. The table provides suicide figures for the Irish Republic.¹⁵²¹ According to Chisti et al. (2003) Ireland has the fastest growing CS rate in the EU, this being largely a male phenomenon¹⁵²². However, according to the Irish Minister for Health, (Anonymous, 2004b) Ireland, with 10.2 suicides/100,000 people, came 17th out of 24 European countries, a figure below the European average of 14.9. Lithuania topped the list with 39.6 and Greece occupied the bottom with 3.1. According to Mullins (2005) the European Union experienced 58,000 suicides and 50,700 deaths from road traffic accidents (RTA) per annum respectively. According to the OECD report *Health at a Glance 2009* the Irish RTA death rate fell by 60% during 1970-2006 (OECD average = 58%).

Official suicide data, Republic of Ireland (ROI)

Statistics on CS have been kept since 1942. According to Walsh (2008) CS rates rose until WWI, fell until 1970, then rose slowly but this rise accelerated during 1990-2001 and then fell. He cautions against drawing too many conclusions about trends since numbers are small, especially for females. Also, figures vary because yearly summaries on vital statistics precede annual reports by 2 years. Walsh (2008, p. 55) makes the interesting proposition that Irish CS rates may have fallen when we exported people who killed themselves abroad and then rose when emigration declined and we welcomed immigrants from Eastern Europe. (see Harding &

¹⁵¹⁹ Founded 1987: 120 Wall St, 22nd Floor, New York, NY 10005 or 888-335-AFSP or www.afsp.org.

¹⁵²⁰ This gives identity of deceased, date/place/circumstances of death, and whether death was accidental, homicidal, suicidal, or undetermined whether accidental or not.

¹⁵²¹ The Irish suicide rate rose from 2.38 to 10.69 per 100,000 population from 1945-95. The rate for men of 65 or more years rose from 9.4 to 17.9 between 1976 and 1993, and was 17.17 in 1995 with women at 4.32. Between 1995-9 18 males and 3 females aged 5-14 years committed suicide. Over the same period there were 1,799 male CS and over 400 female CS. Hanging accounted for 857 male suicides and 104 female suicides, while drowning was the method used by 376 males and 141 females. Unreported cases for that period are suggested to run at 5%.

¹⁵²² The male rate being similar to the EU average while the female rate remained low.

Balarajan, 1996) There is some evidence from the US that a disposition towards mood and anxiety disorders may be acquired early in life by spending ones childhood in the USA.(Breslau ea, 2009)

<u>Year</u>	<u>Number of suicides</u>	<u>Comments</u>
1945	71	Not much faith can be placed in early statistics
1965	51	Lowest on record
1970	52	1.75/100,000 in 1970 v 7.87 in 1983; 44M:8F
1989	255	The 1988 rate for men was 12.2/100,000 and 3.4 for women; the overall rate for 1988 and 89 being 8.0
1990	311	Rate = 9.0; 6 fold increase over 20 years previously; 4,114 suicides over past 20 years, an average of 206/year; >3M:1F
1991	318	235M:66F; rate in ROI was 9 versus 8.3 in UK; increase in young males
1992	353	Rate = 10.2; 295M:85F
1993	357	
1994	353	280M:73 (rate = 9.89/100,000 – not distributed evenly, e.g. Mayo = 11.59); 6 aged 5-14 years; biggest group (77) = 15-24
1995	383	86 in 25-34 age group, 82 in 15-24, and 4 in 5-14
1996	378	310M:68F
1997	433	355M:78F; 8 aged 5-14; 103 aged 15-24; 99 aged 25-34 ¹⁵²³
1998	514	Rate = 14.1/100,000; 433M:81F; highest numbers in 20-29 group ¹⁵²⁴
1999	439	Rate = 12.1; 349M: 90F
2001	448	80% were males
2002	451	Rate = 11.5/100,000 (343 deaths from RTAs; 31 from homicide, 77% being males) ¹⁵²⁵
2003	444	3 inpatients committed suicide ¹⁵²⁶
2005	432 ¹⁵²⁷	354M:78F; M<35 yrs = c. 40%
2006	409	Rate = 9.6/100,000; 78% M and 22% F (Death from RTAs = 285, a rate of 6.7/100,000); if 66 undetermined deaths are added the figure becomes 475 (11.2/100,000)
2007	*1528	
2008	424	CSO
2009	527	CSO – highest figure to date; 80% male; 40% of CS were < 45 years old

Notes: Violent methods increasing. Main rise is in young men. Rural > urban. CS rates for ROI can vary with source, e.g. compare above with McGuinness.(2007) CSO: Central Statistics Office

In 1991, CS was the eight leading cause of death in the US, at 30,000 deaths per year, with the greatest numbers made up by young adults and the greatest rates being among the elderly, especially elderly white males. In Ireland deaths from CS equalled those on the roads in 1995. In 1992 and 1997, the number of CS in France and the Republic of Ireland respectively exceeded the number of deaths from road traffic accidents (RTA) for the first time.¹⁵²⁹ In the Republic of Ireland in 2001 there were 448 suicides and 357 deaths from RTAs. Despite the increase in CS relative to RTA-related deaths the 2010 funding for the National Office of Suicide Prevention and the Road Safety Authority are €5.1 million and €40 respectively. Gunnell ea (2003) found that succeeding generations of UK males born after World War Two experienced increasing rates of CS at all ages, a finding which has also been recorded in Canada and the US. According to Gunnell and Middleton,(2003) whilst the standardised suicide rates fell by 18% between 1981-98 in

¹⁵²³ Rate in ROI in 1997 = 11.94/100,000 (Hungary, 38.6; Mexico, 2.3); there were 31,605 deaths in ROI in that year and 1.4% were by suicide. Webster (2003) states that Lithuania has the highest rate (51/100,000) worldwide.

¹⁵²⁴ Highest recorded figure to that date. Highest rate in Kerry (23/100,000) and lowest in Longford (3.3) – figures for counties vary with the year but Eastern Region tends to be relatively low.

¹⁵²⁵ 111 suicides (11/100,000 pop.) in ROI in quarter 2 of 2003 = 30% of deaths in 15-24 age group and one-quarter of deaths in 25-34 age group; males, 83%; females, 17%.

¹⁵²⁶ A significant percentage were on leave or AWOL. Compare with 3 in 1866 when hospitals (asylums) were closed environments.

¹⁵²⁷ 431 is an alternative figure.

¹⁵²⁸ Different sources give widely differing figures for 2007. The National Office for Suicide Prevention (www.nosp.ie) Annual Report (2008) states that 481 CSs (given as 460 in Anonymous [IMN, Sept. 15, p. 8], 2008!) were recorded in 2007 'slightly lower than in previous years', which makes no sense when placed beside CSO figures for CS. A glance at the graph in that publication shows very little change in CS rates from 1980-2005, whereas males and females had highest rates in 1998 with a tendency to decrease thereafter, but the line representing the 1998 peak does not reflect these changes! Provisional figures from the National Office for Suicide Prevention suggest that CSs fell to 424 in 2008. An OECD report (*Health at a Glance 2009*) gives the mortality rate from suicide for Ireland as 8.9/100,000 (the OECD average being 11.1), indicating a continued decline since 2003.

¹⁵²⁹ Alcohol excess is common to many CS cases and RTA (and domestic) fatalities in Ireland.(Bedford ea, 2006)

England and Wales, the potential years of life lost before age 65 years increased by 5%. The UK suicide rate in 2007, a record low, was 7.5/100,000 population; there was a sustained decline in CS rate among males aged less than 25 years; CS among psychiatric inpatients fell from 216 in 1997 to 136 in 2006; and CS in prisons fell from 65 in 1997 to 60 in 2008.

Young male CS in England & Wales (Biddle ea, 2008a)

Rates more than doubled from early 1970s to the 1990s

Rates peaked in 1990 for 15-24 year olds and then fell

Rates peaked in 1998 for 25-34 year olds and then fell

In 2005 rate in males aged 15-24 = 8.5/100,000 (peak of 16.6 in 1990)

In 2005 rate in males aged 25-34 = 15.7/100,000 (peak of 27.9 in 1998)

According to Webster (2003) the average CS rates in Western Europe and North America were 5 and 4.1/100,000 respectively. Rising suicide rates in young males is a global problem.(Wasserman ea, 2005) However, CS rates in young men fell steadily in England and Wales since the 1990s, reaching their lowest point for almost 30 years in 2005¹⁵³⁰.(Biddle ea, 2008a)

CS and self-mutilation are coded in DSM-IV-TR under an F code: 'other conditions that may be a focus of clinical attention'.

Prediction of CS

'Unless and until significant new risk predictors are developed and evaluated, it is unjustified to assume that a suicide can be predicted'.(Chiles & Strosahl, 2005)

'...more important than constructing a list of risk factors is establishing the meaning of the patient's current life experiences to that person at that point in time'.(Harwood, 2008, p. 561)

'No form or protocol can encompass all possible risk factors'.(Simon, 2008, p. 1638))

Predicting suicide is very poor,(US Preventive Task Force, 2004) even if cases are seen shortly before death,(O'Shea ea, 2000; Carroll-Ghosh ea, 2003; Dubovsky ea, 2003) and even if they are inpatients.(Powell ea, 2000) We are better at predicting immediate risk than telling the future. CS is rare and suicidal ideation is common, leaving us with a base rate problem. Perhaps one percent or more of parasuicides go on to kill themselves, but which 1%?¹⁵³¹ Risk factors retrospectively identify groups of people who have killed themselves rather than prospectively identifying individuals who may do so. They have a high sensitivity but low specificity, spewing out many false positives.¹⁵³² Castle ea (2004) found that thoughts about death, thinking about suicide, bizarre behaviour and making violent threats distinguished CS from accidental death in both blacks and whites; reports of community complaints and problem drinking were associated with CS in whites more than in blacks; and no variable conferred greater risk for CS in blacks than in whites. Of note, racism data were not available to the researchers. Also, Gunnell ea (2004) found that less than 0.5% of people who experience suicidal thoughts go on to CS. Also, whilst past AS has a higher standardised mortality ratio than any psychiatric disorder, physical illness, or substance-related disorder,(Simon, 2008, p. 1641) most people who kill themselves have no known history of AS.(Malone ea, 1995) Human beings are complicated and cannot be reduced to mere statistics; what an event means emotionally to one person at one point in time can have a totally different meaning at another time, and the same event can have very different meaning for different people. It is important to ask patients what reasons they have for living.

In a psychological autopsy study of 85 suicides aged over 65 years of age at death, Waern ea (2002) found that 97% (v 18% in living comparators) had at least one Axis I diagnosis, commonly recurrent major depression or substance use disorders. Increased risk was also associated with minor depression, dysthymic disorder, psychosis, single episode major depression, and anxiety disorder. Comorbid Axis I disorders were found in 38% of suicides (15 subjects) with major depression. Cavanagh ea,(2003) in a systematic review of psychological autopsy studies, found a median of 91% of suicides (varying widely depending on

¹⁵³⁰ The authors explain this as being partly due to catalytic converters (that oxidise CO to CO₂), but point out that all major means of CS have declined.(Biddle ea, 2008a) Less unemployment and a falling divorce rate may be other positive factors.

¹⁵³¹ According to Owens ea (2002) the non-fatal repetition rate after one year is 15%; the risk of CS after 1 year is 0.5-2% and above 5% at 9 years. Jenkins ea (2002) and Suominen ea,(2004) have shown that the risk for CS following parasuicide persists for many years, even for the entire adult lifetime.

¹⁵³² It has been shown that for every 100 suicides predicted the forecast proved wrong in 97 times!(Pokorny, 1983)

methodology) had a 'mental disorder' (authors unable to draw conclusions about individual disorders or sociological variables) and comorbid substance abuse was a major risk factor.

Predictors of AS or CS may differ between the sexes.¹⁵³³

Questionnaires are most useful for research when used in a population for long-term prediction, but do not replace individual clinical assessment. Beck's scale for suicidal intent (Beck et al, 1974) is widely used in clinical practice but seems to show poor agreement with clinician's rating of the same phenomenon. (Keeley et al, 2002) Harriss et al (2005) found this scale most predictive for the first year and for females.

Important in determining suicidal intent *at the time of the act of self-harm*

Premeditation - buying a rope, securing a flat unknown to others, saving up tablets, getting tablets from many sources

Secrecy - precautions against discovery

Not alerting potential helpers

Being alone

Final acts - writing a will, insurance cover, a suicide note

Violent or aggressive act

Low lethality act believed by the person to be lethal

It is important to consider suicidal intent even in very young children. (Connolly, 1999) About 46 Irish children under the age of 14 years commit suicide annually, the rates¹⁵³⁴ (per 100,000) for 5-9 year olds and 10-14 year olds being 0.1 and 1.0 respectively.

Potential warning signs of suicide in adolescence

Withdrawal from family/friends/wider social interaction

Loss of interest in formerly enjoyed activities

Major functional changes (social, scholastic, and occupational)

Major changes in behaviour/personality

Self-neglect (hygiene, clothes, make-up) or self-deprecation

Parting with prized possessions

Low mood/sadness/despair/hopeless or irritable/aggressive/angry or poor emotional control

Preoccupied with death or suicide of others (as shown in words, reading, writing, drawing, or TV programme choice)

New/increased impulsiveness/risk-taking

Large weight increase/decrease

Poor sleep

Alcohol/substance use

These 'signs' must be weighed in the context of the individual's life story and circumstances as individually they may reflect normal adolescence. Do the adolescent's peers view their friend as having changed significantly or being ill?

Extended suicide

Talk about harming someone else who is also believed to be suffering e.g. child, parent, or spouse

Passive suicide

Kills self though deliberate neglect, e.g. transplant patient stops immunosuppressant (e.g. cycloserine)

Passive death wish

Wishes to die but not by own action

Suicide pacts (O'Shea et al, 2000)

¹⁵³³ Looking at people with major depression, Oquendo et al (2007b) found that a family history of suicidal acts, past drug use, borderline personality disorder, and early parental separation increased risk in males, whereas prior AS (incl. lethality of same), suicidal ideation, subjective depression, less reasons for living, borderline personality disorder, and cigarette smoking increased risk in females.

¹⁵³⁴ Based on figures released by National Office for Suicide Prevention in their 2008 Annual Report.

Agreement between at least two people to commit suicide together¹⁵³⁵ account for 6/1,000 suicides in England and Wales (rate of 6/10,000,000 people of at least 15 years of age)
 May be between married couples or, less commonly, between family members
 Typical case is female, 60 years old, married, high social class
 Majority either mentally ill or have history of mental disorder
 Commonest diagnosis is depression
 Alcohol is not a big factor
 Have been arranged between strangers over the internet in Japan - details worked out via special suicide websites (Rajagopal, 2004)
Dyadic deaths ('murder-suicides': O'Shea ea, 2000)
 Person kills someone else before ending own own life¹⁵³⁶
 Uncommon
 Perpetrator usually male
 Victim usually female
 Commonly share a close relationship
 Motivation varies but includes money worries and emotional rejection
 Barraclough and Harris (2002) looked at homicide followed by suicide in England and Wales during the period 1988-92 and that this was mostly a 'family affair' - men, mainly of low socioeconomic status, kill their kin and women (typically premenopausal) kill their young children - a few men kill strangers

Almost 1% of people discharged from UK psychiatric in-patient facilities kill themselves over the next 12 months, accounting for 10% of CS. According to Crawford,(2004) the classic post-discharge CS is a non-White unemployed male aged over 45 years who lives alone and is socially isolated; he was recently admitted for the first time, had suicidal ideas at the time of admission, was diagnosed as having depression or affective psychosis, deliberately harmed himself in the past, and experienced a sense of hopelessness; and discharge was 'unplanned', important personnel were on leave/leaving, the consultant was 'new', admission was for less than a week, and the time lapse before contact was made with services after discharge was relatively long.

Feeney ea,(2005) looking at parasuicides seen in a Dublin general hospital emergency department, found that emergency staff had a tendency to overrate suicide risk relative to the evaluations of a liaison psychiatry service.

Prevention¹⁵³⁷ of CS

'Even with the best possible care, a small proportion of patients with major depressive disorder are likely to die by suicide'. (APA, 2002, p. 491)

'Suicide is not solely positioned in the domain of mental health services'. (Department of Health and Children, 2003)

'Since suicide is affected by sociocultural factors, there is no safe indication that what has worked somewhere will work elsewhere'. (Bertolote, 2004)

'...the diversity of causes is so great as to ensure that any search for generic solutions is futile'. (Walsh, 2008, p. 59)

The psychiatrist should strive to develop and maintain a therapeutic relationship with the patient.

Frequency of consultations should reflect the results of suicide risk assessments¹⁵³⁸. However, extraneous factors may operate between appointments to undermine our best efforts. (Simon, 2008, p. 1648)

Documentation should be sufficiently robust to reflect the efforts of the treating clinician.

The least likely to telephone SANELINE in Britain are males and young people (Fakhoury, 2000) and whilst young men are over-represented in Irish suicide statistics they are unlikely as a group to use mental health services. (Burke & McKeon, 2007) Any attempt to reduce CS rates must take account of the complex

¹⁵³⁵ Not all cases involve mutual consent, e.g. the coerced female survivor with no history of mental illness or self harm and the dead, depressed, male instigator who had a history of self harm.

¹⁵³⁶ Although the term is also sometimes used to cover suicide pacts.

¹⁵³⁷ Under the *Health (Miscellaneous Provisions) Act 2001* the Irish Minister for of Health and Children reports each year to both Houses of the Oireachtas (legislature) on measures taken by health boards during the previous year to prevent suicide, basing his/her report on the Annual Report of the National Suicide Review Group. The Health Services Executive published a strategy for suicide prevention in 2005 (Health Services Executive, National Suicide Review Group, and Department of Health and Children, 2005) which acknowledged that no one group can take on this preventive role on its own.

¹⁵³⁸ Risk assessment is particularly important at the time of discharge.

array of forces acting together to produce these rates. Also CS rates may not be a good indicator of mental health service delivery.(Desai ea, 2005) Calling things by different names, such as ‘unnatural deaths’, tends to blur official suicide rates. Restriction or removal of one method may be replaced by another.(Ohberg ea, 1995; Isometsa & Lonnqvist, 1998) although efforts in this area (which must be monitored for compliance) are worthwhile. Certainly, a dramatic example of a measure that led to a reduction in CS is offered by the substitution of coal gas (carbon monoxide) by natural gas: Kreitman (1976) suggested that this led to a 30% fall in English CS rates but Walsh (2008, p. 62) is sceptical about any such effect in Ireland¹⁵³⁹. Car exhaust toxicity was reduced by legislation on catalytic converters. Nevertheless, determined people will most probably find a way to end their lives.(Edwards, 1995b) and car exhaust seems to have been replaced by hanging.(Amos ea, 2001)

Most suicides have avoided contact with mental health services, only some 25-30% having had contact annually with such services in the UK. However, contact with the GP in the month before death (often for physical complaints) may be more common (50%) in the elderly suicide.(Harwood, 2008, p. 559)

Native American Indians who kill themselves were less likely to attend health services than those who attempted suicide.(Gaw, 2001, p. 33)

Luoma ea,(2002) in a review of 40 studies, found that 3 of 4 and 1 of 3 CS cases had primary care and mental health service contact respectively within a year of death; 45% and 20% had primary care and mental health service contact respectively within a month of death; and older adults were more likely than younger adults to see their primary care provider within their last month of life. In a retrospective study relying on accident and emergency records, 39% (85) of 219 ‘probable’ CSs in Leeds attended an accident and emergency department in the year before death, but only 15% of these were because of non-fatal self-harm; final visits occurred a median of 38 days before demise.(Gairin ea, 2003) According to Carroll-Ghosh ea,(2003, p. 1474) over three-quarters of patients seen by health care professionals within a month of CS ‘do not communicate their intent to do so’.

Cohen (2003, p. 438) points out that 10-40% of eventual suicides make prior attempts on their lives, 60-90% of suicides do not make prior attempts on their lives, and, therefore, if we were able to prevent everyone who had made prior attempts on their lives from killing themselves we would still not prevent the majority of suicides!

We do not know how many ‘parasuicides end up in Heaven’ by accident and how many ‘parasuicides’ are actually failed suicides. Bostwick and Pankratz (2000) reported an 8.6% lifetime prevalence of CS in those who were ever hospitalised for suicidality; among affective disorder patients who were hospitalised without specification of suicidality the lifetime risk of CS was 4%. It is far from clear what psychosocial and physical interventions prevent repetition of self harm.(Hawton ea, 1998) Van der Sande ea (1997) compared an intensive psycho-social intervention (brief admission to special crisis unit and problem-solving after care) with whatever care the clinician thought appropriate and found no differences in outcome on a number of measures such as repeat of AS or hopelessness scale scores. Increases in admission after overdose of psychotropics have paralleled increases in admission after overdose of non-prescription analgesics, suggesting a trend that may be outside medical power to change. Economic and social policies (jobs, social cohesion, etc) are more likely to affect CS rates than would medical or public health measures.(Kelleher, 1998; Appleby ea, 1999; O’Shea ea, 2000; De Leo, 2004) However, some social findings in CS might derive from psychopathology and alcohol abuse. A programme aimed at removing stigma from help-seeking, improving knowledge of mental health issues, increasing coping skills, and changing policies and social norms in the US Air Force is reported to have produced a sustained reduction in the CS rate.(Knox ea, 2003) Programmes aimed at school children have been shown to be effective.(Walsh, 2008, p. 62) Rising rates of CS in children and adolescents must ultimately point to psychosocial stress. Reductions in socioeconomic deprivation may reduce suicide rates, especially in young men.(Hawton ea, 2001b) Chiles and Strosahl (2005, p. 191) believe that we resort too readily to hospitalisation for suicidal behaviour. It may inadvertently reinforce such behaviour. Doctors should focus on treating mental illness. People should be encouraged to see their doctor and to say how they feel. The doctor should be vigilant and forthright in questioning about thoughts of self-harm. Enquiries should be made about any plans and preparations relating to suicide. Monitoring of compliance needs to be improved, especially in males and young people. A documented pre-discharge suicide risk evaluation is a wise

¹⁵³⁹ ‘As always there were other methods [of committing suicide]’.(Walsh, 2008, p. 62)

practice. Improved ward design and removal of fixtures that can be used for hanging are common-sense approaches to reducing suicide among in-patients.(Meehan ea, 2006)

Interventions that might protect the patient in hospital¹⁵⁴⁰ (Hunt & Kapur, 2007)

Be particularly vigilant during first week
Review structure/layout of ward
Remove potential ligature points
Keep observation protocols under review
Exits from open wards should be observed carefully
Consider supervision for patients on leave

Interventions that might protect the patient after discharge (Crawford, 2004)

Periods of trial home leave before final discharge
Information about problems that may be experienced at home
Advice on sources of support and help
Avail of experience of other service users
Nurses that help patient regarding health services/carers/follow-up/crisis
Meeting with out-patient staff
Buddy system involving trained service users
Day hospital attendance
Early out-patient follow up¹⁵⁴¹

Interventions that might protect the patient in prison (Dooley, 1997; Frater, 2008)

Improved monitoring, especially at time of reception and young people
Attention to substance use and mental illness
Safer cells
Remove ligature points
Better access to meaningful activity/Samaritans/trained listeners
Post-release arrangements for support

Research performed in Dublin (Bolger ea, 2004) suggests that young people want to talk to someone when in crisis; they asked for access to an informal, 24-hour service provided by staff with experience in mental health, alcohol and substance disorders. Hunt ea (2006) stress targeting schizophrenia, dual diagnosis and loss of service contact in young people. Particular attention should be paid to detecting and treating depression in the elderly, especially those who have a physical disorder or who are socially isolated.(O'Connell ea, 2004; Hunt ea, 2006)

The vexed question of what to do about the intoxicated person who expresses suicidal thinking was addressed by McCaffery ea.(2002) They found no specific guidelines from the RCPsych and little consensus among psychiatrists. Not surprisingly, the Medical Defence Union's opinion was couched in terms of terms of self-defence for a possible future legal hearing. Walsh (2008) stated that reducing alcohol consumption would reduce CS rates but bemoaned the fact that little had been done about this at a national level. Indeed, the monies necessary to fund official tackling of suicide in Ireland have been slow to materialise.(Mulholland, 2009)

Education of GPs on suicide and depression produced useful short-term reductions in CS rates in one famous study (Gotland), but it was estimated that booster courses every few years would be needed to maintain the effect.(Rutz ea, 1992; Morris ea, 2005) According to Baldwin ea,(2002, p.102) until more definite evidence becomes available, the most useful strategy in reducing suicide rates in the elderly is the diagnosis and management of depression by GPs.

In real life, treatment of depression with antidepressants reduces the risk of suicide in all age groups¹⁵⁴².(Cougnard ea, 2009) Rising unemployment rates are associated with increases in rates of suicide,

¹⁵⁴⁰ Fawcett ea (2003) reviewed CS of 76 inpatients: 42 were on 15-minute observations and 9% were being 'specialled' (1:1 nursing) or with a member of staff at the time of death!

¹⁵⁴¹ See also Meehan ea.(2006)

¹⁵⁴² This study, a decision analysis model, compared depressives given antidepressants versus those not given these medicines. Sensitivity analysis showed that continuing to take the medication was the most important preventative measure.

homicides, and deaths from alcohol abuse, and, not surprisingly considering the cost of fuel, a decrease in road-traffic deaths.(Stuckler ea, 2009)

Self-mutilation/self-cutters (non-suicidal self-injury)

The commonest methods of self-injury in one British study of attendees at an accident and emergency department (Horrocks ea, 2003) were self-laceration (72.4%), punching walls/banging head (8.6%), and hanging (4.7%). In contrast to self-poisoners, wrist-cutters are classically younger, commit acts of low lethality, are no more likely to have made previous suicide attempts, complain less of depression but more frequently of feeling empty or tense, have sudden unpredictable mood swings, are often diagnosed as having a personality disorder, are abusers of drugs and alcohol, experienced sexual difficulties and are promiscuous, came from broken homes with parental deprivation, have difficulties in communicating, and leave hospital against medical advice. The typical pattern involves painless cutting after a period of depersonalisation, followed by relaxation and repersonalisation after bleeding. Some feel better after seeing their own blood.

Hawton and Catalan (1987) classified self-injury (other than overdose) into superficial self-cutting (usually wrist or forearm - little or no association with suicidal intent), serious self-injury (e.g. deep cutting, shooting, hanging, jumping from a height - usually associated with serious suicidal intent), and self-mutilation (these patients may be disfigured, are usually psychotic, and may or may not endanger life).

Van der Kolk ea (1991) found that cutters had a history of childhood trauma, neglect and abandonment. Such patients may react to life stresses as a return to earlier experiences. Dissociation under stress is not uncommon.

Tantam and Whittaker (1992) urge viewing self-wounding as a communication ('to influence the behaviour of others and to manage internal emotions': Lloyd-Richardson ea, 2007); the therapist should assist the patient to express need more adaptively. The positive side of suicidal ambivalence needs reinforcement.(Chiles & Strosahl, 2005, p. 28) Cognitive and behavioural techniques may help.

In most cases, self-inflicted injury is only part of a long history of psychogenic illness. The family is often very disturbed and may harbour a 'secret' such as sexual abuse. Life circumstances may play an important part in determining whether remissions occur in the future. In general, the main associations with self-injury are intellectual disability, psychosis, being in prison, and having a disorder of personality.

Self-mutilation is common among soldiers in battle. This may be a ploy to get home, the British 'Blighty wound'.

Joyce ea (2010) conducted a family study on the molecular genetics of depression and personality in which a proband had been treated for depression. They concluded that self-mutilation and attempted suicide overlapped only partially although both phenomena could be predicted by mood disorder diagnosis and harm avoidance. They found that self-mutilation had a strong association with bipolar affective disorder and they urged readers to consider the latter rather than borderline personality disorder when assessing self-mutilation. It seems to this author that one should consider both conditions in practice and these findings (Joyce ea, 2010) will need further research to see if they apply more generally to self-mutilators.

Morbidity in the Medical Profession

'More than ever before, clinicians are being asked to do more with less and treat complex disorders in time-limited fashion'.(Rudd, 2000)

'Management must be more accountable for the doctors in its employment'.(Murphy, 2005)

'At the organisational level, physician burnout is associated with reduced workplace productivity and efficiency'.(Wallace ea, 2009)

A survey of US doctors in the early 1990s found that 40% would not choose the same career if they were starting all over again. Research on stress in the medical profession is strongly associated with Firth-Cozens, a clinical psychologist in Leeds. Firth-Cozens (1994, 2003) points out that work stress originates from a complex interaction of doctor (self-critical, blame-accepting), work environment (lack of support, unreasonable demands), poor education (time management, ways of dealing with difficult patients¹⁵⁴³) and

¹⁵⁴³ See Lalanda (2009) for a discussion of dealing with the 'challenging patient'.

so on. It has been argued that doctors may enter medicine because of some early noxious life experiences and that, when medicine fails to help them resolve such conflicts, they become disillusioned and distressed. According to Firth-Cozens, (2003) 28% of doctors and 18% of the general working population suffer from excessive stress levels. Stressed doctors err more often. Predictors of a more positive work milieu include high self esteem, satisfactory support with work-related problems, lower perceived workload, a positive view of leadership, low work-related exhaustion, and having a sense of participation in the organisation. (Thomsen et al, 1998)

Factors leading to low morale and caseness on GHQ-12 in the medical profession (Thompson, 1988)

High work demands/insufficient resources

Role ambiguity – responsibility without authority; multi-professional team members 'equal'

Role conflict – loyalty to employer v loyalty to patient

Poor social support – less support from colleagues in the community than in hospital ('staff mess')

Lack of feedback on job performance – e.g. How am I doing? How do I develop personally? Longterm career plans?

Lack of influence on workplace decisions – managers plan and consultant input negated

Compromising professional standards – inability to tailor interventions to individual patients – possibly related to catchment area/sectorisation

Mental illness is common in doctors, especially alcoholism, drug dependence, and affective disorders. It may be the characteristics of the empathic doctor that make him prone to breakdown. Sources of stress include diagnostics and therapeutics, the death of children, domestic problems due to work, premorbid factors including personality variables, job insecurity, frequent moves, poor intercollegiate relations, demanding relatives of patients, administrators, being asked to be administrators instead of clinicians, (Stranjalis, 1993) rapid changes in job structure, long hours, over involvement with patients, and living in unfamiliar cultures. Perceived stressfulness is equated with 'overwork', but this is not necessarily directly related to the number of hours worked (Murphy, 2009)¹⁵⁴⁴; it is also equated with 'talking to distressed relatives', 'effects on your personal life', and 'serious treatment failures'. (Firth-Cozens, 1987) Sleep deprivation and fatigue probably has a greater adverse effect on routine duties than on emergency responses or novel situations. (Samkoff & Jacques, 1991) Quality of sleep (e.g. expecting to be called) may be important. However, reports of juniors falling asleep when driving are very worrying. (Marcus & Loughlin, 1996) Lack of sleep may impair performance and lead to symptoms of depression, anxiety, confusion, anger, and psychomotor impairment. (Gaba & Howard, 2002) Concern has been expressed about the implications for patient safety and quality of care provided by overworked doctors in America, as well as the resultant mental health of such physicians, senior as well as resident (i.e. housemen). (Gaba & Howard, 2002) US paediatric residents who are depressed¹⁵⁴⁵, but not those who have burnout, make an excess of medication errors. (Fahrenkopf et al, 2008) West et al (2009) found that fatigue, sleepiness, burnout, depression, and reduced quality of life were independently associated with an increased risk of future self-perceived medical errors among Mayo Clinic residents. Doctors in Jerusalem who have PTSD have excess anxiety, depression, negative coping strategies, and burnout, and are reluctant to receive treatment. (Einav et al, 2008) American doctors are more likely to be divorced if they are psychiatrists (surgeons come next), female, married before graduating, have low academic achievement, if the parents do not die before the doctor graduates, if they have high anger levels or perceive themselves as being less emotionally close to patients. (Rollman et al, 1997)

Mental health of psychiatrists (Firth-Cozens, 2007)

High levels of depression, burnout¹⁵⁴⁶, stress, and suicide¹⁵⁴⁷

¹⁵⁴⁴ Although it is often subjectively put down to long hours and, in England the Court of Appeal decided in 1991 that health authorities must not injure a doctor by requiring excessive hours of service.

¹⁵⁴⁵ 20% and 74% of the sample met criteria for depression and burnout respectively. This was a small, brief study with a 50% response rate and a low number of errors. Selection bias cannot be ruled out. (McLay & Ross, 2008)

¹⁵⁴⁶ See Harrison. (2007)

Low job satisfaction

Possible increased rate of alcohol/substance misuse¹⁵⁴⁸

Sexual relationships with patients (boundary violations)

Causes: organisational (clinical/administrative load), individual vulnerability (e.g. early experience of abuse, family history of psychiatric disorder)

Doctors have an excess mortality from suicide, hepatic cirrhosis or accidental poisoning. The higher rate of suicide among doctors may partly be explained by more successful attempts at suicide. 85% of female doctors have children within a decade of qualifying, which often leads to a conflict between family and career. Female doctors may be more inclined to early suicide than are male doctors. Also, according to the British Medical Association, (BMA, 1993) perhaps half of female junior doctors become depressed. Young male doctors are the most likely medical practitioners to be assaulted, especially if they are in psychiatry, and particularly if they are in training as psychotherapists. (Davies, 2001; O'Shea, 1988; Dhumad ea, 2007¹⁵⁴⁹; Rush ea, 2008¹⁵⁵⁰) In the UK, psychiatrists, accident and emergency doctors and GPs are the most vulnerable to violent attack (Schnieden, 1993) whereas women doctors and doctors in radiology, pathology, psychiatry,¹⁵⁵¹ and anaesthesiology may be at particularly high risk of suicide. (BMA, 1993) High levels of

Like Chiron (half-man, half-injured beast) of old, doctors are sometimes viewed as being better healers if they have experienced personal suffering. The idea that doctors must show persistence, ability to delay gratification, love of hard work and self-sacrifice, and an unwillingness to express career doubts can be dangerous. Job stress increases as the demands of work increase and decreases with increased feelings of control over the job and improvements of social support. People like to feel they are being rewarded for what they put into their job.

Kumar (2007) suggested that burnout is particularly common among psychiatrists, which is debatable. The argument is that psychiatry is a stigmatised branch of Medicine, that psychiatrists are always struggling for resources, and that complex judgments are part of the job.

Lucey (2009) has reviewed the concept of burnout, a phenomenon that is not unique to Medicine but one that afflicts about one-fifth of doctors. Leaving out people who are totally unsuited to the practice of Medicine, work overload, feeling poorly managed or poorly resourced, direct involvement in the suffering of others, high patient expectation levels, home-work interference, domestic interruptions, administrative load, and personal characteristics (committed, high-functioning, external locus of control, avoidant, obsessional/perfectionist, a tendency to feel rather than think, low stress tolerance, and low self esteem) are risk factors. Working for an organisation that appears to lack values or is cynical is unhelpful, as is lone practice. Victims complain of physical and emotional exhaustion, diminished personal accomplishments in previously high-functioning individuals, cynicism, and reduced ability to care. There are irritability, problematic absenteeism, and reduced job satisfaction. All aspects of life, including domestic, are adversely affected. It is not due to another mental disorder.

Solutions to burnout must come from multiple sources, e.g. the employer, clinicians themselves, colleges, and society. It would be very interesting to study the reasons for 'early retirement', even when it is a contractual option. Practitioners should feel able to acknowledge that the problem exists. Many issues need to be addressed, such as sense of control over work, part-time work/flexi-time, child-care, holiday leave/cross-cover/locums, career breaks/change, sabbaticals, and modulation of the workplace/home interface.

Other important matters to be addressed are building a vision and trust in the mission, reasonable rewards, fairness, and consistency. (Lucey, 2009) Counselling for burnout in Norwegian doctors reduced emotional exhaustion and less exhaustion was associated with working less hours. (Isaksson Rø ea, 2008)

¹⁵⁴⁷ According to Thapar (1989), it has not been confirmed by research that psychiatrists are particularly prone to suicide within the profession.

¹⁵⁴⁸ US medical students who drink excessively may be less likely to see the point in counselling patients about alcohol. (Frank ea, 2008b) It is the author's experience that this fact applies more generally within the medical profession.

¹⁵⁴⁹ Dhumad ea (2007) found that London psychiatrists (64.8% response rate) were most vulnerable to assault if junior (32.4% over 12 months for SHOs v 12.4% of all psychiatrists) or on a psychiatric ward, there was little or no formal psychological help, and vulnerability was not influenced by prevention/management of violence courses or by attitudes to violence on the part of their patients.

¹⁵⁵⁰ This questionnaire study of psychiatric trainees in Ireland suffers from having only a 46.5% response rate. Training in breakaway and induction seemed good but 72% felt threatened and 16% had been physically assaulted.

¹⁵⁵¹ Famous names include Socrates, psychoanalysts Wilhelm Stekel and Bruno Bettelheim, artist Vincent Van Gogh of Holland, and psychiatrists Frank Fish of Liverpool and Richard Asher of London. Ludwig II of Bavaria drowned both himself and his psychiatrist (Bernhard von Gudden, inventor of the microtome) in Starnberg Lake in 1886! The Englishman, Thomas Addison (1793-1860), of anaemia and adrenal fame, suffered from severe bouts of depression and ended his life by jumping from a window in Brighton. The Alsatian Joseph Meister (1876-1940) who was vaccinated against rabies in 1885 by Louis Pasteur became concierge of the Institut Pasteur and shot himself when he failed to stop Germans from entering the crypt where Pasteur's body lay. Ernest Hemingway and a number of his relatives were victims of suicide. Some other examples are given in the table:

Name	Year of death	Detail	Method
------	---------------	--------	--------

stress, anxiety and depression have been found among senior doctors and managers in the British National Health Service. (Caplan, 1994) Richards (1989) reported that over three-quarters of doctors surveyed had treated themselves with antibiotics, a quarter with hypnotics, almost one in twenty with antidepressants, and almost 3% with opiate analgesics. Availability and knowledge of pharmacology and therapeutics are important factors in suicide within the medical profession.

Anxiety is a common complaint among doctors. Extra stresses on female doctors include lack of senior female role models, conflicts between career and family, prejudice and attitudes of male colleagues, and loneliness. Litigation is a major modern stressor.

Working in ICUs carries particular stresses. Accident and emergency departments carry certain stresses for juniors: intense workload, diagnostic uncertainty, unsociable hours, and fatigue.

15-35% of medical students suffer from some form of psychiatric morbidity. Perceived sources of stress include consultants (!), exams, finances, and family issues. Some are afraid to seek advice in case this might have adverse career implications. (Gaughran et al, 1997) Curran et al (2009) used the BDI and the CAGE with medical and business students at TCD and UD in Dublin. The response rate was 62.7%. Almost 14% of students scored at least 10 on the BDI and a quarter scored at least 2 on the CAGE. The only difference between the two groups was that alcohol abuse was more common among business students than among medical students. About 6% of students reported suicidal thinking in the last month and such thinking was more likely in the presence of stressful life events and absence of social support.

In the first postgraduate year, one-quarter to one-third of interns suffer from clinical depression, but this figure tends to decline with the passage of time. Long hours, lack of sleep, poor diet, poor social supports, large bank loans, feelings of inadequacy, and separation from home may be important factors here, as are the abuse of alcohol, and the use of drugs for physical illness or for recreation. (Firth-Cozens, 1987) US interns (Sen et al, 2010) showed a significant increase in depression scores on the 9-item *Patient Health Questionnaire* during internship and this increase was associated with certain pre-internship (being female, US medical education, difficult early family environment, history of major depression, and increased neuroticism) and intra-internship (long hours of work, perceived medical mistakes, and stressful life events)

Antony, Mark	30 BC	Roman politician/general	Stabbing
Berger, Hans	1941	Invented EEG	Hanging
Brutus	42BC	Assassin of Julius Caesar	Stabbing
Capucine	1990	French actress	Jumping
Cleopatra	30 BC	Egyptian ruler	Snake bite
Clive, Robert	1774	Clive of India	Cut throat
Diesel, Rudolf	1913	Inventor of diesel engine	Drowning
Freud, Sigmund	1939	Father of psychoanalysis	Morphine
Gelhorn, Martha	1998	US war correspondent	Poison
Goebbels, Joseph	1945	Nazi propagandist	Poison
Hancock, Tony	1968	British comedian	Overdose
Hannibal	182BC	Of elephant fame	Poison

Krupp, Friedrich Alfred	1902	Industrialist/homosexual	Controversial (stroke?)
Levi, Primo	1987	Italian author	Jumping
Monroe, Marilyn	1962	US actress	Overdose (controversial)
Nero	68	Roman emperor	Stabbing
Plath, Sylvia	1963	US poet	Gas
Raubal, Geli	1931	Hitler's niece/lover	Controversial (murder?)
Ray, Margaret Mary	1998	David Letterman stalker	Locomotive
Rommel, Erwin	1944	German field marshal	Poison (to save his family)
Rudolf, Crown Prince	1889	Austro-Hungarian heir	Suicide pact (murder?)
Sanders, George	1972	British actor	Overdose
Spilsbury, Sir Bernard	1947	British forensic pathologist	Gas
Stevens, Inger	1970	Swedish actress	Overdose
Tone, Wolfe	1798	Irish patriot	Cutting
Vicious, Sid	1979	Of the Sex Pistols	Heroin
Wells, Horace	1848	Dentist, early anaesthetist	Cutting + chloroform
Woolf, Virginia	1941	British novelist	Drowning
Young, Gig	1978	US actor	Gunshot (murder-suicide)

factors; also, having at least one copy of a less-transcribed 5-HT transporter protein gene was associated with increased likelihood to report depressive symptoms during internship. When the *GHQ* and *Symptom Checklist for Depression* were used, 46% of one group of female junior doctors scored above the criterion for depression.(Firth-Cozens, 1990) Medical students may also show high levels of psychosocial morbidity. Creed(1993) reckoned that doctors' spouses have a standardised mortality ratio of 275! Junior doctors, especially if female or foreign, often perceive that they are subject to bullying.(Quine, 2002; Cheema ea, 2005)

General practitioners (GPs), who are prone to depression,(Caplan, 1994) experience stress from night calls, emergencies during surgery hours, and interruptions in family life. Violence against GPs is particularly likely during nocturnal home visits. Anxiety, intoxication, and long waits are important precipitants.

Relatives may often be the aggressors. Training in coping strategies and time management may benefit GPs,(O'Sullivan ea, 2005) as it would other members of the profession.

Thapar (1989) points out that prevention and early detection are important. Support groups ('three wise men', 'sick doctor schemes', etc.¹⁵⁵²), guaranteed confidentiality, and brief psychotherapy can all play their part, and university psychiatric help for students should be widely available. Doctors should not be made to feel stigmatised if they seek help, and treatment should not be unduly modified because of their professional status. Senior staff should take an interest in their junior and be supportive. Doctors have to overcome stigma, misguided professional loyalty, a tradition of self-treatment, and fear of jeopardising career and job prospects if they are to step forward for help. Female doctors should never be discriminated against. Doctors should not hope that drug dependent colleagues will somehow snap out of it, making this a excuse for inactivity. Experience in the US suggests a favourable outcome at five years for physicians treated for substance use disorders and that the programmes offered have an appropriate mix of therapy, support and sanctions.(McLellan ea, 2008) Similar positive outcomes have been recorded in Canada.(Brewster ea, 2008) Rostering flexibility for working mothers and the needs of female staff need to be taken into account in planning.(Blunt, 1990) Shift systems may be superior to orthodox working schedules in selected instances. Doctors who give the impression of rushing an interview are more likely to be the objects of litigation or complaints about care. Not everyone understands that sometimes doctors are in a hurry.

Counselling or cognitive therapy may help stressed doctors. Part-time work is becoming more popular, as is early retirement. Seventy percent of British NHS psychiatric consultants opting for early retirement have cited bureaucracy and 52% interference by managers in clinical decisions.(Thompson, 1998) The actual workload needs urgent attention.(Benbow & Jolley, 1998) A safe working environment should be mandatory. To err is human and occasions of error should be tackled as learning opportunities,(Firth-Cozens(2003) although the litigiousness of society may militate against this in practice.

Doctors and responsible others should utilise strategies that reduce the level of stress to which they are exposed (see box).

Things doctors might do to reduce personal stress (after Iversen ea, 2009)

Doctor-initiated

Find and use mentors
Take care of self (exercise etc)
Reflect on ones emotions/reactions
Challenge your own unhelpful beliefs
Spend time with non-work related others (e.g. friends)
Ring-fence time for other things (e.g. religion, hobbies)
Time management

Employer/educator-initiated

Medical school – mentoring, peer support networks, training in team work and leadership, health care, asking for help
Junior medical years – supervision, discuss problem cases and mistakes, support network, work-occupation balance
Rest of career – flexible childcare, have say in way of working and workload

¹⁵⁵² Confidential 'phoneline for Irish Sick Doctor Scheme: 01-2887695. In Britain 'phone 0171-9355982 for local help.

Women: some further considerations

We may tend to place women on a pedestal, and deny her ability to be incestuous or otherwise a poor mother.(Welldon, 1991) Of women who kill, most kill their own offspring; of men who kill, only 3 in every 20 kill their children.

In the urban West, women with chronic severe psychiatric illness may be more likely to live with their families, while men live in hostels.(Conning & Rowland, 1991)

Depression in treated samples shows an approximately 2:1 female predominance. This applies equally to studies of prevalence in the community. According to Paykel (1991), much of the excess occurs in married women aged 25 to 45 years with children. Explanations might include expression of distress (depression in women, alcohol abuse in men), biology (hormones), and social (carer status, young children: see Kennedy & Hickey, 2005) factors. Romans ea (1993) conducted a follow up of New Zealand women in the community and found that onset of non-psychotic psychiatric disorder was associated with being separated or divorced, coming from a large family, having poor social networks, living alone, having few social role responsibilities such as a paid job or motherhood, being in poor physical health, and being financially insecure. Those women who were less likely to have their disorder remit were middle-aged, financially poor, and had poor social relationships at initial assessment. Psychosocial factors may be less important in determining outcome in severely depressed women.(Andrew ea, 1993) Premenstrual exacerbation of major depression is endorsed by by most female sufferers and it may be a marker for more prolonged episodes.(Kornstein ea, 2005)

Ashton (1991) reported that European and North American women are prescribed over twice as many psychotropic drugs as men.

Classical patient with thick-case notes (O'Shea & Falvey, 1991)

Female

Many admissions

Long periods in hospital

Presents early in life

Separated or single

Loses work during her illness

Excess of medical disorders

Reared in care, having lost a parent, in particular her mother, in early life

History of legal and social worker contact

Unstable psychiatric diagnosis

Often has a personality disorder

May have a low IQ

History of alcohol and substance abuse

Subjectively and objectively, the strain and burden may be greater in female carers of demented than in their male counterparts, perhaps relating to different role expectations and coping strategies.(Morris ea, 1991)

In 1991(Oppenheimer, 1991), women comprised one-third and 1% of alcohol abusers in the US and UK respectively. Such abusers tend to be of childbearing age.

Women commit all types of crime but much less often than men.(Heidensohn, 1991) Female crime is often associated with socio-economic marginalisation. Courts may view women as doubly deviant. Provisions, in or out of custody, are inadequate for females. Women, as potential victims of crime, are more fearful than men are.

More women report a history of sexual contact in childhood (CSA) than do men.(Sheldrick, 1991)

Female referrals to an eating disorder clinic had a 30% history of CSA and a 52% history of having a personality disorder.(McClelland ea, 1991) Perkins and Rowland (1991) suggested that long-term community psychiatric services might not serve the needs of women as adequately as those of men.

Grief, normal and abnormal¹⁵⁵³

Brian O'Shea

'A touch or a hug will often do more to facilitate grieving than any words'. (Parkes, 1998)

'Death is not only the great equalizer, it allows us to value life'. (Levine, 2000)

'Those who can die live freely'. (Karen Blixen in Out of Africa, quoted in Göttsche, 2002)

'Death is seen as a tragic failure rather than the necessary culmination of a good life'. (Taylor, 2002)

'Traditional Christians craved the good death; moderns seek the prolongation of pain-free life'. (Porter, 2004)

Reactions to stressful experiences can be normal, as in uncomplicated grief, or abnormal, as in abnormal grief, PTSD, acute stress reaction, or adjustment disorder. PTSD may complicate grief. There is no time cut-off for normal grief. As part of the ageing process, people discard the youthful fantasies of immortality with varying degrees of success.

Definitions

Bereavement refers to the situation of having lost a significant other through death.

Mourning is the process of adjusting to bereavement.

Grief is the personal experience of mourning.

We can grieve for anything that we have lost, (Hollins, 2005) including friends¹⁵⁵⁴, pet animals, a limb, youth, physical prowess, or a famous person. Going into an institution such as a nursing home can be a major loss event¹⁵⁵⁵. We can grieve before we lose something, anticipatory grief. Mental illness in a close relative may evoke complex emotional reactions, including grief, hate, sorrow and fear of developing the same disorder. (Stålberg et al, 2004) Those given a chance to talk about a loss before it happens are often less distressed later than those not given the opportunity. Caplan, of crisis theory fame, elaborated on such primary prevention measures as the use of domestic pets to offset loneliness. Milner (1966) described a man with amnesia following bilateral temporal lobectomy that mourned afresh every time he learned that his uncle had died! Enlargement of the left ventricle has been reported in the bereaved. The support offered by a spouse may have a protective role for physical health during parental bereavement. Lack of social support, mental illness, conflict or excessive dependency, and alcoholism, may increase mortality after loss of a close other. Bereavement has early and late effects on mortality. It affects many aspects of a person's life. The early effects include coronary heart disease. Possibly, the earliest manifestation may result from ventricular arrhythmias. The late effects are less clear. It is difficult to distinguish the effects of social isolation and low social support on the heart from that exercised by bereavement, since men return to the

¹⁵⁵³ Modern scientific interest in bereavement dates to Erich Lindemann and the Coconut Grove fire in Boston, Massachusetts during World War Two. Lindemann influenced a generation of Boston investigators, including Gerald Caplan, Robert Weiss, and Colin Murray Parkes, Parkes bringing this work in England. (O'Shea et al, 1982) The British organisation 'Cruse - Bereavement Care', formerly the 'National Organisation for Widows, Widowers and their children', was founded in 1959 and offers counselling, advice, practical information, and opportunities for social contact. It is available to all those bereaved by death. Useful sources of practical information and contact numbers in Ireland are O'Connor et al (undated) and the *Irish Medical Directory*.

¹⁵⁵⁴ Loss of friends from AIDS has a deleterious effect on AIDS progression, even with HAART. (Leserman et al, 2007)

¹⁵⁵⁵ Prior vulnerability, contrasts between former and new living quarters, and the amount of say the person has in the move influence psychological outcome. (Tobin & Lieberman, 1976)

mortality curve of the control group once they remarry. Lymphocytic response seems to be diminished¹⁵⁵⁶ in early bereavement, in major depression and in other forms of stress, (Rogers & Reich, 1988) but enhanced immune response has been reported in those people anticipating grief. (Spurrell & Creed, 1993) Elderly widowers may be more likely to die in the months after loss of a spouse than are widows, (Benjamin, 1985) and widows have increased rates of both major depression and anxiety disorder during this time. (Surtees, 1995) However, it has been suggested that widows do better than still married women in the longer term because they have an increased sense of mastery and have learned new skills! The dying may displace their hostility onto the doctor and the aged may displace it onto the young who misspend their youth. Depression should be considered if the dying do not want to see relatives. Depression is common after the loss of a spouse, especially for young widows and widowers with a history of depression. (Zisook & Shuchter, 1991)

Doctors can feel disappointed because they don't achieve their own expectations. A patient's death may trigger personal fears or ideas of guilt in the physician. We need to grieve. A balance must be struck between one's own needs and those of our charges, we must acknowledge fallibility and accept help as needed. We too often see death as something to be avoided, postponed or resisted at the expense of a humanistic approach to the dying. (Clark, 2002; O'Shea, 2002; Cassem & Brendel, 2004)

Most people want to die at home whereas, at least in the UK, most will die in hospital, care home, hospice, or elsewhere. Only 18% die in their own homes in the UK. (Riley, 2008) Few people discuss how they would like to die.

Irish Medical Council 2009 guidance on end of life care (medicalcouncil.ie)

There is no obligation to start or continue a treatment or artificial nutrition and hydration that is futile or disproportionately burdensome, even if it prolongs life

The clinician should carefully consider when to start or stop attempts to prolong life but should ensure pain relief and reduction of distress

Patients may refuse treatment and clinicians should respect 'living wills' (advance healthcare plans)

If death occurs, discuss the circumstances with the family (unless patient recorded an objection)

Do not participate in any way in active killing of the patient

Gündel et al (2003) showed eight bereaved females photographs of the deceased and of strangers and they were also exposed to words specific to the death event and neutral words. Both stimuli (fMRI) activated the posterior cingulate cortex, the medial/superior frontal gyrus, and the cerebellum; the pictures activated cuneus, superior lingual gyrus, insula, dorsal anterior cingulate cortex, inferior temporal gyrus, and fusiform gyrus; whereas words activated precuneus, precentral gyrus, midbrain, and cerebellar vermis.

Distinguishing grief from depression*

Grief

Intense symptoms for at least 1-2 months**

Usually no suicidal ideation***

Visions or voice of deceased transient only****

Pangs interspersed with normal feelings

May blame deceased

Improves with time

*If in doubt, treat for depression – antidepressants do not retard the grieving process. See Kendler et al (2008) who doesn't see the value of distinguishing these two phenomena.

**Cultures differ in the degree to which distress is expressed openly, a fact that must be considered before labelling grief as being pathological. (Parkes, 2000)

***But bereavement was the commonest recent major event in the lives of Cork suicides for both sexes in Kelleher et al (2000)

****Often drowsy at the time of experience.

Depression

Longer duration

Such ideas are common

May have sustained depressive delusions

Continuous, pervasive depressed mood

Blames self

No change or worsening

With regard to stillbirth, it is important to know when to promote grieving and when not to blow the event up out of proportion in the mind of the bereaved. (Bourne & Lewis, 1991; Stillbirth and Neonatal Death

¹⁵⁵⁶ But mildly so. (Calabrese et al, 1987)

Society¹⁵⁵⁷, 1991) Not every woman wants to hold her stillborn child and not everyone who does fares better emotionally than those who never see the dead baby.(Hughes ea, 2002) Loss of a pregnancy may be associated with stronger grief reactions in women who lose the baby later in pregnancy, have a more neurotic personality, have more pre-loss psychiatric symptoms, and have no living children.(Janssen ea, 1997) Many women who lose a pregnancy will have symptoms of depression, anxiety and somatisation during the first 6 months or so, but are generally indistinguishable from women having a live baby at one year.(Janssen ea, 1996) The final chance of having a child by a relatively elderly couple that ends in a stillborn baby may be of vastly greater significance than an early spontaneous abortion affecting a young couple. Religion may offer solace for many,(Parkes ea, 2000, p.15) Therapists dealing with perinatal loss should suggest to relatives that they might consider keeping photographs and a footprint, registering a name and preparing a funeral. It is suggested that women experiencing a stillbirth be nursed on a gynaecology ward instead of a postnatal ward after delivery. Anticipatory guidance involves covering such topics as how to explain the loss to others, giving away clothes and toys, meeting friends with young babies, and anything else that may help the woman to cope when she goes home.

Fathers may be almost as anxious antenatally as the mother when there is a history of previous stillbirth.(Turton ea, 2006)

The death of a child may lead to depression and anxiety in the parents that take years to subside.(Kreicbergs ea, 2004a) Parents who feel that their child is aware that he or she is close to death may later regret not having talked about this to the child.(Kreicbergs ea, 2004b) The death of a child may be handled insensitively by professionals,(Finlay & Dallimore, 1991) and parents should have a say as to the setting wherein their child spends his/her last days, e.g. ICU versus a more homely ward.(Anonymous, 2007) Relatives need relatively unrestricted time with the body in a calm environment. Tokens of remembrance, such as hair or nail clippings, may be collected. Organ donation should be discussed in a very sensitive manner. It has been suggested that induction of delivery should be considered as soon as feasible after diagnosis of death in utero.

In the 'replacement child syndrome'(Cain & Cain, 1964) a child is specifically conceived to replace a dead sibling, or an existing sibling may be forced into taking this role. Such parents have an intense narcissistic investment in the dead child. The mother may have experienced unusually high numbers of family losses in her own childhood. The home may have a funereal atmosphere with a palpable obsession with links to the deceased.(Oglethorpe, 1989) Interestingly, Turton ea (2001) found that PTSD was common after stillbirth, especially if conception occurs soon after the loss.

Men may be more secretive about infertility than are women and men may experience difficulty performing sexually according to prescribed schedules. Occasional cases of infertility are associated with non-consummation or anorexia nervosa. The woman may feel empty, worthless or 'not like a woman'. She may harbour guilt over past sexual acts and regret over past induced abortion or she may blame herself for delaying attempts to conceive for career reasons. She may either increase or reject sexual activity. In some cases in vitro fertilisation (IVF) may simply postpone acceptance and grief work. Some cases who do conceive may paradoxically become depressed, possibly as a let down after years of fantasising about how wonderful ordinary parenting would be. Some couples may proceed to IVF too early because of advertising pressures.(Burt & Hendrick, 2005, p. 122) The artificiality of providing specimens and seeing doctors may interfere with the spontaneity of sexual (and other interpersonal) relations. GnRH agonists (e.g. leuprolide and goserelin), used for endometriosis, may cause depression or labile emotions. Clomiphene, used to induce ovulation, may be associated with depression, anxiety, and poor sleep. Assisted reproduction is associated with a small increase in low birth weight and congenital defects, although the great majority of such babies are normal. Older women who conceive as a result of medical intervention are at increased risk of having babies with chromosomal abnormalities. Support groups may help infertile couples.(Stotland, 1996)

When parents discover that their child is intellectually disabled they are less likely to reject the child if the latter is not grossly disfigured and if they have had time during which they can bond before a suspicion that not all is well can arise. They may develop grief because of lost hopes,¹⁵⁵⁸ anger that it happened to them or because they were wrongly reassured, denial of the reality of the situation, anxiety for future children or

¹⁵⁵⁷ Founded in 1978 in Britain as the Stillbirth Association.

¹⁵⁵⁸ Loss of the 'perfect child' (Bicknell, 1983)

about the effects of the disability on the index child or older siblings, or they may feel guilt and a sense of recrimination as they look for possible causes. They need a chance to talk and adjust. Chronic psychosis in a child may trigger severe, prolonged grief in parents.

The intellectually disabled themselves may express grief in ways other than speech, such as insomnia, anorexia, searching, externally-directed aggression, a decline in intellectual or other skills, incontinence, or indifference. The fact that intellectually disabled people are living longer means that more of them experience the death of loved ones.

The relatives of suicides tend to be shocked, to search for an explanation, to find it difficult to share feelings, to feel guilty or stigmatised (often reinforced by the media and others: Harwood *et al.*, 2002; de Groot *et al.*, 2007), or to feel relief (if the relationship with the suicide was poor). There may be an increased mortality from suicide among the bereaved following suicide, although attribution of cause is difficult because, for example, there may be a shared tendency to affective disorder. The same difficulty applies to interpreting reports of a history of exposure to suicide attempts or threats by friends or relatives in the histories of suicide completers: shared cultural and genetic factors act as confounders. Therapists, who may themselves be severely distressed, (Hendin *et al.*, 2004) should initiate early contact with the bereaved family. (Hawton & Simkin, 2003) Peers may suffer traumatic grief (Melhem *et al.*, 2004) and peer support groups may be helpful in coping with suicide among friends. (Ness & Pfeffer, 1990; Robinson, 2005) Murder of a loved one may be followed by persistent fearfulness, anger toward the perpetrator, and intrusive repetitive images of the murder as imagined to have happened. (Rynearson, 1984) Rynearson (1995) found that only child sexual abuse and lack of religious faith were associated with seeking treatment after the murder of a family member; adults who seek treatment under such circumstances are highly reactive to all measures of trauma, grief, and death imagery.

War produces many psychiatric casualties, including prolonged grief in young widows of combatants whose bodies have never been seen. The combat zone militates against the normal expression of grief. Different cultures have their own customs in situations of grief. (Parkes *et al.*, 2000) Black (1987) examined the ways of three Indian groups: Hinduism (e.g. the family is in mourning until the thirteenth day after the cremation, when a special ceremony takes place), Sikhism (various religious items, e.g. brooch, must be left on the body), and Islam (Moslems mourn for three days after the funeral and visit the grave every Friday during the following forty days). The Sikhs do not mind if the body is touched by non-Sikhs but the other two groups do¹⁵⁵⁹. Modern life in the West often means that people live far from families of origin so that coping with loss may be a lonely psychological task.

Loss of sight leads to grief. Denial may hamper rehabilitation. The prognosis should be made clear.

Voluntary organisations should be involved and groups, if available, are useful. Deafness and aphasia are other losses. Relatives need a shoulder to lean on.

Common losses, which elicit grief reactions, include close relatives, friends, sexual partners, social status, self-esteem, and even parts or functions of the body. The loss may be only feared as in separation anxiety. Freud held that the bereaved regresses and incorporates the lost object. His benevolent feelings can then be smothered by sadism without hurting the loved one because only himself is assaulting him. The memory is rejected, incorporated into the ego by identification, and finally it is brought before the superego for condemnation. Depression is more likely to follow loss if the relationship with the deceased was largely negative. According to Klein, we can handle loss better if we succeeded in childhood in relating to others, especially mother, as a whole person and were accepting of mixed feelings of love and anger. Winnicott saw the internalised image of a reliable 'good enough' mother from childhood as providing a lasting source of inner strength and confidence that helped us negotiate loss.

Lieberman (1983) holds that morbid grief may develop and become life threatening if bereavement is concealed from a patient and not discussed soon after the loss.

The first stage of normal grief is numbness, the shock being too much. Disbelief and denial take over. The person is dazed, depersonalised and in 'another world'. After hours to weeks the initial shock subsides. Reality encroaches on consciousness and anxiety rises. Blame may be aimed at the self or projected onto ambulance men, doctors, or elsewhere. Anorexia, preoccupation, declines in efficiency and constant going over the past are the order of the day. Normally, with the aid of defence mechanisms, recovery takes place over some months. Anniversaries and other reminders may bring back sadness later. Factors, which suggest

¹⁵⁵⁹ Wear gloves if it is essential to touch such a body.

that a family will effectively resolve its grief, include cohesiveness in the absence of enmeshment, an ability to grapple with conflict, and adaptability. Factors associated with maladaptive grief in families include poor or unsupportive communication, disengagement and stifling of emotional expression, excessive guilt or anger, blaming or fighting with other members, inability to resolve normal daily family conflicts, inflexible roles, and persisting dependence on the lost person. In other words, anything that avoids, distorts, or prolongs grief augers badly for the future. (Kissane & Bloch, 1994)

Renvoize and Jain (1986) reviewed anniversary reactions. Of particular interest is the case of a woman who lactated as part of an anniversary reaction to the delivery of her stillborn child. The defences employed include: searching by the bereaved; denial of the loss; talking about the loss ad infinitum; intellectualisation (talks without facing the associated feelings); identification with the deceased (dressing or talking like him, identical symptoms to those suffered by the deceased, etc.); somatisation (physical complaints); litigation against caretakers or others; idealisation (lost person praised to an exaggerated degree); and mummification or preservation of dead body, a lock of hair, or objects belonging to the deceased¹⁵⁶⁰.

C Murray Parkes studied bereaved psychiatric patients and devised his famous division of bereavement reactions into grief and modified grief and non-specific reactions.

Grief and modified grief: typical or usual grief (see above) follows fairly predictable course over a period of months, culminating in a return of interest in the affairs of the world. Chronic grief is a magnified reaction spread over a long period of time, and the person may have guilt, self-blame, identification symptoms and/or aggressive or delinquent behavior. In the very young or very old, inhibited grief is manifested by symbolic expression. Delayed grief means that weeks/years pass before symptoms occur. In a 13 month follow up almost one in ten subjects showed chronic grief but none had delayed or absent grief. (Middleton et al., 1996)

Non-specific reactions: psychosomatic disorders (ulcerative colitis, asthma), neuroses (hypochondriasis, phobias, depersonalisation), depression or mania, and others, such as alcohol abuse.

Parkes subdivided abnormal grief into (1) unexpected grief follows a major loss which is unexpected and untimely¹⁵⁶¹; anxiety, shock and disbelief are common; the dead person seems to be in one's presence; self-blame and the need to remain faithful make it difficult to express grief fully and hence to make a fresh start; (2) ambivalent grief follows loss of relationships which have been punctuated by fights and mixed emotions; the bereaved feels relief at the loss - relaxed at first; later there is severe pining and despair; it may become chronic and contain marked elements of self-punishment; and (3) in chronic grief, full grieving begins early but doesn't seem to end. Dependent relationships are more likely to end this way. Parkes makes the point that it is not always the 'dependent' partner who ends up this way, i.e. different degrees of symbiosis may exist so that it is the apparently stronger, domineering partner who may lose out emotionally through loss of someone to smother.

The intellectually disabled respond to loss, often for the only person who understands them, with behavior or neurotic problems. They may be kept back from the funeral or placed in an institution with unfamiliar surroundings, often facing strangers for the first time, when their carers die. (McLoughlin, 1986) Whilst bereavement experienced by children may necessitate major readjustment, most of them develop normally after such an event (*vide infra*). Young and Papadatou (2000) state that children should be encouraged (but not pressured) to attend funerals, be supported by trusted elders, and be given an opportunity to see and touch the deceased.

When a young child is cared for by strangers in a foreign environment he often shows a classical sequence of responses: protest, despair, and then detachment. When the child returns home he shows clinging behavior because of separation anxiety.

Emotionally neglected children may show none of the normal fretting and so on when placed in hospital. They may eventually take an excessive interest in hospital staff¹⁵⁶²; autistic children, on the other hand, do not improve rapidly on removal from the home.

John Bowlby and others have undertaken detailed studies of the development of affectional bonds and the consequences of their disruption at the Tavistock Clinic. The Platt Committee's findings incorporated

¹⁵⁶⁰ Queen Victoria left out Prince Albert's breakfast tray after his death.

¹⁵⁶¹ Unexpected death of a loved one may precipitate PTSD. (Breslau et al., 1999) In fact, within the average community, sudden loss of a spouse may be a more frequent cause of PTSD than are the various forms of personal violence. (Breslau et al., 1998)

¹⁵⁶² Reactive attachment disorder in DSM-IV is divided into the wary child with frozen watchfulness and the over friendly one who indiscriminately goes to anyone.

recommendations based on their research. Mothers were not to find their children unavailable outside hospital visiting hours. The separation was most traumatic when the child was in his second or third years. James Robertson made the famous film 'A Two-year-old Goes to Hospital' in 1952. From this work developed a form of psychotherapy for anxiety, depression or emotional detachment. The steps are: provide a secure base for the patient; explore self and relationship with others; examine client's subjective views of on-going relationships, including that with the therapist; examine his deductions about relationships and the actions he takes as a result; ask if his reactions are appropriate; and ask why he reacts in these ways. Are his ideas based on unresolved and earlier attachment problems?

One of the things that a child learns growing up is constancy. An object torn into two pieces still has the same volume as the whole. If mother leaves the room she has not run away. Later on we know that if a boyfriend talks to another girl he has not necessarily decided to be unfaithful. Failure to incorporate these emotion-laden lessons is at the root of much adult morbid jealousy and separation anxiety.

Early loss of a parent is important. Parental loss before the age of 17 years has been said to increase the chances of depression developing in later life. (Browne *et al.*, 1977; Roy 1978) Roy (1981 a, b) has added further evidence for this in depressives and in chronic undifferentiated schizophrenics. The role of early parental loss in attempted suicide is still controversial. What may be more important is the reason for the loss - it may be unrelated if it occurs through natural causes - and it may be more related to parental discord and intentional separation of parent from child. (Crook & Raskin, 1975) Perris *et al.* (1986) do not support early loss of a parent through death as a precursor of adult depression, 'though parental death may be an important variable for individual patients'. Deprivation of love may be an important psychological risk factor in the background of depressive disorders.

Bereavement in the elderly is a life event with significant consequences for personal health. Some areas keep an at-risk register of the recently bereaved. Local resources, official and voluntary, are employed in crisis intervention to avert disaster, such as suicide.

An interesting problem is the case of the demented spouse who functions reasonably well before the death of the supervising partner, only to need institutional care immediately thereafter.

Brown, Birley and Paykel have done pioneering work on life events. It has been recognised for many years now that the mortality rate rises steeply among the bereaved during the first 6-12 months after bereavement. Coronary thrombosis occurs in excess during this period.

Brown postulated that the intermediate factor might be depressed affect:

LOSS → DEPRESSION → CORONARY THROMBOSIS.

Illnesses often cluster together. Rahe, in the 1960s, found that the death of a spouse was regarded as possibly the most stressful of life events. Bereavement may be associated with increased adrenocortical activity and increased serum prolactin and growth hormone levels.

There are many mundane factors at work in the bereaved, such as self-neglect, poverty, ambivalence towards the deceased, anxiety for one's own health, and lack of companionship. (see also McAvoy, 1986)

The widowed of both sexes have an increased mortality if they change their address. (Helsing *et al.*, 1986)

Bereaved people need to balance confronting and avoiding loss in order not to be overwhelmed. Grief stages (numbness, pining, disorganisation/despair, and reorganisation) are not rigid and can pass back and forth.

Caplan urged that professional help be given early in social *crisis*, believing that the best work can be done in the initial 4-6 weeks, it being then that the patient is most open to influence. In the management of psychiatric breakdown in battle Sargant and Slater had been advocating early intervention since World War II. Erich Lindemann's (1900-74) study of the Coconut Grove nightclub fire¹⁵⁶³ (1944) underlies much of Caplan's crisis theory.

In the 1970s, Mechanic divided people experiencing stress into Copers and Non-Copers. People vary widely in the effect that stress has on them. Important determinants of this are previous experiences of stress and the circumstances prevailing at the time, presently available supports, affective state, and the symbolic significance of the event and its immediate antecedents for the individual. During the early 1940s, Adler examined 46 victims of the Coconut Grove disaster who were treated in a Boston hospital. He

¹⁵⁶³ Club in Boston, November 28, 1942; 491 fatalities.

diagnosed anxiety neurosis in 25 at three months and in 13 at nine months. There is little scientific evidence to support a contention that the Samaritans¹⁵⁶⁴ have any real effect in reducing the suicide figures, although they do provide a valuable service for the distressed and lonely. Also, there is evidence that contacting people by telephone one month after discharge from an emergency department for deliberate self-poisoning may help to decrease the number of repeat attempts over one year.(Vaiva ea, 2006)

Grief is a normal reaction to the loss of physical function. It is often misdiagnosed for major depressive illness.(Steward & Shields, 1985) The prognosis in such cases depends on the severity of the disability, the premorbid personality, and the available supports in the family, community, and so on. The symptoms of grief include preoccupation with the lost object (limb, function, person), physical distress, inappropriate behavior, hostility and denial. These signs weave in and out of the patient's daily activities, and wax and wane over the course of time. Amputation or loss of a body part can be particularly problematic in those who avoid facing up to the loss, are obsessed with it, or who have unresolved sexual problems.(Maguire & Parkes, 1998)

Glass (1959) proposed a useful way of looking at the response of people to catastrophies: the pre-impact period - 'won't' happen' (denial); the warning period - inefficient overactivity; the impact period - may be very short - psychological reactions may be limited to automatic responses; the recoil period - underactivity and apathy (as in 'combat fatigue'); and the post-impact period - the most important inefficient behavior patterns are hostility, anger, and resentment, directed against those held directly responsible, towards the government and its organs who may be reckoned to have acted improperly, or could have behaved in a better way, or even towards society in a non-specific way.

There has been an increase in active interest in *dying* patients. Parkes (1978) examined the fears of the dying and believed that while they might be viewed as realistic fears the physician had a role to play.

Nurses can help both patients and relatives to express their feelings. The chief fears found were removal from relatives, familiar environment, and occupation, plight of dependants, losing control, crying, or not dying well, being a burden, lack of self-sufficiency because of weakness, and incontinence, confusion, or mutilation. Pain was only a major concern in a few cases. What constitutes a good death varies with the individual,(Saunders ea, 2003) religion and secularism.(Walter, 2003) Spiritual and psychological issues may be paramount for both patient and family.(Jolley & Tapley, 2010) A holistic approach is essential.(Neuberger, 2003)

Kübler-Ross(1970) sequence of attitudes towards dying:

Shock
Guilt
Denial¹⁵⁶⁵
Fear
Anger
Sadness
Bargaining
Acceptance and resignation

Self-help groups for bereaved parents may offer an opportunity to share grief, e.g. Stillbirth and Neonatal Death Society (Irish SANDS).

Shelley (1986) advocated the use of routine assessment of terminally ill patients by a psychiatrist and included social workers and a clerical dimension in the team. Patients with good premorbid personalities who are able to express their feelings are able to cope better. Those with a past history of unresolved painful loss are sensitised to their own potential loss. Most cases feared the process of dying more than death itself; the former process was associated with fears of pain, loss of body function, lack of dignity, as well as being a burden on their families. An unknown fate led to cognitive and emotional confusion. Depression, guilt and anger were common findings. Denial (common) could inhibit emotional resolution or

¹⁵⁶⁴ 1850 60 90 90, jo@samaritans.org, www.samaritans.org.uk. Samaritans founded by Rev. Chad Varah, London 1953.

¹⁵⁶⁵ Weisman (1972, 1974) introduced the term '**middle knowledge**' for the common phenomenon seen in dying patients where they were intellectually aware of their fate and wanted detailed information but at the same time spoke as if they were not dying and did not want to be reminded about this: simultaneous acknowledgement and repudiation. This may become apparent, for example, when there is a recurrence of a fatal disorder. Patients may practice denial to different people at different times, i.e. denial is inconsistent.

even lead to refusal to comply with medical advice. Identification with patients and idealisation, especially of the doctor, were common. Cancer was difficult to cope with because it could not be directly visualised. The staff often felt uncomfortable with emotionally distressed patients and they felt threatened by attempts to discuss the dynamics of their reactions, and they wanted to put the patients on 'rarely needed' antidepressants. Therapists should be aware of their own defence mechanisms. Often, staff distance themselves from the dying by offering false reassurance ('You'll be fine') or by selective inattention ('So your toe is sore?'). Female doctors and those who cared for patients for prolonged periods of time may experience particularly strong emotional reactions to the death of patients, and junior doctors need support from their seniors on such occasions. (Redinbaugh *et al.*, 2003) Yardley and Lunt (1986) reported that nurses looking after dying patients might incur greater stress from their relationships with their colleagues than from issues related to death or dying. Brugha (1993) divided decreased mood in the terminally ill into appropriate and transient feelings of loss and grief, depressive adjustment reaction, and depressive illness, although the distinction between the latter two can be difficult to make in practice. Depression may be under treated in this group for a number of reasons, such as viewing it as appropriate to the circumstances or considering treatment so close to death as being inappropriate. The same care must be taken when explaining antidepressant drugs (and in choosing which one to use) to the dying as is required at other times. The stronger is the religious belief among relatives or friends of a dying person the more quickly and completely is resolution of grieving in survivors. (Walsh *et al.*, 2002) Religious requirements of the dying, including those of minorities, has traditionally been underemphasised in the training of professionals in favour of physical and psychological dimensions of support. (Gatrad *et al.*, 2003)

Keeping the fact that a child is dying from the child and his/her siblings can create many problems for the family. Children often know that they are dying but are rarely asked how they feel about it. (Black, 1998) Religious belief in a soul is helpful. Home-based care is less upsetting than that given in an institution. Survivors need help, support, information, explanation and, if requested, to see the body. Funerals (and wakes) offer a chance to grieve openly.

The *Intensive Care Unit* brought with it a frightening unfamiliarity. The most useful roles of the psychiatrist in the terminal care unit (ICU) are the supervision of psychological care given by other staff, and the direct management of psychiatric complications. The referred cases suffer mainly from cancer. The reasons for referral, in order of frequency, are behaviour problems, depression, anxiety, communication difficulties, possible psychogenic complaints, anticipation of problems (e.g. difficulty in identifying with a nurse/patient, or a histrionic patient), family problems, and in one case 'threatened suicide' (turned out to be a panic attack). The psychiatric diagnoses most frequently made are depression, anxiety, and various acute and chronic organic brain syndromes. The role of environment in causing delirium ('ICU psychosis') is controversial. (APA, 2002, p. 41)

In his *Discourse on Melancholike Diseases* (English trans. 1599) du Laurens reminds us that 'melancholike persons should never be alone'. It was only recently that we began to 'landscape' our ICUs and CCUs with clocks and calendars. The extended family - as distinct from the smaller nuclear family - and the wake with their opportunities for support and for successful grieving are almost things of the past. We should consider Man as a social animal and not as an animal within society.

Near-death experiences have attracted much attention and are of great antiquity.¹⁵⁶⁶ They are often used to support claims for an existence after death. They are probably often experienced by persons who are not close to death. (Roberts and Owen, 1988) The content of such experiences probably tell us little about the experience of death. (Appleby, 1989) There are three groups of features in such experiences: cognitive - distortion of time, review of one's life, panoramic memory; affective - feeling of peace or joy; and transcendental - visual images of a heavenly world. (Greyson, 1985) One can also get feelings of separation from the body, visions of oneself¹⁵⁶⁷, and a 'tunnel experience' of passing through a dark enclosed space to emerge into brilliant light. (Greyson, 1983) Religious conversion experiences may follow temporal lobe seizures, (Dewhurst and Beard, 1970) or sometimes after a near death experience. They are not found in survivors of cardiac arrest. (Dobson *et al.*, 1971)

¹⁵⁶⁶ The Swiss geologist, Albert Heim (1892) collected the first series of such cases from mountaineers who had survived falls.

¹⁵⁶⁷ These can also occur in states of acute anxiety - autoscapy.

Survivor guilt is present when a person initially is relieved that someone else died instead of him and the feels guilty for having such thoughts. He may believe that he was the one who should have died. There may be difficulties in forming close relationships because of fears of 'betraying' the deceased.

Neuroses, Somatoform & Factitious Disorders

Brian O'Shea

Neuroses

'Neurosis is chameleon-like...Symptoms may be presented to the doctor; problems to the social worker; and sins to the priest'.(Sims, 1985)

'A neurosis is a reaction which would be appropriate at a different time and place'.(Varma, 1989)

'Phobias, obsessions, and compulsions result most frequently from neurotic intrapsychic conflicts, but they also arise in functional or organic mood disorders'.(Sims et al, 2000)

'One of the unfortunate consequences of eliminating...neurosis...has been the need to introduce....co-morbidity'.(Sims, 2003, p. 394)

'Recognition can help the unconscious shoe-horning of free-floating symptoms into the given shape'.(Appignanesi, 2008, p. 36)

The terms 'neurosis' and 'hysteria' are retained here because they are commonly employed in clinical practice, many psychiatrists, not necessarily of a psychoanalytical orientation, do not agree with their eviction, and it is artificial to discuss modern terminology out of its historical context.¹⁵⁶⁸ Benzodiazepines (BZDs) and other anxiolytics may be needed longterm in some psychiatric patients, although care should be taken in certain situations, such as personality disorder or alcohol and substance abuse. Regular review, including discussion with the patient, is recommended. Regarding SSRI doses, the lowest doses are used for panic disorder¹⁵⁶⁹, intermediate doses are used for depression, and the highest doses are used in both obsessive-compulsive disorder and the eating disorders.

The modern term (neurosis) embodies an absence of an organic brain disorder, retention of insight (in touch with external reality), and a personality (whilst often somewhat disordered) that is not grossly abnormal. All neurotic disorders share precipitating, perpetuating and predisposing factors.

'Essential characteristics' of the neuroses (Bateman, 1990)

Patient recognises symptoms as being self-derived

Symptoms have psychological and somatic components

(Unlike acute stress and adjustment reactions) symptoms are out of proportion to external circumstances

Behaviour, social relationships and personality are impaired but usually remain within socially acceptable limits

Insight is retained and the ability to distinguish reality from fantasy is unimpaired

There is no evidence of organic brain disease or damage

¹⁵⁶⁸ This diagnosis entered medical practice in the 17th century. (Shorter, 2005, p. 133) In 1603 Dr Edward Jordan disagreed with King James I's imputation of witchcraft in a woman with strange symptoms, claiming instead that they were of hysterical origin. Jean Fernel of Paris claimed that humans could change into animals by the action of demons (lycanthropy). Smollius, in 1610, used the term hypochondriasis because of the belief that certain mental states were due to subchondral organ (liver, spleen) dysfunction. Falret, in 1822, used the same term to mean an abnormal belief about one's health. Thomas Willis, in 1667, stated that the origin of hysteria was not in the womb, as was the then current theory, but rather in the brain. Jean-Martin Charcot of Paris described *la petite* ('minor'): longlasting stigmata such as visual and sensory phenomena and *la grande* (dramatic outbursts, e.g. strange postures) *hystérie* during late nineteenth century. Thomas Buzzard (1890) was convinced that a 'very large number' of hysteria cases had early multiple sclerosis. In 1772 the term 'neurosis' was used for the first time. (Sims, 1985) In 1784 William Cullen included many diverse disorders under the heading of neurosis - any abnormality of sensation and behaviour where there was no pyrexia or observable lesion. Jeremy Bentham, philosopher and lawyer of the early nineteenth century, believed that we express those motives and desires that we find to be unacceptable to us in a disguised or symbolic way. George Beard, an American psychiatrist, described 'neurasthenia' (mental exhaustion) in 1869. It has been suggested that neurasthenia arose in a setting of increased preoccupation with commerce and material success and major changes in the role of women.

¹⁵⁶⁹ Start low to avoid exacerbating anxiety - higher doses than used for depression may be required later.

The 'neuroses' were not included in DSM III because of its association with psychoanalysis.

In a large study of diagnoses in a population of 300,000 people in general practice carried out in the early 1970s in Britain the consultation rate for all neurotic states was 75.5/1,000/year for men and 162.9/1,000/year for women, giving a rate of over 90% for neuroses amongst all psychiatric diagnoses. The neuroses were found to be very common among the inpatients and outpatients of hospital specialities other than psychiatry, e.g. 15-20% of hospital presentations in the eye clinic. Two-thirds of psychiatric cases seen in general practices were diagnosable as neurotic during the 1960s.

Neuroses commonly presented with individual symptoms, the undifferentiated syndrome being a form commonly seen in general practice, psychiatrists more usually seeing specific syndromes, although diagnostic instability over time is very common. (Tyrer ea, 2004) Only 36% of cases had no DSM diagnosis after 12 years in Tyrer ea. (2004) The commoner manifestations of the undifferentiated form were anxiety, depression, irritability, insomnia, and fatigue. and preferred the term 'general neurotic syndrome', which ran a prolonged course with variation in the predominance of different neurotic symptoms over time. (see Tyrer ea, 2004) Those with higher PSE scores at initial assessment were usually diagnosed as phobic or depressive, and those with lower scores were diagnosed as having anxiety neurosis. Tyrer ea (2004) found that combined anxiety-depression (so-called 'cothymia'), personality disorder, recurrent episodes, and greater baseline self-rated and depression ratings augured a worse outcome at 12 years, whereas initial diagnosis added little to differences in outcome.

The Office of Population Censuses and Survey (OPCS) in Great Britain carried out a survey of prevalence of psychiatric morbidity among adults (16-64 years) living in private households during 1993 using the *Clinical Interview Schedule – Revised*. (Lewis & Pelosi, 1990) 14% of people had a neurotic problem (12 or more on the schedule), females significantly outnumbering males. The most common symptoms were fatigue (27%), sleep problems (25%), irritability (22%), and worry (20%). The most prevalent ICD-10 neurotic disorder was mixed anxiety and depressive disorder¹⁵⁷⁰ (7.7%) followed by generalised anxiety disorder (GAD, 3.1%¹⁵⁷¹). (Mason & Wilkinson, 1996)

National Comorbidity Survey Replication: general population life time/past year (Kessler ea, 2005)

Any anxiety disorder	31.2/18.7
Specific phobia	12.5/8.7
Social phobia	12.1/6.8
PTSD	6.8/3.6
GAD	5.7/2.7
Panic disorder	4.7/2.7
OCD	1.8/1.1
AWP	1.3/0.8

Key: AWP, agoraphobia without panic; GAD, generalised anxiety disorder; OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.

5-HT₂ receptors may be upregulated in depression and downregulated by antidepressant drugs like SSRIs and TCAs. However, both antipsychotic drugs and LSD also downregulate these receptors, and ECT upregulates them!

Annual cost of anxiety disorders to US economy (Greenberg ea, 1999)

Total - about \$42.3 bn
 General medical treatment - \$23 bn
 Psychiatric treatment - \$13.3 bn
 Indirect workplace - \$4.1 bn
 Mortality - \$1.2 bn

¹⁵⁷⁰ The 1-month prevalence of 'mixed anxiety and depression' (lower overall symptom count than ICD-10 anxiety and depression) was 8.8% in a British household sample of 16-74 year olds. (Das-Munshi ea, 2008)

¹⁵⁷¹ According to Kelsey ea, (2006, pp. 145-6) estimates of lifetime prevalence of GAD vary from 4-9%, usually starting in adolescence/early adulthood. It should be noted, however, that, during a given year, 3-7% of children fulfil criteria for overanxious disorder of childhood.

The main theories of causation of neurotic disorders are introduced in the box and discussed further under individual syndromes.

Aetiology of neuroses

Neurotransmitters: Attenuation of GABA leads to anxiety. 5-HT_{2c} receptors may be activated by stress. Antidepressants eventually downregulate 5-HT_{2c} receptors. Buspirone stimulates 5-HT_{1a} autoreceptors (availability of which are reduced in panic disorder: Nash et al, 2008); this reduces 5-HT release which may then switch off the 5-HT_{2c} anxiety signal. Stress increases norepinephrine release.

Behavioural: Maladaptive activity, exaggerated affect, inability to change, preservation of insight; aware behaviour is irrational and inappropriate but feels unable to stop it; learned phenomenon. However, neurotic (emotionally reactive temperament) behaviour often persists without any obvious reinforcement. The early learning theories of Pavlov and Skinner cannot account fully for human learning. Since then there has been increased attention to cognitions intermediate between stimulus and response. Does behaviour therapy work because it mobilises changes in the client's attitudes about himself in relation to his difficulty, rather than because of some conditioning mechanism? (Mackay, 1992)

Psychoanalytic: More appropriate to earlier stage of psychosexual development; fixed at some earlier stage - this becomes obvious under stress; inappropriate and excessive use of defence mechanisms to reduce anxiety; exaggeration of normality. Freud believed that children were aware of only one sexual organ, the penis. It has been suggested that his phallic phase should be renamed the infantile genital stage, the adult genital stage not commencing until puberty. Panic disorder and agoraphobia have been ascribed to parental, especially maternal, loss or separation in childhood – finding oneself in the open, alone, revives memories of the earlier loss.

Sleep: It is interesting to note that panic attacks in panic disorder can occur at night, in one study only during non-REM sleep. (Mellman & Uhde, 1989)

Genes: Anxiety disorder commoner in relatives than in the general population; 41% of MZ and only 4% of DZ twins concordant for anxiety disorder; in support of a genetic input was a study by Lader and Wing (1966) of the reactivity of the autonomic nervous system as measured by the rate of habituation of the galvanic skin response (GSR). Use of hospital-based samples rather than a wider range of anxiety problems in the community at large may have biased early studies. A later twin study suggested that what is inherited is a non-specific tendency to develop neurosis in general and that the environment may then determine the subtype. (Torgersen, 1983; see Andrews, 1996) It is instructive to recall that an initial report of linkage of panic disorder to a locus on chromosome 16 was refuted by the same team! 95% of panic disorder patients and 7% of the general population were found to possess a duplication (DUP25) on chromosome 15 by Gratacos et al (2001) but this finding was not replicated by Schumacher et al (2003) Polymorphisms of the serotonin transporter gene may provide a link between major depression and generalised anxiety disorder. (Ohara et al, 1999) MZ twins are more alike regarding the patterns of their fears than are DZ twins when tested by questionnaire. (Torgersen, 1979) Murray et al (1981), using the LOI, suggested heritabilities of 0.44 for obsessional traits and 0.47 for obsessional states. A number of authors have decried the abandonment of the concept of endogenous anxiety and some put the blame on excessive homage to Cartesian dogma. According to Kendler, (1996) twin studies suggest the identical or similar genes predispose to generalised anxiety disorder and major depression. Hettema et al (2005) suggest that genes predispose to two broad groups of disorders: panic-generalised-agoraphobic anxiety on the one hand and specific phobias on the other, with social phobia being influenced by both genetic factors. A variant of a gene encoding plexin A2 (PLXNA2) may be associated with anxiety. (Wray et al, 2007) The reader is referred to the section dedicated to individual anxiety disorders for further discussion.

Childhood neurosis: Does not necessarily lead to adult neurosis. A far stronger indicator of adult psychological problems is socially unacceptable behaviour in the child. If childhood neurosis does persist it is usually as either a neurosis or a depressive state. Murray et al (2009) stress the importance of parent-child bidirectional influences in the development of anxiety disorders in children: various characteristics (temperamental style of behavioural inhibition or biases in information processing) may constitute inherited vulnerabilities; environmental factors such as adverse life events and exposure to negative information or

(parental) role models; and over-protection of children by anxious parents as a response to characteristics displayed by the child.

Family interactions: Women allegedly 'pick up' neurosis more readily from their husbands than vice versa, although changing social roles may modify this. The strains of an unsatisfactory family life might militate against women more than men. Men were said to turn to alcohol or criminality, but incidence and prevalence of female alcoholism is increasing. Women often become depressed when the children leave home - empty nest syndrome. Neurotic men stay with their wives for more time than non-neurotic men, i.e. they fail to socialise. (Krietman ea, 1970)

Experimental neurosis: Frustration breeds neurotic behaviour in animals - the executive monkey also develops ulcers; degree of stress required is probably greater in less 'neurotic' personalities.

Dissociation disorders: There is splitting off of pathogenic material from conscious awareness; this material nevertheless continues to exert an influence. Janet wrote of state-dependent memory behaviour where events could only be recalled under similar emotional circumstances. Breuer emphasised autohypnosis. Freud described repression and other defences. Abnormal temporal lobe function has been proposed. Iatrogenesis blames therapist suggestion. Earlier abuse, including CSA, is an attractive theory, but no linear causal relationship has been proven. Nevertheless there is some evidence for an association between childhood interpersonal trauma as a whole, and emotional abuse in particular, predisposing to dissociation and depersonalisation disorder in adulthood. (Simeon ea, 2001) Malingering and factitious depersonalisation complete the list of candidates. In practice, dissociation may exist on a spectrum with normal levels at one end and more obviously pathological degrees at the other extreme. Younger people, particularly children, may be more likely to dissociate and to meet criteria for dissociative disorders.

Sociological: Labelling theory (Scheff, Erikson) - people act in assigned ways; doctors are medical police, labelling deviancy as illness. Sick role theory (Parsons) - the advantages of sick role leads to its adoption. Deviance (Lemert) - primary deviance consists of behaviour that initially prompts medical referral, secondary deviance consists of improper advantage taken by the patient of his illness. Socio-cultural factors might account for Orley and Wing's (1979) finding of twice as much neurosis among Ugandan women as among London women.

The patient would say that he felt unwell. 'Depression' and 'unable to cope' were common calling cards. Social function was poor, activities being disorganised by affective disturbance. Coping with trivia was particularly unsuccessful. Non-competitiveness followed from low self-esteem. The patient was fearful, felt inferior, and was racked by shame. There was profound difficulty in enjoying simple things, and overcompensation was common. The sufferer's attitudes varied more than is normal and, because of constant tension, tiredness and listlessness were more or less constant.

Neurotics were known to have a high morbidity. Follow-up of 'hysterics' was said to reveal a high incidence of neurological disease, although these findings have been challenged because the cases seen may have been self-selected since most of them attended neurological centres. Not all studies find organic problems at follow up and re-assessment should probably not be undertaken unless clearly clinically indicated; the advent of neuroimaging may have assisted in reducing the number of cases incorrectly assigned a diagnosis of hysteria. The diagnosis of an 'hysterical disorder' is not one of exclusion - positive evidence for the presence of neurosis must be sought.

Some historical neurotic syndromes

Neurotic depression: Over two-thirds of anxiety disorder patients will develop a mood disorder, particularly depression, during life. (Pigott & Lac, 2002)

In *anxiety neurosis*¹⁵⁷², the trigger may be environmental or symbolic. Freud believed that anxiety could arise from the external world, the Id (unacceptable drives) or the Super-ego (moral constraints). Anxiety may be the predominant neurotic symptom. An anxiety state (circumscribed, occupies a definite period of time; may be recurrent) must be distinguished from an anxiety trait (always an anxious person). Free-floating anxiety infers that no specific focus for the anxiety can be found (? may have generalised from an attachment to a specific stimulus). Fear is elicited by an objective threat; anxiety is said to arise from unconscious conflicts with no objective stimulus.

¹⁵⁷² Freud's *anxiety (actual) neurosis* concept included general irritability, chronic apprehension, attacks of anxiety, and secondary phobic anxiety.

*Writer's cramp*¹⁵⁷³ is one of the 'occupational cramps', 'task-specific dystonias' or 'craft neuroses'. These conditions share the impairment or loss of a learned motor skill¹⁵⁷⁴. The features of writer's cramp are muscle spasm, ataxia, and discomfort when trying to write¹⁵⁷⁵. The clinical picture is very variable. It may be chronic and progressive with fluctuations in intensity, or it may stop spontaneously at any stage. The subject finds it difficult or impossible to write. Treatment strategies varied historically from electric shocks through re-education and exercises to psychotherapeutic analysis of hostility. Our poor state of knowledge was illustrated by the reporting of 8 out of 42 patients with torsion dystonia that commenced with writer's cramp. In fact, writer's cramp is a focal dystonia, a neurological disorder with equal sex incidence and commencing in adulthood. There is abnormal interneuronal function in the spinal cord. Five percent of cases are familial and possibly autosomal dominant with reduced penetrance. Treatment is difficult, e.g. changing the way a person writes or injections of Botulinum toxin into affected muscles. Spontaneous remission is uncommon. (Thompson, 1993)

*Irritable heart*¹⁵⁷⁶ was described by da Costa during the America Civil War (his first case had aphonia lasting for 10 months). The patient is free of heart disease, is convinced that he has such a disease, and complains of palpitations, fatigue, and inframammary pain. The cause is an anxiety neurosis with hyperventilation. Fiorentini ea (1981) found beta-blockers to be useful in controlling the symptoms. Physicians more recently described a 'condition' called pseudoangina that they say is due to exhaustion!

Hypochondriasis could be divided into primary¹⁵⁷⁷ and secondary. It was strongly debated whether so-called 'primary' cases existed as a neurosis or whether they more correctly came under the heading of personality disorder. The neurotic form had its enthusiastic champions. The secondary form was most often a manifestation of depression - other causes were anxiety states (incl. panic disorder: Noyes ea, 1986; Nutt ea, 2002, p. 11), schizophrenia and dementia. Rapid improvement in cases of illness phobia and hypochondriasis was reported in an uncontrolled trial by exposing patients to illness cues (e.g. exercising to try to bring on a heart attack, or reading literature on the feared illness) and banning of reassurance - seeking behaviour (e.g. no visits to hospital for tests, and relatives not to give reassurance when that is requested).

Hysteria: In hysteria, the primary gain resulted from anxiety reduction as a result of adopting a hysterical defence. Secondary gain was the avoidance of some anxiety-provoking situation. Prognosis was worsened if the personality was disordered, there was somatisation disorder (Briquet's syndrome), if there was much secondary gain, and if the illness was perpetuated by environmental circumstances. Analytically speaking, hysterical reactions are unconscious, i.e. they are not malingering - in the latter instance the 'patient' is fully conscious of what he is doing and why he is doing so. One point against the anxiety-reduction model was the finding of increased muscle tone with the EMG in hysterical conversion states, i.e. hysterics have high arousal levels and very low habituation in spite of low overt anxiety. DSM-III divided hysteria into somatoform disorder (hysteria with mainly physical symptoms; also includes hypochondriasis), dissociative disorder (hysteria with mainly psychological symptoms; also includes depersonalisation disorder), and factitious disorders (uncommon self-inflicted disorders). Dooley (1986) viewed hysteria as a form of behaviour rather than as a disease. As a diagnosis it had declined greatly among inpatients and outpatients in the West and in Japan since the middle of the twentieth century, but it still appeared to be common in underdeveloped areas. During WWII, British and Indian soldiers presented more often with anxiety and hysteria respectively. Conversion hysteria was still common in Indian clinics in the late 1980s, where diazepam was preferred to barbiturates in abreaction interviews. However, hysteria had declined significantly in rural Bengal by 1992. The ancient Greeks believed that hysteria was confined to females and resulted from the migrations of the womb¹⁵⁷⁸ about the body, the womb becoming stuck somewhere and leading to problems. As a lay term which it is synonymous with histrionic. Hysterical personalities were self-centred and demonstrative, incapable of deep emotional commitments. Its presence did not greatly increase the likelihood of developing any other 'form' of hysteria. Hysteria is sometimes seen as a mainly female disorder with antisocial personality as its equivalent in males. Some cases of 'epidemic hysteria' have been described where one person caused outbreaks at different schools! Akagi and House (2002) suggest that most cases of hysteria are not seen by psychiatrists, that it has not really gone away, that there are problems of definition and scope, and that acute and transient cases may be missed. In fact, most modern major psychiatric epidemiological studies, such as the British Psychiatric Morbidity Study, (Jenkins ea, 1997) have not attempted to identify hysteria.

Conversion hysteria was said to have become relatively uncommon in recent years but Ford (2008a, p. 396) suggests that they have simply become more subtle and sophisticated unlike 'the dramatic symptoms of the past'. Almost any physical ailment might be represented, especially paresis and blindness. The patient appeared to 'convert' anxiety into a somatic disorder. Conditions like *globus hystericus* (lump in the throat) and torticollis were shown to have a high association with physical illness. Treatment might take the form of psychoanalysis, waiting, hypnosis, the presentation of strong odours in the case of 'anosmia', placebo, psychotherapy, or even sham physiotherapy. In *globus hystericus* ('*globus pharyngis*') the patient feared that he was intermittently choking and unable to breathe; he can sense a lump in his throat; it is not related to swallowing, and can sometimes be relieved by swallowing liquids or solids. Globus pharyngis was reported to be associated with elevated BDI depression scores and recent independent life events and to respond to tricyclic antidepressants and to MAOIs. It was known that hysterical symptoms, e.g. global amnesia, could be 'released' by organic brain disease. Great caution was urged in making a diagnosis of hysteria. In one study (Maurice-Williams & Marsh, 1985) of 14 cases of simulated paraplegics and tetraplegics it was considered that it was rarely possible to determine whether the behaviour was conscious or not. In most cases the paralysis was of short duration and recovered quickly with simple methods of treatment (e.g. chlorpromazine, firm reassurance, and placebo injections). Many such cases probably never come to the attention of psychiatrists.

¹⁵⁷³ Scrivener's palsy, graphic dyskinesia, *crampe des écrivains*, *mogigraphie*, or *fingerkrampf*.

¹⁵⁷⁴ Merskey and Mai (2005, p. 5) suggest that **repetitive use (strain) injuries** (RSI) are usually regarded as 'aberrant habits of muscular usage' rather than motivated loss of function. There is some evidence that hypnosis may reduce pain in the short term in RSI and little evidence for the effectiveness of special keyboards and other ergonomic interventions. (Page & Wessely, 2007, p. 140)

¹⁵⁷⁵ Patients with occupational dystonias may be dismissed as exaggerating their problems because they can perform one task (say use a typewriter) and not another (e.g. play a piece on the piano).

¹⁵⁷⁶ Cardiac neurosis, disorderly action of the heart, effort syndrome of Lewis, neurocirculatory asthenia of Oppenheimer.

¹⁵⁷⁷ A difficult condition to treat, full of concerns for one's health, often resistant to reassurance, often having many hospitalisations and investigations.

¹⁵⁷⁸ *L. uterus*; Gk. *hystera*.

Shalev and Munitz (1986) suggest a re-definition of conversion as 'A variety of illness behaviours, characterised by unexplained symptoms, suggesting a neurological disease, occurring in a wide variety of medical and psychological disorders' (i.e. treat the actual source of distress and stop interpreting analytically). Merskey (1986) advised that if a hysterical patient says that both of his lower limbs are paralysed the examiner should put his hand under one heel and ask him to raise the other leg - the examiner will feel the heel pressing into the ground. In cases of feigned unilateral lower limb weakness, with the patient supine, the *Hoover sign* is positive if there is no downward pressure exerted by the unaffected leg when an attempt is made to lift the affected leg¹⁵⁷⁹.

Camptocormia (curved trunk), a rare largely wartime conversion syndrome resembling a simian posture was described independently in 1916 by Souques and Rosanoff-Saloff. The features include frontal vertebral flexion, passive drooping of the arms, variable genuflexion, and ataxia. Flexion increases on walking, disappearing when recumbent. The posture was probably worsened by stooped walking in trenches. Organic causes exist, e.g. spinal cord or vertebral lesions, Parkinson's disease, and, in one complicated case, sodium valproate. (Kellett & Chadwick, 2004, p. 332) This author has seen cases resembling camptocormia in people on antipsychotic medication.

Dissociative hysteria might involve clouding of consciousness and a loss of memory for events occurring during an episode. Examples are trances and fugues. DSM-III defined dissociative disorders (psychogenic amnesia, psychogenic fugue, and multiple personality) as being characterised by a sudden, temporary change in the normally integrated function of conscious identity, or motor behaviour, so that some part of one or more of these functions is lost.

As Nutt et al (2002, p. 7) point out, DSM-IV is non-hierarchical¹⁵⁸⁰ whereas agoraphobia, social phobia and specific phobia take precedence over panic disorder, i.e. social phobia + panic attacks = social phobia. Lindsay (2008, p. 574) take issue with high US prevalence figures for phobic disorders and suggests that they may be artefacts of diagnostic criteria or rules governing severity thresholds and disorder hierarchies.

Modern classification of neurotic disorders

(a) ICD-10: Neurotic, stress-related and somatoform disorders

F40: Phobic anxiety disorders – divided into agoraphobia, social phobia, specific (isolated) phobias, 'other', and 'unspecified'.

F41: Other anxiety disorders – panic disorder (episodic paroxysmal anxiety), generalised anxiety disorder (GAD), mixed anxiety and depressive disorders (common in general practice), 'other', 'other specified', and 'unspecified'.

F42: Obsessive-compulsive disorder (OCD) – predominantly obsessional thoughts or ruminations, predominantly compulsive acts (obsessional rituals), mixed thoughts and acts, 'other', and 'unspecified'.

F43: Reaction to severe stress, and adjustment disorders – acute stress reaction, post-traumatic stress disorder (PTSD), adjustment disorders (includes culture shock, grief reaction, and hospitalism in children, but excludes separation disorder of childhood – various subtypes depending on duration, and main emotions and/or conduct effects), other reactions to severe stress, and the usual 'unspecified' ragbag.

F44: Dissociative (conversion) disorder (partial or complete loss of normal integration between memories of the past, awareness of identity and immediate sensations, and control of body movements – dissociative amnesia (loss of memory, usually of important recent events/personal information [including those of a criminal, sexual, marital, or financial nature], not organic in origin and too extensive to be blamed on ordinary forgetting or fatigue), dissociative fugue (dissociative amnesia plus an apparently purposeful journey away from home/work during which self-care is maintained; more common following natural catastrophes or during war; patient may become upset when questioned about personal history), trance and possession disorders (temporary loss of both the sense of personal identity and full awareness of the surroundings; may act as if taken over by another personality, deity, or 'force'), dissociative disorders of movement and sensation (loss of/interference with movements/sensation, not explicable by somatic medical knowledge – some people react repetitively to stress in this way; dissociative movement disorders (e.g. paralysis, ataxia, apraxia, etc not explicable somatic medical knowledge), dissociative convulsions or hysterical pseudoseizures, dissociative anaesthesia and sensory loss, an 'mixed' cases), and 'others' such as Ganser's syndrome (giving 'approximate answers'), or multiple personality disorder. There are also transient such disorders found in children/adolescents, and a ragbag 'other' category (psychogenic confusion and the twilight state).

¹⁵⁷⁹ This *sign* or *test* can also be stated as consisting of downward pressure on the affected leg when the patient tries to raise the unaffected leg. Pressure arises from synergistic muscular contraction. The examiner's hand is held under the heel that is not being raised.

¹⁵⁸⁰ One can diagnose more than one anxiety disorder simultaneously in the same patient.

F45: Somatoform disorders – repeated presentation of physical symptoms and requests for medical investigations, negative findings, and failure of reassurance. Divided into somatisation disorder (complains of symptoms), undifferentiated cases, hypochondriacal disorder (complains about having a serious and progressive disease), somatoform autonomic disorder (symptoms suggesting disease of body part or system that is innervated by the autonomic nervous system, e.g. ‘gastric neurosis’, ‘cardiac neurosis’, ‘nervous diarrhoea’, psychogenic hiccup, and psychogenic hyperventilation), and ‘persistent’, ‘other’, and ‘unspecified’.

F48: Other neurotic disorders, i.e. neurasthenia (weakness, fatigue, and various psychosomatic symptoms like dizziness or dyspepsia; a common diagnosis in China; includes ‘fatigue syndrome’), depersonalisation-derealisation disorder (where these are the predominant complaints; ICD-10 states that they resemble ‘near-death experiences’), ‘other’ (e.g. Briquet’s syndrome, dhat, koro, latah, occupational neuroses like writer’s cramp, psychasthenia, and psychogenic syncope), and ‘unspecified’.

(b) DSM-IV: Anxiety disorders

A single panic attack¹⁵⁸¹ cannot be coded (vide infra)

Agoraphobia

Panic disorder (recurrent panic) without/with agoraphobia

Agoraphobia without history of panic disorder

Specific phobia (formerly simple phobia)

Social phobia (social anxiety disorder)

OCD

PTSD (re-experiencing of extremely traumatic event plus symptoms of increased arousal and avoidance of stimuli associated with the trauma)

Generalised anxiety disorder (GAD: at least 6 months of persistent and excessive anxiety and worry – includes overanxious disorder of childhood)

Anxiety disorder due to general medical condition/substance-induced

(c) DSM-IV: Somatoform disorders

Presence of physical symptoms suggesting but not explained by general medical condition – also not explained by substance effects or another psychiatric disorder like panic disorder:

1. Somatisation disorder (‘hysteria’, ‘Briquet’s syndrome’) – polysymptomatic condition starting before age 30 years, extending over a period of years, and characterised by a combination of pain, GIT, sexual and pseudoneurological symptoms
2. Undifferentiated somatoform disorder – unexplained physical complaints of at least 6 months duration, below threshold for 1. above
3. Conversion disorder (*vide infra*)
4. Pain disorder¹⁵⁸² – descriptions are often dramatic and vivid and pain ‘explains’ all difficulties
5. Hypochondriasis – preoccupation with fear of having, or the idea that one has, a serious disease based on the person’s misinterpretation of bodily symptoms/functions

(d) DSM-IV: Factitious disorders

Physical or psychological symptoms intentionally produced/feigned to assume sick role; not due to malingering (intentional production of symptoms with goal that is obvious when environmental circumstances are known, e.g. to collect insurance); motivation is a psychological need to assume sick role; absence of external incentives for behaviour; divided into –

1. with predominantly psychological symptoms/signs
2. with predominantly physical symptoms/signs
3. with combined psychological and physical symptoms/signs

(e) DSM-IV: Dissociative disorders (*vide infra*)

Somatisation disorder

As a phenomenon, the most common psychiatric disorders that are associated with somatisation are not the somatoform disorders, but rather depression, panic and adjustment disorders. Undifferentiated somatoform

¹⁵⁸¹ Some people experience panic as a normal reaction to significant threat, e.g. combat.

¹⁵⁸² Co-morbid personality disorder is common, especially histrionic, dependent, and passive-aggressive.

disorder (DSM-IV-TR; also called 'multisomatoform' disorder) is probably the commonest somatoform disorder in the community in the USA¹⁵⁸³.

DSM-IV-TR criteria for somatisation disorder are simply a shortened version of Guze's original criteria for Briquet's syndrome¹⁵⁸⁴. It is not true that these patients only complain of (multiple and unexplained) physical symptoms, complaints of psychological ('psychoform' symptoms) and interpersonal difficulties being quite common. The MMPI may mimic multiple psychiatric disorders in such patients. Many psychiatrists believe that this disorder and hypochondriasis, because of their intransigence and longevity, best belong with the disorders of personality. In fact, there have been reports of excess of antisocial personality disorder in first-degree relatives of patients with somatisation disorder.(Lilienfeld *et al.*, 1986) Various theories concerning the origin of adult somatisation have been proposed, e.g. lack of parental care during childhood followed by childhood illness, i.e. being ill becomes a powerful form of communication and commands attention; childhood hospitalisation; illness in significant others;(Craig *et al.*, 2002) and CSA. Stern *et al.*'s (1993) controlled study of females with somatisation disorder reported an excess of personality disorder, especially passive-dependent, histrionic, and 'sensitive-aggressive'. According to Martin *et al.*,(1985) attempted suicide is common, but not suicide itself.

Patients with somatisation disorder are inconsistent historians.(Yutzy, 2003)

Complaints vary and may be forgotten between consultations. Details can be elusive and inconsistent. Efforts at clarifying vague complaints may leave the clinician confused. Exaggeration is common, e.g. 'I bled for days'. The style is histrionic (unlike the hypochondriac who tends to be obsessional). A sense of urgency pervades presentations. Patients may have co-morbid depression¹⁵⁸⁵, anxiety, parasuicidal tendencies, and drug abuse.

Cloninger (1994) suggests that the best discriminators between somatisation disorder and somatic illness, in cases where thorough investigation leaves aetiology obscure, are multiple organ involvement, early onset and chronic course but no physical signs related to abnormalities of structure, and no characteristic laboratory abnormalities of suggested physical disorder. MS, SLE, acute intermittent porphyria, and haemochromatosis may be mistaken for somatisation disorder. Cloninger (1994) considers anxiety disorders, affective disorders, and schizophrenia¹⁵⁸⁶, to be the main psychiatric disorders that may mimic somatisation disorder. He states that histrionic traits, sexual/menstrual problems, and social impairment support a diagnosis of somatisation disorder. The psychiatrist should read the patient's medical records¹⁵⁸⁷. Bass and May (2002) provide a useful overview of somatisation disorder under the heading of 'chronic multiple functional somatic symptoms' (CMFS). According to these authors, over 4% of the general population and 9% of tertiary care referrals have this syndrome. Each GP has 10-15 cases. The actual prevalence varies with the number of symptoms required for a diagnosis. Most cases are female, although reducing the number of symptoms required and eliminating female-specific symptoms (e.g. menstrual) greatly decreases the female-male divide. Recurrent depression, chronic interpersonal difficulties¹⁵⁸⁸, drug abuse, an emotionally deprived childhood, and physical or sexual abuse as a child are commonly recorded. Other characteristics are a disturbed personality and voluminous case notes. They suggest regular (if infrequent) and scheduled (not dependent on symptoms) interviews, focused physical examination, avoidance of excessive tests,(Ring *et al.*, 2004) avoiding accumulation of drug treatments (taper as needed), diplomatic reframing (reattribution) of somatic complaints by linking them to life circumstances, use of problem lists, coopting a relative as a therapeutic ally, aiming at coping (not curing), examination of maintaining factors¹⁵⁸⁹, and remembering that a poor relationship with the therapist may reflect poor parental care/emotional deprivation in childhood. Instead of trying to sell a single aetiology to the patient,

¹⁵⁸³ Page and Wessely (2007, p. 128) argue that symptom overlap and heterogeneity with individual syndromes suggest that functional somatic syndromes are not discrete conditions and may be products of medical specialisation.

¹⁵⁸⁴ Although DSM requires onset before age 30 years, most cases have some symptoms by adolescence or early adulthood, full criteria been met by the mid-twenties. Pierre Briquet (1796-1881) wrote a book on hysteria (1859) while working at the Charité Hospital in Paris.

¹⁵⁸⁵ It has been questioned whether such patients actually have a disorder called depression or simply complain excessively.(Yutzy & Parish, 2008, p. 617)

¹⁵⁸⁶ A large chunk of psychiatry! Patients with somatisation disorder may panic or be depressed, and somatisation may sometimes precede schizophrenic breakdown.

¹⁵⁸⁷ Not all of which may be available in one site.

¹⁵⁸⁸ It is not uncommon for affected females to marry antisocial males and to be rather inadequate parents themselves.

¹⁵⁸⁹ E.g. depression, dependency needs, marital problems, or medico-legal claims.

the clinician should help him or her to understand how many interacting factors (genes, personality style, and life events influence physiology) interweave to produce current circumstances. This approach opens up multiple avenues for intervention (Kontos & Querques, 2008, p.757). However, after training in reattribution, GPs have been shown to give mixed psychosocial and somatic messages (possibly making patients' worries about physical illness worse) to patients and not to probe for underlying psychosocial issues.(Morris et al, 2010)

Hypochondriasis¹⁵⁹⁰

Hypochondriasis is most likely non-categorical. It varies along a continuum of severity¹⁵⁹¹, with or without overvalued ideas, e.g. milder cases seen by GPs may be receptive to reassurance, at least transiently. Hypochondriasis has been seen as a neurosis, a personality disorder¹⁵⁹², a depressive equivalent, a bereavement reaction, and a variant of OCD. There is no rule preventing the one patient having features of somatisation disorder, conversion disorder, and hypochondriasis. There is little evidence for genetic transmission in hypochondriasis. Childhood factors include abuse, neglect, and positive feedback during illness. Interpersonally, it is a form of care-eliciting behaviour. There may be symptom identification with deceased relatives. Culture may add to the problem by an emphasis on keeping super-fit, although hypochondriacs are not noted for taking precautions against health hazards like quitting smoking or taking a proper diet¹⁵⁹³.(Fava & Grandi, 1991) There may be a tendency to misinterpret bodily sensations as disease. Sufferers check themselves repeatedly in mirrors, feel the pulse, or look up medical sources (books, *MIMS*, *PDR*, *Merck Manual*, Internet, etc.) looking for information. They may keep their own medical records. They fear getting old and dying. The differential diagnosis is wide and includes illness phobia¹⁵⁹⁴ and delusional disorder, somatic type¹⁵⁹⁵. The patient classically relates her tale in excessive detail but without emotion (unlike the drama of somatisation disorder). Emotional life is constricted. Social, occupational and sexual activity is limited.

CBT helps, at least in the short term, compared to waiting list controls. SSRIs have also been advocated.(Noyes, 2005; Greeven et al, 2007)

Surprisingly, hypochondriac patients may deal with actual somatic disease realistically! The symptoms wax and wane over time, becoming worse when the patient is stressed. Media coverage of illness or hearing of illness in another person may exacerbate health concerns.

Multiple personality disorder (MPD)

MPD (*dissociative identity disorder* in DSM-IV-TR)¹⁵⁹⁶ is characterised by the appearance of more than one personality, each one, supposedly, being unaware (consciously) or only partially aware of the others' existence.(O'Shea, 2000a) The term *alter* refers to another personality whereas *co-consciousness* refers to the simultaneous awareness of multiple personalities. There may be marked mood changes, changes in

¹⁵⁹⁰ ICD-10 but not DSM-IV includes dysmorphophobia under this rubric.

¹⁵⁹¹ The concept of '**health anxiety**' is much broader than that of hypochondriasis.(Rief et al, 2001) Life events, including somatic illness, may provoke short-lived hypochondriasis. Persistent cases may relate to comorbidity with axes I and/or II disorders.(Kirmayer & Looper, p. 425) Health anxiety, as in concern/anxiousness re possible disease, was associated with frequent consultation in a two-practice Dublin study.(Conroy et al, 1999) '**Medically unexplained syndromes**' (MUS) is a common phenomenon in GP and, although variously defined, usually refers to complaints that have no established somatic or psychosocial origin. Underlying disorders include pain due to depression, the physical symptoms of anxiety, and undifferentiated somatoform disorder.

¹⁵⁹² No specific type is associated with this disorder. Symptoms, e.g. distrusting doctors, could equally be viewed as symptoms.

¹⁵⁹³ Perhaps believing one has a serious disease and a foreshortened future renders healthy change appear redundant.

¹⁵⁹⁴ Fear of developing as distinct from having a disease, as when a person unreasonably fears developing AIDS on being exposed to someone with that condition. The unreasonableness is clearly recognised by the patient and somatic symptoms are not a major component. There is fear or discomfort on being exposed to thoughts of illness. A community survey found illness phobia in 5% of subjects.(Noyes et al, 2000)

¹⁵⁹⁵ Delusions are often bizarre/unrealistic.

¹⁵⁹⁶ Sims (2003, p. 221) suggests that *person* or *persona* (L. mask) may be a better term than personality when applied to MPD. Mitchill may have described the first case in 1816: Mary Reynolds, an English woman in Pennsylvania. The Bordeaux asylum surgeon Eugène Azam (1822-99) described the case of Félicité, a seamstress, during the 1870s. Her primary personality was 'present' for the birth of her many children but it appears that it was the secondary personality who became pregnant! Probably the most famous case was that of Eve.(Thigpen and Checkley, 1957) FR Schreiber has described the case of Sybil who had 16 personalities. Some authors have reported on as much as 100 'recent cases' and others have discovered it in 3.3% of 299 general adult psychiatric inpatients in a North American teaching hospital. Reporting of individuals with 100 or many more 'personalities' have excited some commentators to suggest that there is a competition afoot! The Californian 'Hillside Strangler', Kenneth Bianchi, faked MPD and hypnosis, and thus fooling psychologists and psychiatrists to avoid capital punishment. Maldonado and Spiegel (2008, p. 683) state that the increased number of reports of MPD are unlikely to be due to suggestion alone and hold that a reduction in misdiagnoses (e.g. schizophrenia) and better recognition of the prevalence and consequences of child abuse are other likely explanations.

handwriting, the idea that unfamiliar people know one, or that unfamiliar objects are found in one's possession. A significant proportion of cases report hearing voices that have an internal origin. Among the characteristics of the alternate personality are various mood states, various attitudes toward the primary personality, the same or opposite sex, or different chronological ages. The criteria have been criticised as vague and overinclusive by Piper.⁽¹⁹⁹⁴⁾ DSM-IV-TR includes MPD under the dissociative disorders (see below) and is described therein as the presence of 2 or more distinct identities or 'personality states' that recurrently take control of the affected person's behaviour accompanied by an inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness. Pierre Janet described the mechanism dissociation - elements of consciousness split off to assume an autonomous existence which analysts invoke for this and many other hysterical phenomena, such as amnesia and fugue states. A childhood history of significant trauma, especially child physical or sexual abuse (up to 83% claim a CSA history: Yutzy, 2003, p. 678) has been reported, as has fulfilment of criteria for PTSD in adulthood, although the evidence has been strongly criticised.^(Piper, 1994) Vermetten *et al.* (2006) found smaller hippocampal and amygdalar volumes in female MPD patients compared to healthy controls. Hypnosis has its enthusiasts as a diagnostic or therapeutic instrument in these cases,^(Maldonado & Spiegel, 2003, p. 726) although not everyone would see the wisdom of this approach. The alternate personality tends to be blamed for promiscuity, self-mutilation, etc. Many psychiatrists hold that the disorder is iatrogenic and culturally dependent, whilst others believe that it is induced by media coverage. Merskey (1992) described the diagnosis as a 'misdirection of effort which hinders the resolution of serious psychological problems in the lives of patients'. He retains the right to diagnose occasional changes in temperament (constitutional tendency to react to stimuli in a particular way; component of personality that is heritable, developmentally stable, based on emotion, and immune to social/cultural influence) or apparent personality style as dissociative in nature. Some authors decry the fact that many years passed before the condition was diagnosed. Cardeña and Gleaves (2007, p. 495) call on disbelievers to prove their point.¹⁵⁹⁷ Conversion symptoms, somatic complaints, malingering, and factitious disorders are not uncommon in MPD cases. Maldonado and Spiegel (2008, p. 684) state that one usually finds evidence of comorbid Axis I and Axis II disorders in MPD patients, especially depression, substance use disorders, and borderline personality disorder, as well as self-mutilation. They also state (p.698) that dissociation occurs worldwide but is more likely to take the form of MPD in the West and possession states in the East.

Dissociative disorder

DSM-IV-TR defines dissociative disorders as disruption in the usually integrated functions of consciousness, memory, identity, or perception of the environment. It may be of sudden or gradual onset, transient or chronic. There are 4 subtypes. In dissociative (psychogenic) amnesia¹⁵⁹⁸ the person cannot recall important personal information, usually of a traumatic or stressful nature, and the amnesia is too extensive to be explained by ordinary forgetting. Freeman (1993) wrote that 'it is probably impossible to distinguish [hysterical] amnesias from conscious malingering unless the patient confesses'. In dissociative (psychogenic - as distinct from that due to depression or epilepsy) fugue¹⁵⁹⁹ there is sudden, unexpected travel away from home or work, accompanied by inability to recall one's past and confusion about personal identity or the assumption of a new identity. Dissociative identity disorder is the DSM term for MPD (*vide supra*). Twilight¹⁶⁰⁰ (dreamy) states are characterised by disorientation for time and place and impaired short term memory, as if dreaming. Awareness is restricted and attention is poor. Memory may be divided into explicit/episodic and implicit/semantic. The former involves recall of personal experiences identified with the self, e.g. 'I went shopping yesterday'. The latter involves the execution of routine operations, such as driving a car. There may be different anatomical locations for these two systems, e.g. hippocampal formation and mamillary bodies for episodic memory and basal ganglia and

¹⁵⁹⁷ A sceptic might add that this is similar to a disbeliever in alien abduction being asked to produce contrary evidence.

¹⁵⁹⁸ Pope *et al.* (2007) found no record of cases of dissociative amnesia before 1800 and suggest that it is culture-bound syndrome dating from the nineteenth century.

¹⁵⁹⁹ **Fugue states** can also be associated with cerebral pathology, alcohol and other drugs, malingering, factitious disorder, lath, and amok. Therapy (psychological, amytal, or hypnosis) is aimed at helping the patient to recall what happened leading up to the fugue. Brief fugues often resolve spontaneously whereas chronic cases may prove to be beyond help. *Pibloktoq* or 'running syndrome' in the Arctic is probably a dissociative fugue. Other **culturally determined fugues** may include *possession states* in India, *amok* in Indonesia, *lath* in Malaysia, *bebainan* in Indonesia, and *ataque de nervios* in Latin America.

¹⁶⁰⁰ Unfortunately (David, 2009, p. 5), *twilight states* can refer to one of a number of syndromes ranging from 'hysterical' (neurotic) to certain complex partial seizures.

cortex for procedural memory. Leading from these thoughts, it has been suggested, speculatively, that the automaticity of certain dissociative disorders might follow from the separation of self-identification/explicit memory from routine activity/implicit memory. There is fMRI evidence that dissociative disorder is associated with enhanced working memory¹⁶⁰¹. (Elzinga et al, 2007)

Benzodiazepines may worsen dissociation.

The differential diagnosis of *wandering* includes psychogenic fugue (long journey, behaviour normal, amnesia – may be patchy – for episode, +/- assumption of new identity, may last for days), postictal fugue (less purposeful and briefer), depression, acute stress disorder, malingering, dementia, delirium, alcoholic 'black-out', head injury, and hypoglycaemia.

Conversion

The term 'conversion' assumes transformation of unconscious psychic conflict into a physical symptom. This is difficult 'prove' unless there is demonstrable temporal proximity between psychosocial stress and symptom onset or if similar circumstances previously led to 'conversion' in the same patient. Conversion disorder is commoner in females (married women in Lahore in one study: Chaudhry et al, 2005) than in males and usually, but not exclusively, commences in late childhood or early adulthood. More severe forms of sexual and/or physical abuse in childhood are reported more often by conversion disorder patients. (Roelfs et al, 2002) Healthy controls feigning a motor difficulty have different cerebral functional scan results to those reported in patients with similar conversion motor symptoms (Spence et al, 2000) but it is difficult at this stage of our knowledge to know what is cause and effect, a problem (in this author's view) with much neuroimaging.

DSM-IV-TR conversion disorder

- Unexplained* symptoms** or deficits affecting voluntary motor or sensory function suggesting a neurological or general medical condition
- Psychological factors judged to be important

*By general medical disorder, drugs, or culturally sanctioned behaviour or experience.

**Cannot simply be pain or sexual functioning.

Culturally sanctioned behaviour or experience would include ladies swooning in years gone by or 'seizures' during religious ceremonies. Conversion disorder appears to be more common in rural, less educated, non-Western societies, and may be influenced by lack of opportunity for protest. (Kay & Tasman, 2006, p. 253)

The common assumption that conversion phenomena are more commonly left-sided is not supported by the evidence. (Stone et al, 2002)

Tunnel (tubular) vision

Can only see directly ahead no matter how near or far he focuses (in normal vision horizons widen as eyes focus on objects further away)

Aetiology

Majority - psychological causes

Others - end-stage glaucoma, retinitis pigmentosa, bilateral occipital lobe lesions with macular sparing, migraine

May occur as an aura in TLE

In cases of psychogenic blindness, a vertically striped cylinder is spun in front of the patient. In people with normal vision this will produce involuntary (optokinetic) nystagmus. Visual-evoked responses are another possible test. The therapist might prescribe plain glass in spectacles to allow the patient to save face when his vision is 'restored'. Cases of so-called functional dysphonia have been said to have difficulty expressing their true feelings! However, one must not miss organic dysphonia¹⁶⁰². In fact, many authorities consider view the majority of 'functional' dysphonias as seen today as examples of dystonias and treat

¹⁶⁰¹ Unlike PTSD which is associated with impaired working memory. (Clark et al, 2003)

¹⁶⁰² Recurrent laryngeal palsy, Parkinson's disease, myasthenia gravis, and disorders of the vocal cords or ventilatory function.

them as such. When a supine patient flexes a thigh to lift the leg there is a downward contralateral leg movement that can be felt by the examiner's hand held under the heel. A patient with psychogenic hemiparesis will show Hoover's sign (lack of downward movement of the 'unaffected' leg when the patient tries to raise the 'paralysed' leg).

Rutter and Hersov (1985) followed up children diagnosed as having conversion hysteria for 4-11 years and almost half were shown to have an organic disorder! Conversion disorder and neurological disorders often coexist.(Fricchione ea, 1999) Suspicion of an underlying somatic disorder should be highest for older patients. Among the many conditions misdiagnosed as hysteria over the years are temporal lobe epilepsy and basal ganglia A-V malformations. In hysterical aphonia there is no vocal cord paralysis (*only* voluntary cord adduction is impaired) and the patient may be able to cough or hum.

Outcome factors in conversion disorder

Better

Mood disorder

Acute onset

Clear precipitation by stress

Early treatment

High IQ

Worse

Personality disorder.

Many conversion disorder patients are subsequently found to have somatisation and other neurotic disorders.(Mace & Trimble, 1996; Şar ea, 2004) Slater's (1965) finding of an excess of neurological disorders on follow up has received little support.(Mace & Trimble, 1996) Nevertheless, the present author has seen a number of acute cases labelled 'hysterical' that turned out to be organic, e.g. subarachnoid haemorrhage, Guillain-Barré syndrome, and cerebral thrombosis. Also, Chaudhry ea (2005) followed up 107cases (83% female, mean age at start of 23.2 years, 58% married, 73% positive for family history of psychiatric disorder) of conversion disorder in Lahore for 15 years and found that 20% still has conversion disorder, 5% had epilepsy (3 case of complex partial seizures, one case of tonic-clonic seizures), 1 patient had an arteriovenous malformation, 2 cases had vascular headache, 19% had comorbid major depression, and 55% did not fulfil DSM-IV criteria for any disorder. Stone ea (2005) conducted a systematic review of the literature and found that there has been a 4% rate of misdiagnosis of conversion symptoms since 1970. Conversion disorders can be complicated by contractures (e.g. Achilles tendon), pulmonary embolus, and bed sores.

Hysterical overlay

This term is often employed by psychiatrists to infer an inconsistent miscellany of symptoms, signs and behaviours reminiscent of classical hysterical syndromes but here occurring as a reaction to real organic disorder. This phenomenon is more common than pure conversion. Thus a man with known heart disease develops precordial pain with no ECG or enzyme changes or the epileptic has a non-epileptic seizure. It must be realised that organic pain does not always correspond to dermatomes. It is not sufficient to diagnose conversion or dissociation simply on the basis of the non-finding of an organic disorder – positive evidence of a hysterical illness must be sought. Hysteria, in either its conversion or dissociation guises, is rare after 40 years of age, most cases starting before 35 years. Hysteria with onset in middle or old age may be a harbinger of another primary condition.

Hysterical psychosis

Some patients, who often have hysterical personality traits, were said to become abruptly and transiently psychotic when under stress. Hallucinations, when present, were usually visual, vivid and well formed. There could also be delusions, paranoid thinking, bizarre depersonalisation, and grossly unusual behaviour. Immigrants with poor understanding of the local language were typical victims. General care was superior to medication. Hirsch and Hollender (1969) suggested that the modern equivalent is borderline personality disorder with brief psychotic episodes.

Obsessive-compulsive disorder (OCD)

This common disorder¹⁶⁰³ was previously thought to be rare¹⁶⁰⁴, a misconception probably due to the secrecy in which patients often cloud their symptoms, and reliance on hospitalisation rates rather than community rates. The lifetime prevalence in the general population is 1.6-3%¹⁶⁰⁵. In the USA, OCD is said to be the fourth most common psychiatric diagnosis after phobias, substance-related disorders, and major depression. OCD affects equal numbers of males and females or a slight excess of females, although it may come on earlier in males. The mean age of onset is 22 years. Familial cases may have an earlier onset (not all cases are familial), affect an excess of males, and be frequently comorbid with tics¹⁶⁰⁶ and developmental disorders, as well as anxiety, mood and disruptive disorders.¹⁶⁰⁷ OCD patients are common in non-psychiatric clinics, e.g. dermatology.

Various defence mechanisms are said to operate on OCD. With isolation the person is only aware of the affectless idea, the affect and impulse from the idea being repressed. In undoing, a compulsive act is done to prevent or undo consequences imagined to follow thoughts or impulses. Reaction formation involves patterns of behaviour and conscious attitudes exactly opposite to the underlying impulses. Magical thinking means that simply thinking of something causes it to happen (aggressive thoughts frighten the patient). The ambivalent patient harbours love and hate toward the object; this causes conflict that lead to undoing, paralysing doubts and so on.

There is an argument that OCD belongs with the psychoses¹⁶⁰⁸. Certainly one sees OCD patients who harbour notions of near delusional intensity and with barely discernible insight. DSM-IV recognises this and includes the specifier 'with poor insight' and in such cases the additional diagnosis of delusional disorder or psychotic disorder not otherwise specified is allowed.

The patient suffers as a result of preoccupation with thoughts or actions that he knows to be inappropriate. Resistance to such thoughts or actions heightens anxiety. Obsessional themes are very similar across cultures and nations. He may think about harming someone, being contaminated with dirt or bacteria, or his mind may be filled with obscenities. Obsessional thoughts of harming others with knives may prompt the patient to avoid knives. This is not a true phobic avoidance since the fear is not of knives but of the idea of harming someone with them. Doubts may plague him, such as when he constantly checks to see if he really put that cigarette out. Compulsive hand washing is a common example of a compulsive ritual. Their red excoriated hands may be mistaken for allergic dermatitis.

In DSM-IV (and –TR) OCD, and in contradistinction to DSM-III-R, thoughts (praying, counting, repeating words silently) can be either obsessions or compulsions depending on whether they increase anxiety (obsessions) or reduce anxiety (compulsions). In other words what was seen as anxiety provoking (obsessions) now become anxiety reducing (compulsions)! Compulsions are repetitive behaviours (hand washing, ordering, checking, confessing etc.) or mental acts/rituals (praying, counting, repeating words silently, etc.). Obsessions are thoughts, impulses or images. Such images are frequently vivid, morbid and

¹⁶⁰³ Famous probable cases of OCD include Hakuin (1685-1768, Japanese Zen master), Martin Luther (1483-1543), Howard Hughes (1905-76, American millionaire), and John Bunyan (1628-88, author of *Pilgrim's Progress* and *Grace Abounding to the Chief of Sinners*).

¹⁶⁰⁴ Nutt and Ballenger (2005, p. 73 *et seq.*) point out that until 1984 OCD was usually said to affect 0.05% of the population. They also state that not everyone agrees with modern prevalence figures, critics pointing out the scope for exaggeration inherent in the *Diagnostic Interview Schedule* and use of lay people.

¹⁶⁰⁵ **Isolated obsessions (80%) and compulsions (50%)** are common in the general community. For the majority of people such symptoms are often said not to be excessively upsetting, do not take up a large part of their waking hours, and do not significantly interfere with function. However, Fullana *et al.* (2009), using data from the prospective longitudinal Dunedin study of an unselected birth cohort found that both phenomena were common in other psychiatric disorders and in people without mental disorder; in the latter they did cause significant interference; harm-checking was the commonest symptom dimension; anxiety/depression and obsessions (especially aggressive/shameful thoughts) but not compulsions led to help-seeking; and obsessions and compulsions at age 11 were associated with later OCD.

¹⁶⁰⁶ Non-OCD relatives also have an excess of tics and relatives of Tourette patients (even those patients without OCD) are at increased risk for OCD. (Bloch & Leckman, 2008, p. 652)

¹⁶⁰⁷ Some workers (Issler *et al.*, 2010) suggest that OCD comorbid with bipolar disorder may be a different condition from pure BP on the basis that the former may be more severe, have an excess of depressive episodes and residual symptoms, a higher risk for treatment-emergent mania, and anxiety and impulse control burden.

¹⁶⁰⁸ Some experts suggested the term '*obsessive-compulsive psychosis*'. They draw a comparison between this situation and depression with and without psychosis. Nutt and Ballenger (2005, p. 81) suggest that 5-45% and 15% of patients with chronic schizophrenia have OCD symptoms and OCD respectively; many such people are able to tell the difference between internal and external sources of such symptoms; and adding anti-OCD medication may improve OCD symptoms found in people with schizophrenia.

violent, e.g. the man who 'pictures' men's genitalia every time he looks at a (dressed) man, or repeatedly visualises a bad accident or the funeral of a friend. According to DSM-IV, some patients do not have good insight into the excessiveness or unreasonableness of their obsessions and compulsions.

Excessive hoarding, wherein persons cannot throw anything out in case it may sometime prove to be needed, may be due to OCD¹⁶⁰⁹, (Hollander & Simeon, 2003, p. 582) and OCD-related hoarding may be mediated by reduced activity in the cingulate cortex. (Saxena et al., 2004)

Four factors were generated by meta-analysis of symptoms in OCD (Bloch et al., 2008): symmetry, forbidden thoughts, cleaning, and hoarding.

No single theory accounts for the symptomatic heterogeneity of OCD. (Abramowitz et al., 2009)

Cowie (1961) stated that the children of obsessional neurotics have an increased risk of non-specific neuroses but not of obsessional symptoms *per se*. However, Jenike (1989) reported that 20% of the nuclear family have overt obsessive-compulsive neurosis and another 15% have a subclinical form of it. Like OCD cases, their first-degree relatives have deficits in cognitive flexibility and motor inhibition. (Chamberlain et al., 2007) Collection of neuropsychological data at ages 13 and 32 years (Grisham et al., 2009) revealed evidence of premorbid impairment in visuospatial abilities and some executive functions in those who went on to develop OCD.

Blanes and McGuire (1997) suggest that there may be two extreme forms of OCD, a primary type and a neurodevelopmental type. Head-to-head, these two types are characterised respectively by female/male preponderance, late/early age of onset, episodic/chronic course, mild/severe symptoms, frontal/visuospatial neuropsychological impairment, some increase in/excess of soft signs, a good/indifferent treatment response, and a different profile of associated conditions (mood, anxiety and eating disorders v developmental). Nestadt et al. (2009) derived three classes of OCD based on comorbidity using multi-level latent class analysis: simplex (major depressive disorder [MDD] is common); tic-related (mainly males; very conscientious; tics are common, mood disorders rare); and affective-related (mainly females; young age at onset; obsessive-compulsive personality features; panic disorder and affective syndromes are common; low conscientiousness).

About 20% of patients have tics as well as OCD. An increased incidence of obsessive-compulsive symptoms occurs in Sydenham's chorea and Tourette syndrome. Monoclonal antibodies identify a B-lymphocyte antigen (D8/17) which is a trait marker for susceptibility to rheumatic fever as a complication of group A streptococcal infection. An excess of D8/17-positive cells have been found in children with Sydenham's chorea, streptococcal infection, and childhood-onset OCD or Tourette syndrome or chronic tic disorders.

PANDAS¹⁶¹⁰

Occurs mostly, but not exclusively, in childhood (Bodner et al., 2001)

Associated with tics and/or OCD related in time to streptococcal infection

ADHD symptoms may be present (Popper et al., 2003, p. 907)

Exacerbations may follow further infections

Anxiety, oppositional defiant disorder, and depression may be present

Often indistinguishable from Tourette disorder

Basal ganglia often normal on neuroimaging (Dale & Heyman, 2002)

There may be a role for anti-basal ganglia antibodies in a 'significant subgroup' of OCD cases (Dale et al., 2005)

Penicillin was ineffective in one pilot study of 37 patients (Garvey et al., 1999) but plasma exchange significantly reduced obsessive-compulsive symptoms in a small (N=10) study. (Perlmutter et al., 1999)

It has been suggested that 'canine acral lick', a form of excessive licking in dogs and cats (often increased by stress) that responds better to antidepressants with a serotonergic profile, might be the canine version of

¹⁶⁰⁹ However, compulsive hoarding is not confined to OCD. (Pertusa et al., 2008) **Causes of hoarding** include OCD, stimulant abuse, autism, anorexia nervosa (uneaten food), Prader-Willi syndrome, Tourette disorder, schizophrenia, schizotypal personality disorder, and anankastic personality disorder. CBT is helpful in the treatment of compulsive hoarding. (Gaston et al., 2009) Compulsive hoarding is common and heritable, at least in females. Non-shared environment also likely plays a part in aetiology. (Iervolino et al., 2009)

¹⁶¹⁰ Paediatric autoimmune neuropsychiatric disorders associated with streptococcal infection. Existence of PANDAS is not universally accepted. (Jankovic & De Leão, 2003)

OCD. Checking by rodents induced by a dopamine agonist may also serve as an OCD model.(Dvorkin ea, 2006)

Genes and OCD

Twin OCD concordance studies: MZ 87%: DZ 47%

Evidence of sequence variation in SCL1A1 gene (encodes neuronal glutamate transporter on chromosome 9p) in OCD (Arnold ea, 2006; Wendland ea, 2009); sequence variation in this gene may explain obsessive-compulsive symptoms induced by atypical antipsychotic drugs.(Kwon ea, 2009)

Association between OLIG2 (gene for oligodendrocyte lineage transcription factor 2 on chromosome 21q)¹⁶¹¹ and OCD in absence of Tourette disorder.(Stewart ea, 2007)

OCD may be due to excessive activity of orbitofrontal-limbic-basal ganglia-thalamic circuitry.

Electrical stimulation research conducted in the early 1970s suggested that the cingulate area might be important in the genesis of compulsive movements. Tests of saccadic function in OCD suggest an abnormality in guiding behaviour on the basis of an internal representation of the task goal, rather than a problem with inhibiting reflexive behaviour; latencies on an antisaccade task are increased.(van der Wee ea, 2006) EEG evidence suggests prefrontal and basal ganglia abnormalities.

Neuroimaging suggests that orbito-fronto-subcortical dysfunction is important in OCD. PET scans has shown increased cerebral blood flow (CBF) in orbitofrontal cortex and dorsal parietal cortex and reduced CBF to the caudate nucleus in drug-free OCD cases. Fractional anisotropy, a measure of water self-diffusion, is bilaterally reduced in anterior cingulate gyrus white matter in OCD.(Szeszko ea, 2005) Increased metabolic rate in the cingulate cortex in OCD on PET has normalised after SSRI treatment, and a reduction in glucose metabolism in the head of the right caudate nucleus has been documented following treatment with either fluoxetine or behaviour therapy. Drug-naïve OCD patients may have a small globus pallidus.(Szeszko ea, 2004) Reduced blood flow to the right inferior frontal cortex has correlated with illness severity. CT scans may show reduced caudate volumes bilaterally – this could lead to inadequate filtering of output from orbitofrontal regions. MRI scans may have longer mean T1 values for frontal white matter and have shown small caudate nuclei. However, caudate volumes have been reported as normal if care is taken to exclude cases with neurological symptoms. There have been reports of increased frontal glucose metabolism and increased blood flow in the medial-frontal cerebral cortex. Female patients undergoing MRI have been reported to have less total white matter and more total cortical volume than controls. Statistical parametric mapping of segmented magnetic resonance images revealed increased regional grey matter density in multiple cortical (incl. left orbitofrontal cortex [OFC]) and subcortical (incl. thalamus) areas and reduced grey matter density in posterior brain areas (e.g. left cuneus and left cerebellum). In OCD following symptom provocation, fMRI shows activation in medial orbitofrontal, lateral frontal, anterior temporal, and insular cortex, as well as in the caudate nucleus, lenticular nucleus, and amygdala, effects that are absent in control subjects. All these findings have been interpreted as indicating heterogeneity in OCD populations. Neuroimaging is still beset with highly technical methodological problems.

Radua and Mataix-Cols (2009) performed a voxel-wise meta-analysis (N = 401 with OCD; 376 healthy controls) and found that OCD is associated with increased regional grey matter volumes in bilateral lenticular nuclei (extending into caudate nuclei) and decreased volumes in bilateral dorsal medial frontal/anterior cingulate gyri; inclusion of severe cases increased the likelihood of finding increased basal ganglia grey matter volumes; and current treatment with antidepressants had no detectable influence on these findings. In a further voxel-wise meta-analysis (Radua ea, 2010) involving 639 patients with anxiety disorders and 737 healthy controls, anxiety disorders (including OCD) were characterised by decreased bilateral gray matter volumes in the dorsomedial frontal/anterior cingulate gyri; OCD was associated with increased bilateral gray matter volumes in the lenticular/caudate nuclei; and patients with other anxiety disorders (chiefly panic and PTSD) had reduced gray matter volumes in the left lenticular nucleus.

¹⁶¹¹ Important in development of myelin-producing cells and highly expressed in brain regions implicated in OCD.

Neuroimaging findings and OCD summarised

2006

Event-related fMRI - behavioural impairments plus aberrant OFC-striatal and dorsal prefrontal activity in OCD on a reversal learning task that addresses function of that circuit

2008

MRI in drug-naïve paediatric OCD found more gray matter than in controls in brain areas comprising cortico-striatal-thalamic-cortical circuits

Using DTI to measure fractional anisotropy (FA) of white matter, OCD cases had significantly reduced FA in a large region of right inferior parietal white matter and significantly increased FA in a right medial frontal region – relatives also had significant FA abnormalities in these regions

2009

OCD and major depressive disorder (MDD) show different neural patterns in fronto-striatal and paralimbic areas on fMRI during a self-paced reversal learning task in an event-related design

OCD (on fMRI) is associated with functional alterations of cortico-striatal networks; there is abnormal and heightened functional connectivity of ventrolimbic cortico-striatal regions in OCD

OCD patients may involve other people, including the family, in their rituals. They should be encouraged to a firm but sympathetic stance. The present author has found this to be easier in theory than in practice, so enmeshed may third parties become.

Sixty-seven percent and 25% of OCD patients experience major depression and social phobia respectively at some stage. It is often said that only 15-35% of OCD cases have premorbid obsessional traits, yet Bejerot ea (1998) reported that 36% of an OCD sample had obsessive-compulsive personality disorder. Apparent personality disorder, such as dependent or avoidant, may sometimes disappear when OCD is successfully treated.(Ricciardi ea, 1992)

In thought stopping the patient either shouts 'STOP' or gives a sharp painful pull to an elastic band around the wrist every time an unwelcome thought enters the head - eventually he may be able to get the same effect from simply thinking about the band. Stress inoculation training consists of distraction, thought-stopping, and self-guided dialogue. Exposure, stress inoculation training, or both treatments combined resulted in equal improvement that was maintained at one year in female assault victims with PTSD.(Foa ea, 1999)

Another useful strategy is response prevention, e.g. the compulsive hand-washer has his hands smeared with dirt but is not allowed to wash them. *Exposure and response prevention* (ERP), perhaps best combined with discussion of beliefs and feared consequences, is probably the treatment of choice for OCD but is not readily available,¹⁶¹² although it has been administered effectively over the telephone (Lovell ea, 2006) and in group format.(Kearns ea, 2010) Its effects are apparently long lasting. Exposure may need to be in imagination if the nature of some obsessions is antisocial, e.g. harming the self or others. Listening over and over again to a recording of oneself giving a commentary of ones thoughts (or simply deliberately dwelling on ones thoughts) may be beneficial for some cases of obsessional rumination, so-called habituation training. There are reports suggesting that cognitive therapy on its own is not effective in OCD. Drugs that have been found to be relatively successful are phenelzine, tranylcypromine (the author has had good results), the SSRIs, and clomipramine¹⁶¹³. The patient does not need to be depressed for the drugs to work. It is stated in the literature that effective drugs tend to be serotonergic, suggesting a possible 5-HT abnormality. There is some basic research evidence to support this contention.¹⁶¹⁴ Desipramine and nortriptyline, which lack serotonin reuptake activity, are not antipanic agents. Certainly SSRIs are probably safer than many other antidepressants. There is almost always relapse on stopping medication. The usual measure of improvement in OCD is a 35-40% reduction from baseline on the *Yale-Brown Obsessive Compulsive Scale* (Y-BOCS) induced by a 10-12 week treatment. Some patients improve further with longer duration of treatment but generally don't achieve complete remission. Augmentation strategies are

¹⁶¹² See De Silva & Rachman (2004) for a readable overview of OCD. ERP may be usefully combined with SSRIs.(Simpson ea, 2008)

¹⁶¹³ In order to get optimal results up to 300 mg/day of clomipramine given over at least 10 weeks may be required.

¹⁶¹⁴ E.g., prolactin response to serotonin-releasing d-fenfluramine is blunted in drug-free OCD cases.(Monteleone ea, 1997) Also, studies of the 5-HT_{1b} terminal autoreceptor in animals reveal desensitisation following administration of an SSRI. The time frame for this is about eight weeks which is consonant with the time required to produce clinical response in human OCD.

generally disappointing, e.g. pindolol¹⁶¹⁵. Neuroleptics like haloperidol help if there are comorbid tics¹⁶¹⁶ or a family history of tics. SSRIs, especially in high doses, can induce or worsen tics. Clozapine may exacerbate OCD, probably by antagonising 5-HT₂ receptors.

Not all authors are enthusiastic about the benefits derived from exposure therapy and pharmacotherapy of OCD¹⁶¹⁷.

For refractory, disabling cases, limited-site psychosurgery¹⁶¹⁸ offers amelioration with low risk¹⁶¹⁹ whereas repetitive transcranial magnetic stimulation¹⁶²⁰ (rTMS) may be ineffective. (Sachdev ea, 2007) There is preliminary data for the effectiveness of chronic deep-brain stimulation¹⁶²¹ in OCD. (Gabriels ea, 2003) Stimulation of the subthalamic nucleus¹⁶²² reduces Y-BOCS scores but not depression or anxiety in severe OCD and may be associated with operative complications such as infection or haemorrhage. (Mallet ea, 2008)

Skoog and Skoog (1999) described the outcome in 144 Swedish patients after a mean of 47 years from onset of OCD. Eighty-three percent improved, 20% had a complete recovery and subclinical symptoms were found in 28%. Poor outcome correlated with early onset, obsessive-compulsive symptoms, low baseline social functioning, and an early chronic course. So, after several decades, most cases improved, but the majority had clinical or subclinical symptoms. Micali ea (2010) followed up 142 of 222 children¹⁶²³ and adolescents with OCD for over 9 years and found a persistence rate of OCD of 41% and 40% had a psychiatric diagnosis other than OCD; the longer the duration of OCD at assessment the more likely was it to persist; and high baseline psychopathology levels predicted other psychiatric disorders at follow-up. *Obsessional slowness*¹⁶²⁴. These patients form a minority of OCD sufferers. It may relate to covert or overt rituals or indecision with fear of making mistakes or causing disorder, although anxiety levels may be low in practice. Is it a variant of obsessional personality disorder or OCD? Males may outnumber females, there may be a history of prenatal or delivery problems – although most have a history of normal developmental milestones, and there may be a family history of psychiatric disorder in up to half the cases. The pathophysiology may reside in neuronal loops running between the basal ganglia and the frontal lobes. Behaviour therapy is aimed at persuading the patient to speed up and risk making mistakes. This author has found the condition extremely difficult to manage no matter what treatment is used. Attendance at a day centre, often arriving in the afternoon, may be the most that can be achieved.

Depersonalisation

Depersonalisation may occur with anxiety and depression (Baker ea, 2003) or be associated with BZD treatment. Ackner (1954) described the features of this strange experience as ‘always subjective’; the experience being that of ‘internal or external change, characterised by a feeling of strangeness, or unreality ...unpleasant... affect is always involved’. Mellor (1988) excluded the following from the definition: delusional elaboration of the experience; ego boundary disorders of schizophrenia, such as thought insertion; and, loss or attenuation of personal identity. Perhaps most people experience depersonalisation as a transient phenomenon, particularly when fatigued, bored, shocked, in a new or unfamiliar setting, or when deprived of sensory input. Spitzer ea (2006) suggests that there are two different phenomena: compartmentalisation (partial to complete failure to deliberately control processes that we can normally

¹⁶¹⁵ Blocks beta receptors and 5-HT_{1A} receptors to increase serotonin availability in the synaptic cleft.

¹⁶¹⁶ **Tics** (motor or vocal) may be due to failure to inhibit a population of striatal projection neurones which then become overactive leading to disinhibition of the relevant thalamocortical projection neurones. Excess dopamine appears to be involved.

¹⁶¹⁷ E.g. Sheehan (2004) suggests that they deliver about 30% symptom relief.

¹⁶¹⁸ Especially bilateral stereotactic *anterior internal capsulotomy* (destruction of anterior limb of internal capsule – severs thalamo-orbitofrontal fibres) or *anterior cingulotomy* (bilateral severing of anterior supracallosal fibres of anterior cingulate – changes intra-limbic connections).

¹⁶¹⁹ Cf. Irle ea (1998) for German follow up data: frontostriatal lesions did best; ventral striatal lesions associated with later substance dependence, and, 3 cases, those with obsessional personality disorder plus OCD did least well.

¹⁶²⁰ TMS involves using a handheld electrical coil in order to generate a pulsed magnetic field which passes unimpeded through scalp and bone and induces electric fields that depolarise cerebral neurones.

¹⁶²¹ For example, electrical capsular stimulation. Originally used in treatment-resistant Parkinson's disease, deep brain stimulation works via an electrode in the brain that connects to a pacemaker; continuous electric stimulation instead of a lesion; bleeding and infection are possible.

¹⁶²² Stereotactic MRI, ventriculography and other techniques help to localise the nucleus so that electrodes can be placed correctly.

¹⁶²³ Only 61% (142/222) of these young people and their parents agreed to take part.

¹⁶²⁴ Described by Rachman in 1974.

influence with willpower, such as an inability to bring normally accessible material into awareness) and detachment (subjective feeling of alienation of self or external world).

Depersonalisation disorder as a primary condition is probably rare (grouped with DSM-IV dissociative disorders), although one London *tertiary referral service* dealing with depersonalisation found it in 71% of 204 consecutive referrals (Baker *et al.*, 2003), and consists of a repeated or persistent feeling of being detached from one's mental processes or body that is accompanied by intact reality testing. There is a feeling of unreality or estrangement, mental activity and external life proceed as normal but have a different feel to them, and they stop having any significance for the patient. Patients appear to be in a heightened state of alertness but with a less than expected response to unpleasant stimuli, suggesting a selective inhibition on emotional processing. (Sierra *et al.*, 2002) The disorder tends to affect young people, to have a sudden onset, and the course is often chronic.

In *hemidepersonalisation* there is the feeling that half of the body is unreal or doesn't exist. This lateralised phenomenon is usually right-sided and associated with a focal parietal lesion. In *reduplicative paramnesia* or *double orientation* the patient believes they are in two places simultaneously. *Doubling* refers to the notion that consciousness resides outside the body, perhaps high above the head. Other phenomena include a foreign feel to one's own body, mental behaviour, or behaviour; enlargement or diminution in size of the extremities; etc.

Differential diagnosis

Epilepsy including TLE¹⁶²⁵

Migraine

Brain tumour/trauma

Cerebrovascular disease

Encephalitis

General paresis

Alzheimer's disease

Huntington's disease

Spinocerebellar degeneration

Hypoglycaemia

Mania

OCD

Hysteria

GAD

Phobic anxiety

Schizoid personality disorder (some cases)¹⁶²⁷

Treatment consists of treating any cause of secondary depersonalisation, whereas therapy for the primary disorder is largely untested. Hypnotic induction of transient depersonalisation has been suggested as a way of helping patients understand and gain control over the phenomenon: the patient is encouraged to replace the secondary anxiety reaction with a pleasant feeling of floating or heaviness; and patients may be advised to view their problems on an imaginary screen as a way of 'detaching' them. CBT may help some patients.

¹⁶²⁵ Demonstrated by neurosurgical stimulation of temporal cortex.

¹⁶²⁶ Alcohol, barbiturates, BZDs, scopolamine, clioquinol, β -blockers, cannabis, PCP and related compounds, and hallucinogens.

¹⁶²⁷ Can be severe and persistent.

Fluoxetine was not efficacious for depersonalisation disorder in a placebo-controlled double-blind study. (Simeon et al, 2004)

Generalised anxiety disorder (GAD)

GAD is uncommonly diagnosed by mental health professionals but is common in primary care and in chronic medical populations. (Taylor et al, 2008, p. 440) Despite associated disability, GAD is often missed, ignored, or treated only briefly. The birth of GAD from the soup of anxiety neurosis owes something to Klein's creation of panic disorder, (Klein, 1964) i.e. what remained was renamed as generalised anxiety disorder. (Tyrer & Baldwin, 2006) Human beings need a certain range of anxiety to function adequately, neither too much or too little. 'Double anxiety' refers to the longterm low grade anxious feeling found in GAD patients plus the superimposed briefer periods of increased anxiety that are experienced as part of this syndrome. British soldiers serving in Northern Ireland were found in one prospective study (Lawrenson & Ogden, 2003) to have increased somatic symptoms, anxiety, and social isolation, but no increase in depression ratings. As part of the US National Comorbidity Survey, the one-year prevalence of DSM-III-R GAD was estimated as 4.3% for females and 2% for males. DSM-IV GAD 1-year prevalence for threshold and sub-threshold GAD has been reported as 1.5% and 3.6% respectively (Carter et al, 2001); rates in women and older subjects were 2.7% and 2.2% respectively. The term 'signal anxiety' is sometimes applied to the alerting quality of the sensation, as when it alerts a student to study for an examination. Stein (2003, p. 15) suggests the term 'basic fear circuit' for the brain parts that may be activated in GAD: amygdala (fear conditioning), bed nucleus of stria terminalis¹⁶²⁸ (free-floating anxiety), and hippocampus¹⁶²⁹ (conflict/avoidance). Using fMRI to assess response to facial expression, Blair et al (2008) found that patients with generalised social phobia had increased responses to fearful as against neutral expressions in the amygdala whereas GAD patients showed excess response to angry expressions in a lateral region of the middle frontal gyrus. Also using fMRI in GAD patients, Nitschke et al (2009) found heightened and indiscriminate (to both aversive and neutral stimuli) amygdala responses, and of anterior cingulate cortex associations (higher pre-treatment activity associated with greater decreases in anxiety/worry) with treatment response.

Potential medical causes of anxiety¹⁶³⁰

Cardiovascular – angina pectoris¹⁶³¹, congestive cardiac failure, dysrhythmia (paroxysmal atrial tachycardia is terminated by the Valsalva manoeuvre), hypovolaemia, intra-aortic balloon pump, myocardial infarction, syncope, valvular disease, etc

Respiratory – asthma, COPD, pneumonia, pneumothorax, pulmonary oedema or embolus¹⁶³², respirator dependence, etc

Neurological – akathisia, encephalopathy, essential tremor, labyrinthitis, postconcussion syndrome, restless legs syndrome, seizure disorder (*especially* TLE), vertigo, etc

Metabolic – hyperadrenalism, hypocalcaemia, hypoglycaemia, hyperthyroidism, vasomotor symptoms in perimenopausal women (dyspnoea, diaphoresis, feeling hot) or due to tamoxifen

Immunological – anaphylaxis, SLE

Secreting tumours – carcinoid, insulinoma, pheochromocytoma (clonidine reduces catecholamine levels in anxious patients but has no effect on the high catecholamine levels found in pheochromocytoma; anxiety may be more obvious than hypertension)

Peptic ulcer disease

*Drugs*¹⁶³³ – adrenaline, alcohol/barbiturate/BZD withdrawal, amphetamines/cocaine, aminophylline/theophylline, anticholinergics, caffeine, reserpine, hydralazine, isoniazid¹⁶³⁴, cycloserine (although D-cycloserine has been used acutely as an adjunct to behaviour therapy in the treatment of

¹⁶²⁸ A component of the extended amygdala.

¹⁶²⁹ Using PET, Wu et al (1991) found that GAD cases did not have the usual left-to-right asymmetry in hippocampal metabolism.

¹⁶³⁰ Anxiety derives from Latin *anxietas*, to choke or upset.

¹⁶³¹ Angina can present with palpitations and breathlessness with little chest discomfort.

¹⁶³² Recurrent pulmonary emboli may present as episodic anxiety, dyspnoea and hyperventilation.

¹⁶³³ Including substance use, intoxication or withdrawal as well as bronchodilators, decongestants, over-the-counter drugs, etc.

¹⁶³⁴ **Isoniazid**, an MAOI, can cause many problems, e.g. mania, psychosis, SLE-like syndrome, mixed neuropathy, and encephalopathy (pellagra – isoniazid inhibits tryptophan conversion to niacin). An overdose can cause seizures that respond to pyridoxine. Its mood altering effects were noted during its use as an anti-TB agent. Later it was found to change monoamine concentrations in animal brains, a finding that led to the monoamine theory of depression.

acrophobia [Ressler et al., 2004] and OCD [Wilhelm et al., 2008]), digitalis toxicity, dopamine, ephedrine/pseudoephedrine, calcium channel blockers, L-DOPA, methylphenidate, monosodium glutamate, neuroleptic and other drug-induced akathisia, NSAIDs, nicotinic acid, phenylephrine, phenylpropanolamine, procabazine, salicylates, steroids, corticotrophin releasing factor*, CCK-4, thyroid hormones, etc. Anxiety can be induced by drugs acting on BZD receptors as inverse agonists (opposite effect to BZDs – β -carboline and diazepam-binding inhibitor), α -2 receptor blockers (e.g. yohimbine), 5-HT agonists (e.g. metachlorophenylpiperazine), caffeine (blocks adenosine receptors), and (see section on panic disorder) sodium lactate. Intravenous lactate, a panic-inducer, reduces plasma GABA levels, and valproate, which increases GABA function by stimulating its synthesis and reducing its degradation, has been reported to block lactate-induced panic. (Belzung et al., 2002) Sodium bicarbonate infusion may be as powerful a panicogen as CO₂ in panic disorder patients, and CO₂ is a common metabolite of both lactate and bicarbonate. CO₂ crosses the blood-brain barrier and induces transient hypercapnia centrally. (Hollander & Simeon, 2003, p. 551)

*CRH increases the startle response via receptors in the bed nucleus of stria terminalis (near amygdala); such enhancement is relatively persistent, whereas fear (short-lived) may be mediated by the amygdala. Startle response to unpredictable aversive stimuli is greater than normal in panic disorder, but not when the stimulus is signalled by a cue. (Grillon et al., 2008) CRH-releasing neurones in the central nucleus of the amygdala project to the bed nucleus.

Problems with DSM-IV-TR GAD: the requirement of 6 months duration is arbitrary and cases of shorter duration may be otherwise indistinguishable; the requirement of ‘excessive worry’ narrows the application of the diagnosis; and the prohibition on diagnosis of panic disorder in the presence of major depression is not in keeping with clinical reality.

Adults with GAD tend to remember their parents as being excessively controlling and overinvolved. (Rapee, 1997) This could instil an excessive fear of the world in the child so that stimuli that would otherwise be met with equanimity are instead reacted to as if they foreshadowed catastrophe. It has been reported that while loss events precede depression, danger events precede anxiety.¹⁶³⁵ Comorbidity between panic disorder, social phobia, and GAD is common. (Yonkers et al., 1996) Chronic GAD often leads to major depressive disorder (MDD). GAD may prolong recovery from treated MDD. Comorbidity of GAD with major depression greatly complicates the clinical picture, with higher levels of suicidal ideation, poorer social function, more other anxiety disorders, eating disorders, and somatoform disorders, than is the case for major depression without GAD. (Zimmerman & Chelminski, 2003) Hamilton (1988) put anxiety neurosis with the affective disorders because of a higher concordance in MZ than in DZ twins, a remittent course, and the response found in some cases to MAOIs. Genetically, GAD and MDD may have a common basis with environment deciding the eventual clinical manifestations. (Kendler et al., 1992) Nutt and Ballenger (2005, p. 220) point out that the actions of antidepressants ‘help to dispel the notion that the anxiety disorders are but a variant of depression’, e.g. effective doses differ, time of onset of full therapeutic effect is longer for anxiety, and noradrenergic drugs work for depression but not for OCD. Also, in a 10-year prospective study, Beesdo et al. (2010) found that anxiety and depressive disorders differ regarding risk constellations and patterns over time; they concluded that GAD is a heterogeneous condition that resembles other anxiety disorders more than depressive conditions; however, GAD may differ from depression and other anxiety disorders with regard to family climate (dysfunction and distress) and personality profiles (high reward dependence and poor childhood attachment experiences).

Relative to normal mice, heterozygous GABA-A γ 2 subunit knockout mice are anxious, hypervigilant and less sensitive to benzodiazepines, have decreased brain GABA-A ligand binding. (Tyrer & Baldwin, 2006) Goldberg (2008) has reviewed the tension between those experts who see GAD and MDD, as currently defined, as separate disorders and those who view them as the same condition.

From a cognitive viewpoint, anxious patients have an emotional bias in responding to potentially threatening stimuli, a tendency to interpret situations as being unrealistically dangerous or risky (although

¹⁶³⁵ Whether these are independent events or interpretations based on mental state is difficult to say. Interestingly, it has been reported that loss rather than danger events precede panic disorder.

they usually retain insight into the excessive and inappropriate nature of their worries), enhanced recall for memories associated with threatening situations or past anxiety states, and automatic thoughts associated with themes of danger, threat, uncontrollability (and dislike of unpredictability), or anticipated incompetence. There are high frequencies of negative self-statements, misinterpretations of bodily stimuli, and overestimates of future misfortune.

Some authorities disagree with the DSM stress on worrying in the definition of GAD, instead focusing on tension, psychic and somatic, which in turn may lead to (the avoidance behaviour of) worry¹⁶³⁶. (Rickels & Rynn, 2001)

Somatic concomitants of anxiety are mediated by the autonomic nervous system. Resting blood pressure, skin conductance (expressed as the GSR: galvanic skin response), heart rate, and respiration are not consistently different from the healthy population. (Taylor et al., 2008, p. 441) However, the association of GAD with stable coronary heart disease is associated with an increased risk of cardiovascular events. (Martens et al., 2010)

The responses of the EMG and the autonomic nervous system to repeated auditory stimuli show that they habituate more slowly in anxious people than in normals. Anxious patients have difficulty inspiring whilst asthmatics have problems expiring. The increase in lactate after exercise may be greater in anxiety states than in normals. When attempting to distinguish anxiety from paroxysmal tachycardia one should find out from the patient if awareness of feelings of anxiety or of rapid heart action came first.

Benzodiazepines reduce the central manifestations of anxiety. Beta-adrenoreceptor blockers, such as propranolol (Inderal), reduce the peripheral, autonomic effects. However, they do not reduce palmar sweating because the sympathetic nerve supply to palmar sweat glands is cholinergic. Beta-2 agonists such as salbutamol and terbutaline may cause tremor and a feeling of tension in the musculature. CCK-4-induced anxiety is associated with increased cerebral¹⁶³⁷ and extracerebral blood flow; the increased blood flow may commence in the hypothalamus and later involve the claustrum and insula. (Liddle, 2001, p. 175) DeBellis et al. (2000), using MRI, found that children with GAD had bigger right and total amygdala volumes in comparison to healthy controls.

The 5-HT₂ agonist m-chlorophenylpiperazine (m-CPP) may increase anxiety and anger in GAD but not in healthy controls. (Germine et al., 1992)

Psychological anxiety symptoms include apprehensiveness, irritability, malaise, dizziness, depersonalisation/derealisation, and intermittent low mood. (Marks, 1991) *Metaworry*, or worrying about worry itself, increases worrying in GAD. Insomnia consists of the initial and middle (interrupted) variety. Ideas of reference may occur in some patients, but insight is retained. The somatic symptoms of anxiety include palpitations, breathlessness, precordial pain, paraesthesiae, sweating, cold palms, flushing, tremor, fatigue, dry mouth,¹⁶³⁸ and frequency of micturition. Increased muscle tone accounts for the tremor. Morning vomiting may be associated with alcohol, pregnancy, or anxiety. Despite persistent vomiting, if there is no weight loss a psychosocial cause is most likely. However, beware of vomiting that relieves pain: outrule peptic ulceration. Secondary depression and alcohol abuse are common in psychiatric clinic attenders.

The anxiety reaction resembles the 'fight or flight' reaction in animals.¹⁶³⁹ The bowels and bladder may empty, as every soldier finds out to his horror and disgust on the battlefield. Peripheral changes cause an increase in anxiety, so leading to a vicious cycle of events. Anxious people are slow to adapt to change. EEG alpha waves decrease as anxiety levels escalate.

The middle-aged person who develops an anxiety state for the first time may be depressed or harbouring an organic disease, e.g. carcinoma. Psoriasis is made worse by such factors as anxiety or lithium. Fungal infections of the feet, axillae and perineal regions are common in anxiety states (possibly related to hyperhidrosis).

Management of anxiety

¹⁶³⁶ Patients act as if worrying will prevent an undesired outcome. **Worry**, in fact, impedes processing of emotional material and blocks extinction.

¹⁶³⁷ Anterior cingulate gyrus, claustrum, insula, amygdala, and vermis of cerebellum.

¹⁶³⁸ Xerostomia.

¹⁶³⁹ Hans Selye of Montreal did much of the early work in this area.

Relaxation exercises¹⁶⁴⁰

Breathing exercises to control hyperventilation

Counselling (Donnan ea, 1990)

Supportive psychotherapy

Behaviour therapy (systematic desensitisation)

Cognitive therapy (even brief therapy may help)

Anxiety management groups

Other forms of psychotherapy

Transcendental meditation (TM)

Autogenic training (relax by silently repeating calming, peaceful phrases)

Yoga

Biofeedback

BZDs (in the short term, although a minority need BZDs in the long term¹⁶⁴¹; possibly better than buspirone for somatic symptoms and insomnia [Huppert & Rynn, 2004])

Buspirone¹⁶⁴² (possibly more effective for cognitive than somatic symptoms, and ineffective in panic disorder [Sheehan ea, 1993])

Antihistamines (e.g. hydroxyzine: very sedative and questionable efficacy as anxiolytic drugs: Lader, 1994; Leonard, 2003, p. 236) – however they are relatively safe (hypotension can be problematic) and may prove useful where respiratory depression has to be avoided

Antidepressants¹⁶⁴³ (in the longer term, e.g. imipramine,¹⁶⁴⁴ duloxetine (Nicolini ea, 2009), or the SSRIs¹⁶⁴⁵ – as with buspirone¹⁶⁴⁶, the anxiolytic effect may be delayed for a few weeks; escitalopram 10 mg/day [Baldwin ea, 2006]; venlafaxine has been recommended for GAD and its extended release form offers advantages)(Liebowitz ea, 2005; Nicolini ea, 2009)

Neuroleptics in small doses are useful and justified in persistent anxiety in dependence-prone patients or in aggressive people who may be disinhibited by anxiolytics

Abecarnil (novel anxiolytic beta-carboline: said to have an onset of action in about one week¹⁶⁴⁷ and to be unaccompanied by either rebound or withdrawal symptoms – it may not be as useful for anxiety as BZDs or buspirone

Pregabalin (Lyrica; non-BZD relative of GABA): used for anxiety disorders, especially GAD,(Rickels ea, 2005; Montgomery ea, 2008) diabetic neuropathy, and epilepsy, and perhaps fibromyalgia as well; binds to α -2-lambda subunit of voltage-gated calcium channels and has other downstream effects

Kava reduces anxiety but may cause liver problems (Gale & Davidson, 2007) and parkinsonism (Lees ea, 2009)

The key element in virtually every successful non-drug intervention in the anxiety disorders as a group is exposure to the fear-producing stimulus or situation. Unfortunately, specific psychotherapies are rarely available outside specialist centres.(Cowley & Roy-Byrne, 1997) In anxiety management training, two stages can be discerned: verbal cues and mental imagery are used to arouse anxiety; and the patient is then trained to reduce anxiety using relaxation, distraction, and reassuring self-statements. Changes in life style may be required. Anxious people may turn to alcohol for fast relief.

Some authors state that most cases of anxiety disorder resolve after a few months, whereas others find it to be a chronic illness. If the patient is still anxious at 6 months then he is likely to be unchanged at 3 years. Increases in mortality rates from suicide and secondary to alcohol and smoking have been

¹⁶⁴⁰ E.g. Jacobson's Progressive Relaxation.(Jacobson, 1938)

¹⁶⁴¹ GAD is a chronic disorder (many authorities view GAD as a problem of temperament, often becoming more pronounced with increasing age) so short-term (< 4 weeks) may not suffice and long-term, intermittent treatment may be indicated.

¹⁶⁴² Buspar was withdrawn, December 2009.

¹⁶⁴³ Continue antidepressants for at least 6-8 months and probably for longer in cases if there is some initial response as partial responders may convert late to complete responders.(Nutt & Ballenger, 2005, p. 31)

¹⁶⁴⁴ Withdrawn from market.

¹⁶⁴⁵ Antidepressants and buspirone may be more effective for psychological symptoms and the BZDs better for physical complaints.(Kelsey ea, 2006, p. 149) However, duloxetine and extended-release venlafaxine may tackle both types of symptoms.(Nicolini ea, 2009)

¹⁶⁴⁶ Buspar was withdrawn, December 2009.

¹⁶⁴⁷ It combines with the BZD-GABA complex, being a partial agonist and full agonist at different sites.

recorded.(Allgulander, 1994) In some ways, pure GAD is at least as disabling in terms of quality of life as is pure major depressive disorder.(Wittchen ea, 2000)

Panic disorder

The essential elements of DSM-IV-TR panic disorder are *recurrent* panic attacks *and* persistent *concern* about panic attacks or *behaviour* that is changed because of panic attacks. The notion of panic¹⁶⁴⁸ attacks constituting a distinct form of anxiety disorder (so-called 'panic disorder') dates to Klein (1964) who noted that these attacks responded to imipramine whilst the background of generalised anxiety did not. He did not explain how agoraphobia can occur without panic disorder ('more common than was once thought' [in the US]; Schatzberg ea, 2005, p. 23; Bienvenu ea, 2006) and his failure to find efficacy for benzodiazepines in panic disorder was due to his employment of low doses. It should be noted that not every expert agrees with the removal of panic disorder from the general body of anxiety.(e.g. compare Basoglu ea, 1992 with O'Rourke ea, 1996) Others point out that the diagnosis of panic disorder is not stable, many cases developing alcohol abuse, agoraphobia and depressive illness.(Casey & Craven, 1999) Research conducted by Goisman ea (1995) suggests that agoraphobia without a history of panic disorder, uncomplicated panic disorder, and panic disorder with agoraphobia are really part of a continuum, rather than discrete diagnoses. Females with panic disorder are more likely to be agoraphobic and to have comorbid depression.(Nutt ea, 2002, pp. 17-18) The notion that all panic attacks in panic disorder are uncued is unlikely to be valid.(Welch ea, 2008, p. 542)

In general, about one-half of all cases of panic disorder experience at least one episode of depression at some point during life, although reported figures vary widely. Nevertheless, the high rates of comorbidity do not seem explicable by chance. There are many postulated reasons for this comorbidity: co-occurrence of two common disorders, overlapping diagnostic criteria, those cases with both groups of symptoms have a unique disorder, panic leads to depression, etc. Compared to the relative of someone who is simply depressed, the relative of a patient who has panic plus depression is at greater risk of developing affective, anxiety, or alcohol abuse problems, although the former relative is also at increased risk for developing anxiety (and panic) disorder.

Female cases outnumber male sufferers in all countries. The commonest affected age group for the disorder is 25-34 years. As a generalisation, 1 in 10 people has occasional panic attacks and 2% of people have panic disorder.¹⁶⁴⁹ Infrequent panic attacks can be associated with considerable disability.(Katerndahl & Realini, 1997) Also, agoraphobic avoidance and apprehensiveness may be functional more impairing than the frequency of panic attacks.(Telch ea, 1995)

Panic disorder

DSM-III-R one-year prevalence - 32/1000 women, 13/1000 men

Low lifetime prevalence of 14/1000 reported from Edmonton, Alberta

Higher figure of 29/1000 from Florence, Italy

Taiwan, which reports low rates of most psychiatric disorders - lifetime prevalence of only 4/1000

Baltimore Epidemiologic Catchment Area Study (Eaton ea, 1998) - annual incidence 1.43/1000/year; incidence was greater in females and declined with age; one-third of new cases arose without agoraphobia, but half had anxiety of some sort for many years before meeting criteria for panic disorder; and cases with agoraphobia had milder onsets but slower recoveries than those without agoraphobia

In fact, ECA study showed almost half of patients with one anxiety disorder experienced another anxiety disorder during their lives (Nutt ea, 2002, p. 19)

In various studies, 7.9%-41% of relatives of patients with panic disorder have panic disorder at some point in their lives, compared with 0.8%-8% in the families of controls

Sore neck (fear that a blood vessel will burst from blood pressure or 'wind') affects Cambodians and *wind overload* affects Vietnamese

¹⁶⁴⁸ The word panic is derived from the naughty god Pan who frightened Greeks who ventured into woodland.

¹⁶⁴⁹ **National Comorbidity Survey Replication** (NCS-R: Kessler ea, 2005) found lifetime prevalence rates of 4.7% for panic disorder and 1.4% for agoraphobia without panic. American household survey(Kessler ea, 2006) using CIDI reported the following lifetime prevalence estimates: panic attacks (PA) only = 22.5%, PA + agoraphobia without panic disorder (pd) = 0.8%, pd without agoraphobia = 3.7%, and pd + agoraphobia = 1.1%.

There is some conflict in studies looking at the incidence of panic disorder in African Americans; panic disorder may be complicated by *isolated sleep paralysis* (Bell ea, 1984)
Ataque de nervios is found in Latio groups and resembles panic disorder except that patients show greater loss of emotional control (e.g. by screaming or crying uncontrollably); about a third meeting DSM-IV criteria for panic attack and somewhat less meet criteria for panic disorder (APA, 2009, p. 44)

According to Nutt ea,(2002, p. 43) twin studies have given mixed results and linkage studies have been negative, although Woo ea (2002) suggest that vulnerability to panic disorder, and a poorer response to treatment, may be associated in some cases with possession of the LL COMT genotype.
 Collier (2002) reviewed the interesting possibility that a slightly longer arm of chromosome 15 may cause panic disorder. He points out that joint laxity¹⁶⁵⁰ is more likely in panic disorder. Fluorescent *in situ* hybridisation (FISH) provided evidence of genomic duplication¹⁶⁵¹ in chromosome 15 that is present in only some cells (mosaicism). Unlike other human disease-causing duplications that arise during meiosis, DUP25 appears to arise during mitosis. Possible candidate genes in the affected gene include those for three nicotinic acid receptors and the neurotrophin-3 receptor¹⁶⁵².

Based on dreams and 'screen memories', a connection with separation anxiety has been proposed. There is certainly some evidence to support this claim.(Lipsitz ea, 1994) Nevertheless, such research depends on the accuracy of recollection of parenting styles by grown ups. Aschenbrand ea (2003), based on a 7-year longitudinal study, point out that separation anxiety disorder is not synonymous with panic in children and that it does not necessarily continue as adult panic disorder, although they acknowledge that separation anxiety disorder is more common in the children of people with panic disorder. Nutt ea (2002, p. 46) list parental separation, critical or overprotective parenting, sexual and/or physical abuse, as well as separation anxiety, as childhood risk factors for panic disorder. Nevertheless, the separate diagnosis of separation anxiety disorder persisting into adulthood has been neglected¹⁶⁵³ and such a diagnosis in a parent of a child with separation anxiety disorder may be commonplace.(Popper ea, 2003, p. 931) In a multivariate twin study, Battaglia ea (2009) found that shared genes appeared to explain the continuity of separation of anxiety into adult panic disorder (and the increased sensitivity of both conditions to CO2) but that parental loss in childhood also has a role to play. Propranolol, haloperidol, and perhaps risperidone more than olanzapine may induce separation anxiety in children whilst the medication is taken.(Popper ea, 2003, p. 932)

As reported in depression,(Sørensen & Bech, 2006, p. 14) there may be decreased beat-to-beat variation (reduced cardiac rate variability) in panic disorder patients as a result of decreased and increased vagal and sympathetic tone respectively (Kawachi ea, 1995); such reduced variability being worsened by isoproterenol and lactate and diminished (i.e. increased heart rate variability) by anti-panic treatments such as paroxetine.(Tucker ea, 1997) However, the reduced heart rate variability found in depression may be due mainly to antidepressants, including TCAs and SSRIs.(Licht ea, 2008)

It has also been suggested (Klein, 1993) that panic disorder may be due to a hypersensitive CO2 chemoreceptor system coupled with cognitive distress, the brain reacting as if its owner is being suffocated¹⁶⁵⁴; this 'anxiety sensitivity' may very well be inherited¹⁶⁵⁵. There is some evidence from proton MRS to suggest that hyperventilation may lead to disproportionate increases in brain lactate in panic disorder and that brain lactate is already increased before a lactate infusion in panic patients who respond to lactate compared to those who fail to respond.(e.g. Dager ea, 1995) The same workers later found greater brain lactate increases in panic disorder patients compared to controls after IV lactate infusion. Bellodi ea (1998) found a significantly higher concordance for 35% CO2-induced panic attacks among MZ (55.6%)

¹⁶⁵⁰ ? related to lysyl oxidase.

¹⁶⁵¹ Termed DUP25 – found in 7% of normal population and 68-70% of panic disorder cases.

¹⁶⁵² The latter is the only neurotrophin receptor expressed in the locus coeruleus.

¹⁶⁵³ Shear ea (2006) found that lifetime prevalence for child and adult separation anxiety disorder were 4.1% and 6.6% respectively; one-third of childhood cases persisted into adulthood, but 77.5% developed the disorder as adults. Most adult cases are untreated specifically for this disorder. The patient may be anxious about the health of a loved one, become anxious when the partner goes to work, be unable to sleep when a partner is away on a business trip, telephone him constantly, call personally to a partner's place of work when he cannot be raised by 'phone, etc.

¹⁶⁵⁴ At the opposite extreme in the rare disorder, with attendant risk of death during sleep, *Ondine's curse*. Here we have a hyposensitive suffocation alarm.

¹⁶⁵⁵ However, earlier traumatic suffocation (e.g. almost drowning) is another possibility.(Bouwer & Stein, 1997)

than DZ (12.5%) twins, which favours a genetic predisposition to panic attacks. Miller *et al* (2000) reported no change in resting anxiety levels in panic disorder or normal controls after tryptophan depletion. Only the patient group developed panic after receiving 5% CO₂. Kent *et al* (2001) found that both panic disorder and premenstrual dysphoric disorder patients were very susceptible to CO₂-induced panic attacks, while depressives were immune to this procedure. They concluded that CO₂-induced panic had similar intensity regardless of diagnosis. Pine *et al* (2005) found no support for CO₂ hypersensitivity as a familial marker for panic disorder in children and adolescents but they did replicate a link between childhood anxiety disorders and CO₂ sensitivity, i.e. CO₂ was a marker of anxiety not a familial risk factor for panic disorder. A centrally acting muscarinic antagonist like biperiden (Akineton) may block CO₂-induced panic attacks. (Battaglia *et al*, 2001) Kent *et al* (2005) used PET and doxapram (an acute respiratory stimulant) challenge and found that low perfusion of orbitofrontal cortex was associated with increased anxiety. Electrical stimulation of the dorsal periaqueductal grey matter during neurosurgery causes neurovegetative changes and feeling of terror similar to panic attacks, and PET during lactate-induced panic showed activation of the midbrain tectum, part of which includes the dorsal periaqueductal grey matter. (see Graeff & Zangrossi, 2002)

Flumazenil, a BZD antagonist, caused panic in panic disorder patients but not in well people in one study (Nutt *et al*, 1990) but it failed to induce panic in another study. (Strohle *et al*, 1999) BZDs are less effective in panic disorder patients than under other circumstances, large doses being required. There is MRS evidence of reduced cortical GABA in panic disorder patients but not in well people. This may be a trait phenomenon. (Goddard *et al*, 2004) Using PET and flumazenil tagged with carbon 11, Hasler *et al* (2008) a particularly strong reduction in BZD receptor binding potential in the dorsal anterolateral prefrontal cortex in panic disorder patients never treated with BZDs and also a particularly strong increase in BZD receptor binding potential in the hippocampus/parahippocampal gyrus.

At low doses, the 5-HT₂ agonist m-chlorophenylpiperazine (m-CPP) induces panic in panic disorder patients but not in healthy people.

The CSF content of cholecystokinin in panic disorder cases has been found to be lower than expected. Nocturnal production of melatonin, a derivative of serotonin, may be increased in panic patients. CO₂ inhalation and sodium lactate (both increase cerebral blood flow), CCK4 (cholecystokinin tetrapeptide¹⁶⁵⁶), or isoproterenol (beta-antagonist) can precipitate panic attacks, although whether they are syndrome specific¹⁶⁵⁷ is subject to ongoing research. Transcranial Doppler ultrasonography has shown reduced basilar artery blood flow during hyperventilation in panic disorder patients that may respond to nimodipine, a centrally active calcium channel-blocking agent. Reduced peripheral beta-adrenoreceptor density and decreased cAMP responsiveness normalising with adinazolam treatment has been reported in panic disorder patients who also have agoraphobia. (Maddock *et al*, 1993) It was shown in the 1980s that panic patients actually increased their heart rates after an infusion of the β -stimulant isoproterenol. There is some evidence for cholinergic hyperactivity in panic disorder: augmented growth hormone response to pyridostigmine challenge.

Hypotheses concerning the genesis of panic disorder are outlined in the diagram. According to Gorman *et al*, (2000) heritable factors and stressful life events (especially if experienced early in life) may be responsible for the onset of panic disorder. Drug treatment (especially if serotonergic) might desensitise the 'fear network' and psychosocial treatments might reduce contextual fear and cognitive misattribution at the level of the prefrontal cortex and hippocampus.

Some theories regarding the origin of panic disorder.

After Gorman *et al* (2000):*

¹⁶⁵⁶ Pentagastrin (synthetic CCK-4 analogue) induces panic in normals and anxiety sufferers. (Uhde & Singareddy, 2002)

¹⁶⁵⁷ **Anxiogenic probes** (lactate, CO₂, pentagastrin, etc) produce effects in social anxiety disorder that lie between normals and panic disorder. (e.g. McCann *et al*, 1997)

520

Hippocampus + prefrontal cortex + brainstem ← behaviour Tx

After Klein(1981):

Spontaneous unprovoked panic attack
leads to
Cued panic attacks
leads to
Anticipatory anxiety
leads to
Agoraphobia

After McNally and Lorenz(1987):

It is not misinterpretation of somatic sensations that causes panic, but rather the belief that the sensations *per se* are dangerous.

After Wolpe and Rowan(1988):

Anxiety
leads to
Hyperventilation that causes dizziness + paraesthesiae
which, on repetition leads to
Conditioned stimuli that can provoke panic attacks

After Clark(1988):**

Interoceptive or exteroceptive stimulus
leads to
Perception of threat
leads to
Apprehensiveness
leads to
Somatic sensations
leads to
Misinterpretation of sensations leading to panic attack
leads to perception of threat and vicious cycle repeats itself

After Klein(1993):

Panic disorder is due to excessively sensitive brainstem suffocation alarm

After Shear ea(1993):

Innate irritability + unsettling parental behaviour
leads to
Unresolved dependence/independence issues
leads to
Excess negative affect
leads to
Increased biological sensitivity
if added to
Significant stressor
leads to
Loss of sense of being safe and being in control
if added to
Strong negative affect
leads to
First panic attack

*Based on animal studies. **Vulnerability involves a tendency to think too much about first panic experience with subsequent hypervigilance.

Faravelli ea (1992) found that 78% of panic disorder with agoraphobia patients had their first panic attack in phobic situations as against only 20% of panic disorder without agoraphobia cases. Phobic avoidance is common. These patients are often seen by a variety of specialists before being sent to a mental health expert, e.g. an urologist because of urinary frequency, a cardiologist because of chest pain, (Bass & Mayou, 2002) or a neurologist because panic may mimic epilepsy, especially complex partial seizures. (In fact, to make life complicated, there have been several reports of right focal temporal lesions presenting with panic attacks.) Typical features of partial seizures are short attacks (1-2 mins.), witnessed motor automatisms (e.g. regular swallowing, chewing, or clothes plucking), over 45 years of age at onset, a history of febrile convulsions, and lack of response to conventional antipanic treatments. (Thompson ea, 2000) Panic attacks can rarely be attributed to hypoglycaemia unless there are other pointers to this diagnosis.

There is usually a high level of anticipatory anxiety between attacks, i.e. fear of having another panic episode. The following symptoms were reported in over 80% of cases in a report by Noyes *et al.* (1987): fearfulness/worry/apprehension, nervousness, palpitations, muscle aches/tension, trembling/shaking, dizziness/imbalance/faintness/lightheadedness, fear of dying/going crazy, and hot/cold sensations. DSM-IV-TR defines a panic attack as a discrete period of intense fear or discomfort, in which at least 4 of the symptoms listed in the table develop abruptly and reach a peak within 10 minutes. DSM-IV limits the use of a GAD diagnosis by diagnosing panic disorder after just one panic attack. (Schatzberg *et al.*, 2005, p. 24)

DSM-IV-TR and panic

(a) panic attack

- | | | |
|---|---|--|
| 1. palpitations, pounding heart, or tachycardia | 6. chest pain or discomfort | 10. fear of losing control/going crazy |
| 2. sweating | 7. nausea/abdominal distress | 11. fear of dying |
| 3. trembling/shaking | 8. feeling dizzy, unsteady, light-headed, or faint | 12. paraesthesiae (numbness or tingling) |
| 4. sensations of dyspnoea/smothering | 9. derealisation (feelings of unreality) or depersonalisation (being detached from oneself) | 13. chills or hot flushes |
| 5. feeling of choking | | |

(b) panic disorder

1. recurrent, unexpected panic attacks
2. at least 1 attack followed by at least 1 month of persistent concern about having another attack/worried about effects of attacks (heart attack, loss of control, going mad, etc)/or significant behavioural change related to the attacks
3. with/without agoraphobia
4. Not due to substances/medical disorders
5. Not better accounted for by another mental disorder, e.g. social phobia

Note: Hyperventilation causes hypocapnia and alkalosis with reduced cerebral blood flow. Hence the patient feels dizzy, unreal, changed, or detached.

Behavioural approaches (gradual exposure to a hierarchy of feared situations) can be effective but tend to be distressing to the extent of the patient opting out of the programme. Exposure to panic cues can be brought about by various exercises, e.g. breathing through a straw, running in place, or spinning in a swivel chair. Simple relaxation exercises and respiratory training often fail because the surges of anxiety may come on too quickly to allow conscious control mechanisms to operate; the patient must practice these techniques between episodes so as to become convinced that they can perform them correctly.

Cognitive-behaviour therapy (CBT) is effective (if available: APA, 2002, p. 672, 2009, p. 9; Nutt *et al.*, 2002, pp. 67 & 88), and may have more persistent effects than drugs. CBT may be added at any point in the on-going management of panic disorder. (Welch *et al.*, 2008, p. 547) Panic symptoms can be induced by exercise or hyperventilation for the purpose of analysis and reflection. The patient then has to learn not to assign symptoms to catastrophe such as impending death, loss of control, or madness, but instead to reassign them to a cause of lesser significance. *Interoceptive exposure* refers to the gradual exposure of a patient to feared physical sensations, repeated exposure leading in turn to habituation. Cognitive restructuring is combined with interoceptive exposure. Safety behaviours (e.g. carrying a mobile 'phone or tranquillisers as a 'crutch') may reduce the effectiveness of exposure therapy. CBT has been shown to be at least as good as high-dose imipramine. It has been claimed that some patients who remitted after CBT have lost their vulnerability to lactate-induced panic attacks. CBT helps panic disorder patients to wean off BZDs. Group CBT is effective for panic disorder. (APA, 2009, p. 29)

There is some concern (APA, 2009, p. 27) that the combination of medication plus CBT may interfere with maintenance of treatment response following treatment withdrawal.

Family and insight-orientated treatments (Milrod *et al.*, 2007) have their place, e.g. for family complications or to convince someone of the need for drug therapy. *Panic-focused psychodynamic psychotherapy* (Milrod *et al.*, 1997) has a slender evidence base (Milrod *et al.*, 2007) than that for CBT. It is given individually and is time-limited, i.e. twice a week over twelve weeks. The theory involves assuming difficulty withdrawing from important attachment figures and poor perceived autonomy. The latter may underlie agoraphobic

avoidance behaviour. The transference is used to promote change and to encourage confrontation of the emotional significance of panic symptoms. Symptoms may transiently worsen as material surfaces. Aims include increased autonomy, relief of symptoms, and better functioning.

Psychodynamic approaches are often used together with medication. Supportive psychotherapy and eye movement desensitisation and reprocessing (EMDR) are unhelpful. Relaxation therapy is less effective than CBT.(Siev & Chambless, 2007)

Caffeine¹⁶⁵⁸ and nicotine should be avoided. Comorbid agoraphobia and depression need attention. The present author's practice is to advise abstinence from alcohol: some patients self-medicate for panic with alcohol, others only panic because they are drinking, and anyway one is unlikely to get anywhere as long as alcohol contaminates the clinical picture. Stimulants, cannabis, and sympathomimetics (as in nasal decongestants) can precipitate panic attacks at any age. Regular aerobic exercise, like running, is superior to placebo but less effective than clomipramine.(Broocks ea, 1998)

NICE suggests that benzodiazepines (BZDs) be avoided in the treatment of panic disorder. Alprazolam (originally used in doses up to 4-10 mgs per day in 4 or 5 doses – modern recommendations are 2-4 mgs; O'Shea, 1989 – a therapeutic window of 20-40 nanograms per ml. has been suggested) and imipramine have been advocated for the treatment of panic disorder. Not all studies find an effect for alprazolam that is stronger than placebo and there were doubts as to whether any gains from alprazolam last,(Marks ea, 1993) although some authors reported longterm improvement with alprazolam.(Nutt ea, 2002, p. 75) Briggs ea (1993) found that patients with prominent respiratory symptoms tended to have more spontaneous attacks and to respond to imipramine, while those without prominent respiratory symptoms had more situational attacks and responded more to alprazolam. Boyer's (1995) meta-analysis showed SSRIs to be superior to alprazolam and imipramine for panic disorder.

Clonazepam, now generally seen as the BZD of first choice for panic disorder, has a longer elimination half-life than alprazolam. This allows more stable drug levels and twice daily dosing. Start with 0.25-0.5 mgs/day and increase to 1-2 mgs/day in two divided doses, although even higher doses may be needed for complete relief. There may be fewer problems associated with stopping clonazepam than alprazolam. Patients may be switched from alprazolam to clonazepam by dividing the total daily dose of alprazolam in milligrams to get that for clonazepam.

Lorazepam should be started at 1.5-2.0 mg/day and increased to 4-8 mgs/day as needed. The daily dose should be split into 3 or 4 doses.

What probably matters for efficacy is not so much which BZD that is used but rather that the dose be sufficient, e.g. 40 mg of diazepam v 4 mg of alprazolam.(Noyes ea, 1996) Also, BZDs should be used on a regular schedule than on an as needed (prn) basis.(APA, 2009, p. 30) There is a high relapse rate after stopping BZDs, and probably after stopping any effective drug therapy. Therefore drug treatment may need to be continued for a long time.¹⁶⁵⁹ Cessation of BZDs needs to be done very slowly, over 2-4 months, and at a rate of 10% reduction in dose per week at the most. Patients treated with BZDs for panic disorder have not tended to show tolerance or escalation of doses.(Nutt ea, 2002, p. 77)

Beta-blockers are not effective in panic disorder. Clonidine may reduce symptoms at the start of treatment in some cases but its effects wanes over some weeks¹⁶⁶⁰. Bupropion and ritanserin (5-HT receptor agonist) lack efficacy in panic disorder. Indeed, bupropion may be anxiogenic.(APA, 2002, p. 492) Valproate can be effective.(Lum ea, 1990) SSRIs¹⁶⁶¹, MAOIs¹⁶⁶² (including RIMAs), TCAs¹⁶⁶³, venlafaxine (in low dosage it may be a pure SSRI),(Bradwejn ea, 2005) nefazodone (withdrawn from market), and mirtazepine, but not buspirone,(Deakin ea, 2001) appear to be effective antipanic agents. Data on the newer agents is not as strong as for SSRIs and TCAs. CCK-B receptor antagonists have so far proved disappointing. There is some preliminary evidence for efficacy for inositol, a natural glucose isomer and a precursor of the intracellular phosphoinositol cycle.(Benjamin ea, 1995) Inositol is taken as a powder in juice in large volumes.

¹⁶⁵⁸ Uhde and Singareddy (2002) argue that caffeine sensitivity is greater in panic disorder than in other anxiety disorders and normals.

¹⁶⁵⁹ At least one year according to the APA.(2002, p. 674)

¹⁶⁶⁰ The receptors habituate.

¹⁶⁶¹ Inhibitory serotonergic projections from raphe to locus ceruleus decrease noradrenaline output.

¹⁶⁶² Particularly used for refractory cases.

¹⁶⁶³ Inexpensive, effective, and may be useful in SSRI-non-responders.(Welch ea, 2008, p. 546)

SSRIs need to be used in low dosage to start with, e.g. sertraline 50 mgs/day although usual antidepressant doses (occasionally higher) are often needed for a therapeutic response. They also reduce agoraphobic avoidance. Treatment of panic with antidepressants may cause an initial worsening of symptoms (this may not happen with MAOIs), so the rule is to start with a very low dose¹⁶⁶⁴. Alternatively, low doses of an antidepressant can be added to a BZD and then the dose of antidepressant can be slowly increased; when symptoms have been controlled for some weeks the BZD can be tapered slowly and eventually discontinued. Interestingly, research conducted during the early 1980s found that propranolol pretreatment failed to prevent lactate-induced panic attacks.(Gorman ea, 1983) Response to SSRIs takes at least 4 weeks, and a full response can take up to 12 weeks. Some patients who fail to respond fully to a TCA or an SSRI may respond to a combination of the two.(Tiffon ea, 1994) SSRI therapy, with the possible exception of fluoxetine, should not be abruptly discontinued after prolonged use.

Pharmacotherapy should be continued for a year before consideration is given to possible very slow tapering, e.g. a decrease in dosage every 4-8 weeks¹⁶⁶⁵.

Things to consider before deciding to taper pharmacotherapy

Duration and severity of panic disorder before treatment?

How effective was the drug?

How long was the patient stable on medication?

Stressors operating currently or anticipated?

Motivation of patient to stop treatment?

Understanding of risks, e.g. relapse, abstinence syndrome, possible teratogenicity?

Involvement and understanding of important others in patient's life?

Published complications of panic disorder include peptic ulcer, hypertension, increased mortality from suicide¹⁶⁶⁶ and cardiovascular disease, and abuse of alcohol and other substances. There is no evidence that mitral valve prolapse¹⁶⁶⁷, which is over-represented in panic disorder patients, makes a difference to history, course or response to treatment. However, Coplan ea (1992), in a series of 22 cases, found that treatment for panic disorder improved mitral valve prolapse on the echocardiogram. The direction of causality remains unknown: does panic disorder cause mitral valve prolapse (anxiety places a strain on the heart) or *vice versa*? However, to complicate matters further, mitral valve prolapse may be more common in certain other psychiatric disorders (such as bipolar disorder, GAD, and anorexia nervosa) than in panic disorder and may be associated with similar symptomatology as in panic disorder.(Levenson & Dwight, 2000) Gonzalez ea (2002) emphasise the methodological issues that need to be resolved (use of cardiac disorder control groups and a better definition of mitral valve prolapse) before the relationship between mitral valve prolapse and psychiatric disorders can be clarified. Finally, Hayek ea, (2005) in a review article, pointed out that recent studies found no excess of psychiatric symptoms (including panic disorder) in unselected outpatients participating in the Framingham Heart Study.

A poor prognosis is associated with female sex, hypochondriasis, comorbid depression, alcohol abuse, personality disorder, interpersonal sensitivity, side-effects of medication, failure to improve with treatment, longer duration of illness (Shinoda ea, 1999) and more severe phobic avoidance (agoraphobia) at baseline. Frequency of panic attacks at baseline does not predict symptomatic outcome.(Nutt ea, 2002, p. 34) The condition usually lasts for years and varies in severity over time, with less than half of patients being panic free after up to 20 years of treatment. However, there may, on average, be some amelioration of severity of symptoms in episodes of panic disorder, GAD, and social phobia with the passage of time.(Ramsawh ea, 2009) According to the APA,(2002, p. 676) comorbidity with current or past Axes I (e.g. bipolar disorder,

¹⁶⁶⁴ However, one should not make the mistake of settling for too low a final dose.

¹⁶⁶⁵ An exception might be a patient who becomes pregnant and wants to suddenly stop the medication.

¹⁶⁶⁶ It has been difficult to determine the **contribution of panic disorder *per se* to risk of suicide**. This is because of the very high levels of comorbidity, e.g. other anxiety disorder, affective disorder (unipolar, bipolar), personality disorder (especially common are the 'anxious cluster'), alcohol, caffeine, cannabis, cocaine, nicotine, nasal decongestants and other substance use (primary or secondary).

¹⁶⁶⁷ **Mitral valve prolapse** (floppy mitral valve) is a common cause of mild mitral regurgitation. Aetiology is congenital or myxomatous degeneration. May occur in connective tissue disorders (e.g. Marfan's syndrome). There is dyspnoea, tiredness, palpitations, and oedema/ascites. Benign arrhythmias and atypical chest pain may occur. Embolic CVA and TIAs are uncommon.

unipolar depression) and/or II (e.g. avoidant personality disorder) disorders is the rule rather than the exception.

4-year follow up of panic disorder patients (Katschnig ea, 1995)

Full remission 31%

Episodic course 24%

Persistent course 45%

2-year retrospective study of panic episodes in Dutch general population (Batelaan ea, 2010)

In panic disorder, 64.5% had a remission (mean time to remission 5.7 months)

43.3% still had panic after 1 year

21.4% of those with panic disorder who had remitted had a recurrence

Prognosis of subthreshold panic disorder better than for full syndrome

Remission predictors were being female, lack of ongoing problems, subthreshold status, and low initial panic attack frequency

Ondine's curse (congenital central hypoventilation syndrome)

This condition involves a reduced sensitivity of the brainstem leading to inadequate breathing, particularly when asleep. It is said that panic disorder is its opposite, (Pine ea, 1994) with a hypersensitive or false 'suffocation alarm' system.

Hyperventilation

Lactic acid induces hyperventilation. The symptoms of hyperventilation are dyspnoea, air hunger/suffocation, cold extremities, finger and perioral paraesthesiae¹⁶⁶⁸, tremor, chest pain/palpitation, nausea, abdominal distension, dizziness/fainting, feelings of unreality, and, rarely, tetany. The patient breathes with either an irregular sighing pattern or with a rapid, shallow, regular pattern. Pathogenesis includes neuronal hyperexcitability and vasoconstriction. As can be demonstrated by studying transcutaneous CO₂, hyperventilation is an important mechanism in panic attacks. Blood gas analysis shows hypocapnoea during the acute phase, but chronic cases may have normal CO₂ levels. Unilateral somatosensory symptoms, often left-sided, may be induced and confuse the clinician.

Stage fright (performance or situational anxiety)

Some of the symptoms of anxiety are due to alkalosis secondary to hyperventilation. Actors, and exam candidates, sometimes take propranolol (10-40 mgs) an hour before a performance.¹⁶⁶⁹ Oxprenolol (Trasicor), a partial agonist, causes less bradycardia than does propranolol. Breathing exercises (to slow down the rate of breathing) and re-breathing from a paper bag¹⁶⁷⁰ (to re-introduce one's own carbon dioxide) are useful treatments. The patient who believes he is going to die because of, say, palpitations, can be shown how his symptoms arise (by breathing fast and deep) and how they can be arrested (paper bag). According to Schmidt ea, (2000) breathing retraining did not add to the effectiveness of a particular form of CBT for panic disorder (panic control treatment); indeed it might even interfere with the maintenance of treatment gains! However, this was not the experience of Öst. (2004)

Post-traumatic stress disorder (PTSD)¹⁶⁷¹

'The diagnosis of PTSD may be appropriate in some cases, but physicians should not provide it reflexively in the aftermath of trauma'. (Rosen ea, 2008)

PTSD (O'Shea, 2001; North ea, 2009) is a syndrome¹⁶⁷² starting from days to years¹⁶⁷³ (Van Dyke ea, 1985) after significant psychological stress or trauma¹⁶⁷⁴. Following this time lag, chronic symptoms

¹⁶⁶⁸ Hyperventilation is the commonest cause of distal (face, hands, feet) paraesthesiae, sometimes unilateral and then more often left-sided.

¹⁶⁶⁹ Note: expert advice should be sought; for example, asthma may be induced by beta-blockers.

¹⁶⁷⁰ This can be dangerous in the presence of hypoxia or myocardial ischaemia. (Callahan, 1989)

¹⁶⁷¹ 'Gross stress reaction' was included in the first edition of DSM but failed to re-appear in DSM-II. The inclusion of clinical significance criterion in DSM-IV reduces the conditional probability of the disorder given trauma exposure by about 30%. Cases meeting the criterion are more pervasively and persistently disturbed. (Breslau & Alvarado, 2007) As pointed out by Lloyd (2007, p. 74) partial PTSD syndromes are likely to be more common than the complete syndrome.

¹⁶⁷² A number of authors suggest that PTSD is a superfluous label and could be covered by other disorders of anxiety/mood, or that it was included in DSM-III because of post-Vietnam political pressure. (Kelsey ea, 2006, p. 167) It should be noted that terrorism has effects on the general population, e.g. persistent if diminishing stress, perceived stress to self, reduction in travel, and a more negative world view 7 months after the July 2005 London bombings. (Rubin ea, 2007)

develop that can cause severe social and occupational incapacity.¹⁶⁷⁵ The *DSM-IV criteria* include exposure to a traumatic event with serious injury or threat of injury to self or others associated with intense negative affect. As more combat veterans survive physical trauma doctors will need to prepare for increased rates of psychiatric problems, particularly PTSD, and combat veterans tend to respond less well to interventions than do civilians with PTSD.(Richardson ea, 2010) PTSD causes a major drain on numbers available for combat.(Cohen ea, 2010) Children may exhibit disorganized or agitated behaviour. The traumatic event is persistently re-experienced with distressing recollections.

Children

- Young children may act out the traumatic event in repetitive play
- Child disaster survivor's prognosis may depend largely on the mother's response to the event (Nolen-Hoeksema & Morrow, 1991)
- Chiefly teenage school children on tour ship *Jupiter* in Mediterranean which sank – 52% of survivors developed PTSD; 30% were recovered by 1 year and 34% continued to have PTSD at follow-up (Yule ea, 2000)
- Combat injury in military service members affects both child (especially if there was family distress/disruption before injury; spouse-reported injury severity was not related to child distress) and family functioning (Cozza ea, 2010)

Childhood risk factors for later PTSD

Depression-anxiety and behavioural problems may increase risk for PTSD by increasing vulnerability to PTSD effects of trauma exposure and indirectly by increasing chances of exposure to assault.(Storr ea, 2007)

Koenen ea (2007) followed children born in New Zealand born 1972-3: assessed at ages 26 and 32; at age 26, increased risk of trauma exposure and PTSD was associated with childhood externalizing characteristics and family environmental stressors (maternal distress and loss of a parent); there was an increased risk of PTSD only with low IQ¹⁶⁷⁶ and chronic environmental adversity; low IQ at age 5 years, antisocial behaviour, and poverty before age 11 predicted PTSD due to traumatic events occurring between ages 26-32.

Recurrent, distressing dreams of the traumatic event¹⁶⁷⁷ are experienced. The patient acts or feels as if the traumatic event is recurring, including experiencing illusions or hallucinations.

The core problem in PTSD may be a failure to integrate the traumatic experience leading to memories of the trauma dominating consciousness. Breuer¹⁶⁷⁸, Freud's mentor, noted the release of intense affect by hypnotised patients and interpreted this as representing feelings that underlay presenting symptomatology

¹⁶⁷³ **Delayed onset of PTSD** is controversial and was introduced by DSM III following observation of soldiers not developing symptoms until they returned home. Andrews ea (2007) performed a systematic study and found that de novo delayed-onset cases were rare, but that delayed onset representing reactivation of earlier symptoms accounted for 38.2% and 15.3% of military and civilian PTSD respectively. Hepp ea (2008) followed cases of severe injury for three years: PTSD was present in 6%, 2%, and 4% at 2 weeks, 1 year and 3 years post-injury; persisting PTSD at 6 months or delayed onset were associated with chronicity. Heir ea (2009) examined Norwegians exposed to the 2004 tsunami and found that recalled threat increased from 6 to 24 months and that recall amplification was associated with lack of improvement in PTSD symptoms. Frueh ea (2009) found that delayed onset of PTSD is very rare among US war veterans one year after trauma and they found no cases starting 6 or more years after the event.

¹⁶⁷⁴ Lt. Audie Murphy (1924-71) suffered from PTSD. Combat has probably always produced PTSD or its equivalent. See, e.g. McPherson (1990, p. 734) on the American Civil War. During WWI the French used 'forward psychiatry' or 'PIE' (proximity to battle, immediate treatment and expectancy of recovery, including return to duty) to reduce troop losses but, according to Jones ea, (2007) it was ineffective. Delayed onset might be triggered by a recent reminder of past trauma – Kelsey ea (2006, p. 169) give the example of a mother who suffered childhood abuse who develops PTSD when her offspring near the age at which she was abused.

¹⁶⁷⁵ In DSM-IV the symptoms may appear in excess of 6 months after the event and last for longer than one month; ICD-10 has no duration specifier and states that the onset of symptoms rarely exceeds 6 months. One problem with studying PTSD is the inconsistency with which people report potentially traumatic events.(Hepp ea, 2006) Scott and Stradling (1994) argue that PTSD may follow a single trauma of the type mentioned in DSM but that it may also follow prolonged duress.

¹⁶⁷⁶ Lower IQ may be a predisposing factor in adults for PTSD.(Kremen ea, 2007)

¹⁶⁷⁷ Frightening dreams of obscure content in minors.

¹⁶⁷⁸ Josef Breuer (1842-1925), Austrian physician, is known for his work with Anna O and the Hering-Breuer reflex.

but had dated back to earlier trauma which had not found emotional expression. William Halse Rivers (1864-1922), medical officer at Craiglockhart War Hospital, realised this when treating WWI cases of 'war neurosis'. (Rivers, 1923) He believed that the worst symptoms could be explained better by the patient's attempts to repress memories rather than the trauma itself. In order to integrate an experience we must develop a coherent internal representation of it. Janet¹⁶⁷⁹ (1923) wrote that the traumatised individual could not form a memory of the 'unassimilated happening'. A similar hypothesis was developed by Browne¹⁶⁸⁰ (1990; Magee ea, 1984): 'the unexperienced experience'¹⁶⁸¹.

The sufferer is deeply distressed and physiologically aroused when exposed to internal or external reminders of traumatic event. Persistent avoidance of internal and external stimuli associated with the traumatic event occurs. There is numbing of general responsiveness and persistently increased arousal, e.g. insomnia, irritable or explosive, poor concentration, excessive vigilance, and exaggerated startle response. The syndrome lasts more than 1 month and interferes significantly with functioning. It can be 'acute'/short duration (< 3 months) or chronic (3 months or more). Finally, one can specify if PTSD onset is delayed by at least 6 months after the traumatic event. Some cases may not become fully apparent for much longer. The point prevalence of PTSD in the general population is about 1%. It is chronic or recurring in a high proportion of cases: 12 (29%) of survivors of the 1966 coal slag heap collapse into a school in Aberfan (Wales) met diagnostic criteria for current PTSD at 33-year follow-up. (Morgan ea, 2003) In their systematic review, Fazel ea (2005) calculated that 9% and 5% of refugees resettled in western countries had PTSD and major depression respectively, with 11% of children in this category having PTSD. Studies of MZ and DZ twins who had served with US forces in Vietnam suggest a genetic component in PTSD. Indeed, twin studies suggest that exposure to trauma, perhaps as a function of personality, and subsequent PTSD may be genetic. (Stein ea, 2002) Transgenerational PTSD has been described. Personality disorders of all types are common among patients with PTSD, and there may be no specific relation with borderline personality disorder. (Golier ea, 2003) Intensity of exposure, perceived threat, and losses sustained in the disaster, were not predictive of PTSD in Australian bushfire fighters in early reports but later work (Parslow ea, 2006) suggested that feeling very distressed or being evacuated were strongly associated with PTSD in young adults; introversion, neuroticism, and a past personal or family history of psychiatric disorder were premorbid factors significantly associated with the development of chronic PTSD. A prospective cohort study of US military personnel found that poor mental or physical health before combat exposure significantly increased the risk of symptoms or diagnosis of PTSD following deployment. (LeardMann ea, 2009) Kleim ea (2007) looked at assault survivors and found that mental defeat, rumination, and previous anxiety or depression predicted chronicity. British body-handlers in the Gulf were prone to develop PTSD if they had a past history of psychological problems or if they believed their lives were endangered. British reservists¹⁶⁸² who took part in the 2003 Iraq War were more likely to reported higher exposure to traumatic experiences than were their regular colleagues, yet PTSD related more to domestic problems than events in Iraq! (Browne ea, 2007) Intense stressors were specifically linked to PTSD in a study of Vietnam veterans. The presence of symptoms after 5 years in veterans of the Falklands War was associated with the intensity of combat experience as well as retrospective reporting of emotional problems in the initial period on return home from the war. Interpretation of combat-related PTSD data should be tempered by the knowledge that soldiers may exaggerate or misrepresent their combat involvement. (Frueh ea, 2005) However, heavy combat and low rank was associated with PTSD, anxiety and depression in Australian veterans 50 years after the Korean War. (Ikin ea, 2007) Personal appraisal of threat to life during trauma was the most important predictor of PTSD symptoms in a study of UK soldiers. (Iversen ea, 2008) Proximity to an earthquake epicentre and to a fatal playground shooting by a sniper predicted severity of PTSD in Armenian and Los Angeles children respectively (Nolen-Hoeksema &

¹⁶⁷⁹ Pierre Marie Félix Janet (1859-1947), famous for his discovery of dissociation.

¹⁶⁸⁰ Ivor Browne (b. 1929), Irish psychiatrist.

¹⁶⁸¹ According to Browne (2008) when a person experiences an overwhelming experience they 'freeze' (as happens to an animal caught by a predator: O'Shea, 1988) and fail to 'integrate' the experience into memory so it remains unsettlingly in the present as if it was happening now. If a later stressor activates the non-integrated material an emotionally painful flashback occurs which is imperfectly repressed.

¹⁶⁸² Reservists were older and of higher rank than regulars. They tend to be demobilised quickly, thus denying time for processing adversity.

Morrow, 1991) and actual combat exposure is associated with greater self-reporting of PTSD in US troops than is being deployed but not exposed. (Smith *et al.*, 2008) However, Booth-Kewley *et al.* (2010) used a questionnaire and the PTSD Checklist (cut-off score of 44, 17.1% screened positive for possible PTSD) with over one-and-a-half-thousand US Marines deployed in Iraq and Afghanistan during 2002-7: deployment-related stressors, combat exposure, marital status, and education were significant associations with possible PTSD, but deployment-related stressors had the strongest association. Greater intensity of fear during an earthquake has been reported as strong risk factor for PTSD. (Basoglu, 2004) Elderly Israeli Holocaust survivors were excessively sensitive to the events of the Gulf War. Interestingly, Sharon *et al.* (2009) found that Holocaust survivors, 6 decades after the event, had increased lifetime and 12-month anxiety disorders, more current sleep problems and emotional distress, but no excess of depression or PTSD compared to controls.

Survivors of a mass shooting in Texas had high levels of pre-existing PTSD, although this did not predict post-disaster PTSD. Also, a history of other pre-disaster psychiatric disorders did predict post-disaster PTSD in females only. Nevertheless, most subjects who developed PTSD had no history of psychiatric illness. Research on people working at the World Trade Center site in New York (September 11, 2001: '9/11') by Perrin *et al.* (2007) found that workers with less prior disaster training or experience were more likely to develop PTSD.¹⁶⁸³ Significant psychiatric symptoms (see box) were found in 'Ground Zero',¹⁶⁸⁴ ('9/11') ironworkers (Katz *et al.*, 2009); risk factors included alcohol misuse, injury to or death of a family member/friend/co-worker at Ground Zero, and at least one adverse life event subsequent to September 11, 2001. Although subject to methodological problems, the research of Claassen *et al.* (2010) suggest that the suicide rates fell in areas surrounding the World Trade Center after 9/11.

Psychiatric symptoms among ironworkers at Ground Zero 14-17 months post 9/11 (Katz *et al.*, 2009)

	Ironworkers%	General population% ¹⁶⁸⁵
PTSD	18.5	3.5
Panic attacks	3.2	2.7 ¹⁶⁸⁶
GAD	6.5	3.1
Depression	5.7	6.7 ¹⁶⁸⁷
Positive CAGE	39.3	3.1 and 1.3 ¹⁶⁸⁸

PTSD, posttraumatic stress disorder; GAD, generalised anxiety disorder; CAGE, measure of problematic alcohol intake. Note: 67.7% of participants drank alcohol. 44% increased alcohol intake after 9/11, 36.8% at Ground Zero, and 63.8% after leaving the site. Of the 67.7% who drank alcohol 39.3% were CAGE-positive. 124 (including 1 female) ironworkers participated and 58.9% of these screened positive for psychiatric symptoms.

The prevalence of clinically significant PTSD, depression and anxiety in Sri Lanka 20-21 months after the 2004 tsunami was 21%, 16% and 30% respectively (Hollifield *et al.*, 2008); believing ones life was in danger was the exposure item most strongly associated with symptoms and impairment; and personal strength, family and friends, a Western-style hospital, and religious practice helped in coping.

Exposure to trauma is not random in the general population. (Breslau, 2002) Childhood physical or sexual abuse and lack of religious faith may be predisposing factors for PTSD.

Lack of social support among tortured political Turkish ex-prisoners predicted anxiety and depression, but not PTSD. Negative responses from close others may be more predictive of PTSD in women than in men. (Andrews *et al.*, 2003) Social stigma after surviving a major adverse event, such as the Chernobyl or Nagasaki explosions, although not thoroughly researched, probably acts as a risk factor for PTSD. (Nolen-Hoeksema & Morrow, 1991) Direct experience of violence and poverty increased the risk of PTSD in post-

¹⁶⁸³ Overall PTSD prevalence among rescue/recovery workers = 12.4%; police = 6.2%; unaffiliated workers = 21.2%.

¹⁶⁸⁴ This means the actual site (World Trade Center) where 2 jetliners crashed into the towers in 2001.

¹⁶⁸⁵ 12-month prevalence rates.

¹⁶⁸⁶ Panic disorder.

¹⁶⁸⁷ Major depression.

¹⁶⁸⁸ For alcohol misuse and dependence respectively.

conflict Northern Ireland whereas strong national identification appeared to be protective.(Muldoon & Downes, 2007)

Disasters offer the researcher a chance to avoid some of the methodological problems inherent in life event research because of the wide range of people affected.(Bromet & Havenaar, 2002) Having studied a population before disaster strikes is an added bonus. For example, pre-disaster symptomatology was the strongest predictor of post-disaster symptom severity in one study of Californian university students before and after an earthquake.(Nolen-Hoeksema & Morrow, 1991)

PTSD may be particularly common in soldiers who have suffered acute combat reactions.(Solomon & Mikulincer, 2006) Tokyo firefighters who developed signs of Sarin nerve gas poisoning were more likely to develop PTSD than people who showed only mild, or no, intoxication.(Bromet & Havenaar, 2002) Civilians may develop PTSD after a natural catastrophe, a criminal assault, burglary, divorce, loss of career, concentration camp experiences, rape (Osterman ea, 2003), industrial or traffic accidents¹⁶⁸⁹ (Hepp ea, 2008), air crashes, and terrorist/ hostage experiences.(Galea ea, 2002; Mol ea, 2005) The relatives of murder victims may suffer PTSD and other adverse sequelae.(Mezey ea, 2002) PTSD may occur in as many as 94% of rape victims immediately following the event, this figure halving after 3 months. In the USA, the event most likely to be associated with PTSD is rape for both sexes, followed by threat with a weapon for women and combat for men, with a median duration of the syndrome of 64 months in those not receiving treatment. A prisoner who experiences the hanging of a cellmate may develop PTSD. Chronic PTSD may have adverse effects on offspring. Doctors who had been sued and people who have rescued others may develop PTSD. PTSD has followed traumatic childbirth¹⁶⁹⁰. 17% of train drivers who experienced suicides developed PTSD, and even more developed other psychiatric problems.(Farmer ea, 1992)

Dissociative symptoms experienced at the time of an injury, considered as a strategic response to limit arousal¹⁶⁹¹, may be predictive of later PTSD,(e.g. Birmes ea, 2003) whereas loss of consciousness after a noxious event has been reported by some, but not all, researchers as being protective against developing the syndrome. Persistent dissociation rumination four weeks after a road traffic accident was reported by Murray ea (2002) to be associated with the development of chronic PTSD.

PTSD has a strong positive association with the experience of torture, especially if the torture is perceived as being severe and if the effects on the family of the victim are catastrophic.

The symptoms may be divided into core symptoms and depression/anxiety. Core symptoms are due to re-experiencing the original traumatic event. There is numbing of responsiveness to, or reduced involvement in, the external world, and a variety of autonomic, dysphoric, or cognitive symptoms.

Rape and other forms of sexual violence

Increasing worldwide

At least 20% of women experience rape or attempted rape during life (Welch J & Mason, 2007)

Some authorities put the lifetime risk for rape at up to 50% for women (Bowyer & Dalton, 1997)

About 5% of rape victims become pregnant as a result of the assault and 4% to 56% develop a sexually transmitted infection (Wilken & Welch, 2003)

Rape victims initially may experience shock, disbelief, guilt and shame; days to weeks later they may appear to improve, but then become depressed for many months

Prolonged reactions are associated with:

- Prior psychological or physical problems
- Low socio-economic status

¹⁶⁸⁹ Intrusive symptoms shortly after an accident predicted PTSD.(Hepp ea, 2008)

¹⁶⁹⁰ Olde ea (2005) reported a 2.1% incidence of PTSD among 140 women after childbirth. Perinatal negative emotional or dissociative reactions predicted PTSD at 3 months postpartum. Mangaoang (2009) points out that changes in DSM-IV from previous editions have 'allowed' the inclusion of events within normal experience (e.g. childbirth) within diagnostic decision-making for PTSD.

¹⁶⁹¹ An fMRI study (Felmingham ea, 2008) of dissociated PTSD subjects found increased activation of ventral prefrontal cortex (PFC) in response to conscious fear (shown a fearful face) and of bilateral amygdala, insula and left thalamus in response to non-conscious fear (employing backward masking) when compared to people with non-dissociated PTSD; comparatively, dissociated PTSD subjects had reduced activation in dorsomedial prefrontal regions for conscious fear faces. The authors interpret the results as suggesting that the 'strategic response to limit extreme arousal' role of dissociation operates only when the person consciously processes threat, i.e. enhanced PFC and limbic activity accompanies conscious and non-conscious fear respectively in dissociated PTSD.

- Repeated assaults
 - Alcohol or other substance abuse
- Management principles:
- Cognisance of victim's desires and requirements
 - Time since assault
 - Police involvement
 - Meticulous note-keeping
 - Safety¹⁶⁹²
 - Attention to traumatic sequelae
 - Forensic examination (including samples for DNA)
 - Emergency contraception, etc

*Survivor guilt*¹⁶⁹³ is said to be common among Holocaust survivors and their offspring. Guilt about conduct during combat appeared to strongly predict suicide attempts and preoccupation with suicide in Vietnam veterans with PTSD.¹⁶⁹⁴

War veterans have very high current and lifetime diagnosable major depression.

Low 24-hour urinary cortisol excretion (Young & Breslau[2004] found normal mean urinary cortisol levels) and increased levels of lymphocyte glucocorticoid receptor numbers have been reported in PTSD, which may reflect increased negative feedback sensitivity at one or more levels of the hypothalamic-pituitary-adrenal axis. Young & Breslau (2004) found that trauma as such does not lead to sustained increases in cortisol or catecholamine levels but that PTSD is associated with raised catecholamine levels, and women with PTSD and comorbid major depressive disorder had higher cortisol levels than women with neither disorder or with either disorder alone.

The DST is hyper-negative in PTSD, with enhanced suppression of cortisol. Changes in DNA methylation, or some other mechanism, may underlie some cases of transgenerational PTSD.(Yehuda ea, 2007) In one study (Yehuda ea, 2004) ACTH and cortisol responses to 0.5 mg of dexamethasone were assessed in people with PTSD and in normal controls; PTSD subjects had greater suppression of cortisol and ACTH; the authors interpret their findings to mean that there is enhanced cortisol negative feedback at pituitary level.

Meewisse ea (2007), in a systematic review and meta-analysis, found that overall PTSD patients and controls do not differ in cortisol levels. Low cortisol in patients were more likely if controls were not exposed to trauma, if the patients were female, if there was a history of physical or sexual abuse, or if the samples were taken in the afternoon. The authors admitted that publication bias might have affected their findings.

Adrenergic hyperactivity may be important in the development of PTSD because of certain findings in sufferers:

- (a) increased physiological responsiveness, such as raised blood pressure, to stressful stimuli, or a tachycardia shortly after the traumatic event
- (b) long-standing increases in the urinary catecholamines adrenaline and nor-adrenaline
- (c) lactate and yohimbine, which stimulate the arousal system, cause flashbacks
- (d) positive symptoms (like intrusive memories and hyperarousal) were improved in an open study by adrenergic blocking drugs such as clonidine and propranolol.

An increased level of T3 occurs in PTSD.(Mason ea, 1994)

Pain following injury increases the risk for PTSD (Norman ea, 2008) and adequate analgesia after combat analgesia may reduce the risk for later PTSD.(Holbrook ea, 2010)

Males with a past history of PTSD have been demonstrated to have suppression of cellular immunity.

¹⁶⁹² E.g. in the case of domestic assault a refuge may be required.

¹⁶⁹³ Person feels that he does not have the right to live when so many others were killed.

¹⁶⁹⁴ People from some nations, such as British soldiers from the Falklands War, appear to have functioned better socially than did Vietnam veterans who more often failed to take up ordinary roles, were violent, or practised self-destructive behaviour. This difference may have been due to the different receptions received on returning home.

Hippocampal volume has been reported as diminished in PTSD and might be due to PTSD itself or may relate to the high comorbidity, including alcohol abuse, associated with this syndrome or it might be due to stress.(Winter & Irle, 2004) Some MRI research suggests that reduced hippocampal volume in PTSD may only apply to chronic or complicated cases,(Bonne ea, 2001; Vythilingam ea, 2002) although this is not entirely certain.(Lindauer ea, 2005) Combat-exposed veterans were reported to have smaller cortical volumes (MRI) especially in the region of parahippocampal gyrus, superior temporal cortex, lateral orbital frontal cortex, and pars orbitalis of inferior frontal gyrus.(Woodward ea, 2009) 17 male veterans with combat trauma and PTSD had reduced volumes of CA3/dentate gyrus subfields on MRI.(Wang ea, 2010) To complicate interpretation, a twin study (Gilbertson ea, 2002) suggested that smaller hippocampal volume may be a risk factor for PTSD rather than a consequence of trauma. Bremner ea (2003) conducted MRI and PET on three groups of women: a history of childhood sexual abuse (CSA) plus PTSD was associated with failure of hippocampal activation and reduced (by 16%) hippocampal volume compared to women with CSA but no PTSD, and women with CSA and PTSD had a 19% smaller hippocampal volume relative to women without either problem. Effective psychotherapy is not associated with return of hippocampal volumes to normal.(Lindauer ea, 2005) There is evidence for increased activation of the amygdala after symptom provocation with simultaneous reduction in activity of Broca's area. The latter findings may relate to the role of the amygdala in emotional memory and, in the case of Broca's area, a problem in labelling experience.(Hull, 2002) Shin ea (2004) employed PET a script-driven imagery paradigm in Vietnam veterans with and without PTSD: veterans with PTSD exhibited reduced rCBF in medial frontal gyrus during traumatic (v neutral) script-driven imagery; such changes were inversely correlated with rCBF changes in the left amygdala and the right amygdala/periamygdaloid cortex; in the traumatic condition, symptom severity related positively to rCBF in the right amygdala and negatively to rCBF in the medial frontal gyrus. The authors interpreted their findings as supporting a reciprocal relationship between the medial prefrontal cortex and the amygdala in PTSD. Using a cross-sectional design including MZ twins discordant for trauma exposure, Shin ea (2009), using PET and fluorodeoxyglucose 18, found that veterans with PTSD and their co-twins had significantly higher resting regional cerebral metabolic rate for glucose in dorsal anterior cingulate cortex/mid-cingulate cortex compared to veterans without PTSD and their co-twins; resting regional cerebral metabolic rate for glucose in the same areas in unexposed co-twins correlated positively with combat exposure, severity of PTSD, and use of alcohol in their exposed twins; the authors suggest that resting metabolic activity in dorsal anterior cingulate cortex/mid-cingulate cortex may represent a familial risk factor for PTSD should exposure to psychic trauma follow.

Meta-analysis of functional neuroimaging (fMRI and PET) of emotional processing in anxiety (Etkin & Wager, 2007)

Subjects: PTSD, social anxiety disorder, specific phobia, and fear conditioning in healthy people

All 3 disorders: greater activity than healthy people in amygdala and insula¹⁶⁹⁵

Increased activity in amygdala and insula seen more often in social anxiety disorder and specific phobia than in PTSD

Only PTSD associated with decreased activation in dorsal and rostral ventromedial prefrontal cortex¹⁶⁹⁶

Peres ea (2007) employed SPECT and a script-driven symptom provocation paradigm with subthreshold PTSD cases and found increased activity in parietal lobes, left hippocampus, thalamus and left prefrontal cortex during memory recall after psychotherapy.

According to Neumeister ea,(2003, p. 761) there may be impairment of the neural processes mediating extinction of trauma-related stimuli in PTSD patients. Electrophysiological response to an increase in intensity of a tone may be different in (combat-related) PTSD¹⁶⁹⁷ to normal¹⁶⁹⁸,(Lewine ea, 2002) although not all cases have this response. Early-onset PTSD has been shown in a small study to be associated with

¹⁶⁹⁵ Structures linked to negative emotional responses.

¹⁶⁹⁶ Structures linked to experience/regulation of emotion.

¹⁶⁹⁷ No increase in P200 magnitude with increase in tone intensity.

¹⁶⁹⁸ Linear increase in P200 magnitude with increase in tone intensity.

an abbreviated REM period before sleep stage change or awakening and increased number of REM episodes during sleep¹⁶⁹⁹.(Mellman ea, 2002)

Bryant (2008) discussed the relationship between mild traumatic brain injury (MTBI) and PTSD.(see Hoge ea, 2008) Exaggerated amygdala¹⁷⁰⁰ response impairs regulation (inhibition) of the amygdala by the medial prefrontal cortex (MPC); during fear processing in PTSD there is decreased activation of the MPC and the latter may be damaged by shearing forces (against bone) in MTBI; also, MTBI may impair cognitive capacity to manage traumatic memories and diminish the ability to engage cognitive strategies to manage disturbing experience¹⁷⁰¹. In a study by Carlson ea (2010) of US veterans screened for traumatic brain injury (TBI) by Department of Veterans Affairs facilities over 80% of those with positive TBI screens had psychiatric diagnoses; positive screen but unconfirmed TBI status were at increased risk for having PTSD as well as having depression or substance-related diagnoses; and clinically confirmed TBI status was associated with increased likelihood of having PTSD, anxiety, and adjustment disorders. Excess intake of alcohol (Thomas ea, 2010) and an increased risk of dementia (Yaffe ea, 2010) have been reported in veterans with PTSD.

An Australian study (Dileo ea, 2008) found that male war veterans with PTSD had significant olfactory identification deficits compared to controls. The authors suggested that this suggested a role for orbitofrontal dysfunction in PTSD.

Although not set in stone, as for affective and social phobia, the short (S) allele of the 5-HTT gene may be implicated in PTSD (Lee ea, 2005), as may the long L_A allele.(Grabe ea, 2009) Xie ea (2009) found that the 5-HT transporter 5-HTTLPR genotype (5-HTT promoter length polymorphism) did not predict onset of PTSD on its own but that it interacted with adult traumatic events and childhood adversity (both of which themselves predicted PTSD) to increase risk for PTSD, especially for people with high rates of adult traumatic events and childhood adversity.

Changes in acetylcholinesterase metabolism may persist for long periods after a single stressful event. In mice exposed to stress there is a change in the production of the commonly prevalent synaptic membrane-bound form of the enzyme to a normally rare soluble form, which may compromise capacity to cope with intensified cholinergic stimuli. Stressed *in vitro* mouse hippocampal neurones demonstrate very strong responses to electrical stimulation in the presence of physostigmine. Also, the muscarinic antagonist atropine blocks the response in post-stress neurones more effectively than in controls. There is also evidence for involvement of glutamine in these oversensitive synapses.

Pre-clinical research suggests that neuropeptide Y (NPY) may be anxiolytic and PTSD subjects may have low baseline NPY levels and a blunted NPY response to yohimbine.(Nijenhuis ea, 2002) However, research findings have been conflictual (Seedat ea, 2003) and it may be that reduced NPY levels are due to trauma exposure as such rather to PTSD.

The Mississippi Scale for Combat-Related Post-Traumatic Stress Disorder

Self-report inventory measuring symptom severity and effects on coping

Combat Exposure Scale

Subjective measure of wartime stressors, light stress scoring 1, heavy combat exposure scoring 5

The Structured Interview for Posttraumatic Stress Disorder

Questions asked of patient; delivers a score; event is defined, e.g. captivity, complicated bereavement, witness to death from murder or injury, combat, assault, experiencing threats or a close call, and being injured

MMPI

May predict vulnerability to PTSD symptoms in men prior to combat

Differential diagnosis: Only a minority of those exposed to trauma develop PTSD,(Stein, 2003, p. 41) and there are other outcomes following trauma exposure, including major depression¹⁷⁰².(Marshall &

¹⁶⁹⁹ Such REM fragmentation is not a surprising finding.

¹⁷⁰⁰ The amygdale is important to developing and expressing conditioned fear reactions.

¹⁷⁰¹ E.g. an inability to view traumatic experience as non-permanent.

¹⁷⁰² The chief symptoms among both survivors and relatives in the Herald of Free Enterprise disaster were sleep problems, loss of concentration and anger. The main diagnoses were PTSD, other anxiety states, and depression. Bereavement was associated with grief and depression, whereas non-bereaved passengers were anxious. Women tended to have affective symptoms and men showed an

Rothbaum, 2004; Toomey et al., 2007) Fear et al. (2010) examined the consequences of deployment to Iraq and Afghanistan on the mental health of the UK armed forces and found a low prevalence (4%, especially among reservists) of probable PTSD. The most frequently reported symptoms in this cohort were those related to common mental disorders (19.7%) and misuse of alcohol (13%, especially among regular soldiers). Spouses of soldiers deployed to foreign combat zones are at increased risk of depression, sleep problems, anxiety, acute stress reactions and adjustment disorders. (Mansfield et al., 2010)

Subsyndromal PTSD: Where do patients fall in the classificatory system if they fail to fulfil strict diagnostic criteria for PTSD? For example, van Zelst et al. (2003) found a six-month prevalence of PTSD in 0.9% of elders but 13.6% had symptoms short of full PTSD.¹⁷⁰³ Also, subsyndromal PTSD has escalated to full PTSD during the fiftieth anniversary of the Second World War! (Hilton, 1997) This change appears to have been provoked by media coverage (re-traumatisation).

Acute stress reaction (ASR): This is defined by ICD-10 as a reaction to severe stress that lasts from hours to 3 days. According to DSM-IV-TR, acute stress disorder (ASD) lasts from 2 days to 4 weeks and occurs within 4 weeks of the traumatic event¹⁷⁰⁴. The core symptoms are anxiety (threat) or depression (loss), experienced singly or together. DSM-IV-TR stresses dissociative symptoms¹⁷⁰⁵. It may persist as an adjustment disorder or PTSD, although many people not meeting ASR/ASD criteria still develop PTSD. (Marshall & Rothbaum, 2004, p. 123; Dalgleish et al., 2008) 'Battle exhaustion' or 'battle shock' is an acute, disabling reaction to war that can be seen as 'normal'; most cases recover. Cases should be seen early, mutual support groups are important, and emphasis in therapy should be on the here and now. Very severe cases may experience intense fear, hyperarousal, and 'hysterical' symptoms¹⁷⁰⁶. Others may be withdrawn, apathetic or mute. Support, rest and reassurance are essential, any deeper evaluative approach being deferred. There is evidence that exposure-based treatment may be associated with less intensive PTSD symptoms subsequently than when treatment is with cognitive restructuring. (Bryant et al., 2008b)

Adjustment reaction/disorder (AD): This psychological reaction to new circumstances is divided in ICD-10 into depressive, mixed anxiety-depressive, other emotional, and conduct (with or without emotional) subtypes and in DSM-IV-TR into anxiety, mixed anxiety-depressive, conduct disturbance, mixed emotion-conduct, and unspecified¹⁷⁰⁷ subtypes. AD can last for months to years. DSM-IV-TR criteria state that AD occurs within 3 months of 'identifiable stressor(s)' and it divides AD into 'acute' (duration < 6 months) and 'chronic' (6 months or longer). Before DSM-IV, a duration greater than 6 months necessitated a change in diagnosis. Subtyping of the chronic form is almost the same as in ICD-10. Previous experience and personality, as well as the precipitating event may help in understanding the reaction and intellectual disability is an important predisposing factor. In practice, attributing weight and an aetiological link to the stressor is often easier said than done. (Strain & Newcorn, 2003, p. 770) AD may differ from PTSD in that the stressors are usually less severe (Turner et al., 2005) and within the range of common experience; also, the classical symptoms of PTSD, such as re-experiencing the trauma, are absent. At least in theory, AD should be distinguishable from 'mixed anxiety-depressive' disorder by the lesser weight given in the latter state to a precipitating stressor. In reality, it is often not easy to distinguish AD from other psychiatric diagnoses and, in the milder case, normal reactions to adversity. AD may co-exist with another Axis I diagnosis. AD is often viewed as a diagnosis falling below the threshold for other conditions but this is no comfort for those saddled with the symptoms. Management of AD is similar to that for ASR. The patient should be helped to face his problems and not to avoid situations. Whilst psychotherapy (environmental manipulation, learning to cope with persistent stressors, and developing a support system) is considered to be the primary treatment approach SSRIs may be a safe option when an antidepressant is indicated. Prognosis may be

excess of substance abuse. Reluctance to discuss symptoms and a refusal to attend a psychiatric clinic were common. Generalised anxiety disorder and phobic anxiety disorder have been reported to be more common than PTSD after road traffic accidents. There are a number of reports of falsified PTSD from the military. The main conditions to consider are as follows.

¹⁷⁰³ Interestingly, van Zelst et al. (2003) found that neuroticism and adverse childhood events were risk factors.

¹⁷⁰⁴ Basically, it is either short-lived/subthreshold PTSD (Widiger & Mullins-Sweatt, 2007, p. 13) or 'acute' PTSD (Gilbertson et al., 2008, p. 468).

¹⁷⁰⁵ These **dissociative symptoms** can occur during or shortly following exposure to the traumatic event and consist of subjective numbing/detachment/emotional responsiveness, decreased awareness of surroundings (feeling dazed), derealisation/depersonalisation, and inability to recall some important part of the trauma (dissociative amnesia).

¹⁷⁰⁶ Whilst Kelsey et al. (2006, p. 171) suggest that dissociative symptoms are the chief symptoms of acute stress disorder Gilbertson et al. (2008, p. 467) point out that the emphasis on this phenomenon has been questioned.

¹⁷⁰⁷ A patient who refuses to consciously acknowledge (denial) medically-diagnosed lung cancer and who does not adhere with the treatment plan could be seen as having an 'unspecified' adjustment disorder.

better for adults than for adolescents, AD more often being a forerunner of other psychiatric problems in the latter.(Andreasen & Hoenk, 1982) Should AD evolve into another psychiatric disorder then the latter will need appropriate attention.

Brief psychotic disorder (DSM-IV): Classically, reactive psychosis results from massive stressors related in time to the disorder, it follows a benign course, and the content of the psychosis often reflects the nature of the traumatic experience. A good prognosis is associated with good premorbid functioning, few premorbid schizoid traits, severe precipitating stress, acute onset, affective symptoms, confusion and perplexity, little blunting of affect, short duration, and no family history for schizophrenia.

Enduring personality change after catastrophic experience (ICD-10): This applies to late chronic sequelae of devastating stress. It lasts at least 2 years, and manifests decades after a devastating stressful experience that would affect anyone adversely, e.g. torture, concentration camp experiences, or hostage situations. PTSD may precede it. The clinical features include hostility, mistrust, social withdrawal, feelings of emptiness and hopelessness, feeling threatened and estranged. Organic aetiologies, such as brain damage, are incompatible with the diagnosis.

Other specific phobias include panic disorder with agoraphobia (fear of having a panic attack) and social phobia (fear of being judged by others and/or embarrassing oneself in public¹⁷⁰⁸). Schizophrenic or other psychoses (delusion-based avoidance) and obsessive-compulsive disorder (avoidance of, e.g., dirt or contamination) are not examples of true phobias. Avoidance is based on the initiating trauma in PTSD.

Management: It is important to treat pain adequately following injury.(Norman ea, 2008) Exposure to memories of the traumatic stimulus constitutes a therapeutic factor common to all major theoretical models. Good managerial and organisational factors may have avoided PTSD among police officers that had been involved in retrieval and identification of human remains after a major disaster. However, psychological debriefing and brief counselling of British soldiers who handled dead bodies during the Gulf War did not affect subsequent psychiatric morbidity. Ismail ea (2002) found that Gulf War veterans had no more PTSD than did other veterans; this conclusion is supported by a systematic review.(Stimpson ea, 2003) A controlled (groups based in Bosnia, Gulf, and elsewhere) follow-up of Gulf War veterans (Hotopf ea, 2003) showed a moderate reduction in fatigue and psychological distress but a slight worsening of physical functioning, findings that were interpreted by Clauw (2003) as supporting the contention that these symptoms were not due to a specific environmental exposure (i.e. they are due to a variety of stresses, incl. war) and that they constituted a chronic syndrome similar to chronic fatigue (supported by Ismail ea, 2008), irritable bowel syndrome, or fibromyalgia, what Colonel Deahl,(2005) himself a sufferer, has described as a 'polymorphic collection of chronic, enduring, and in some cases disabling symptoms'. Murphy ea (2008) found that UK soldiers who remembered getting multiple vaccinations before going to the Gulf had multiple physical symptoms but that this did not tally with actual recorded number of vaccinations, i.e. there was recall bias. Thomas ea, (2006) in a systematic review, found that deployment in the Gulf was strongly associated with chronic fatigue syndrome and, to a lesser extent, with multiple chemical sensitivity or chronic multi-symptom illness. As the number of soldiers available for deployment fall duration of deployment increases as does PTSD, GHQ caseness, and multiple physical complaints.(Rona ea, 2007) It therefore seems wise to reduce duration of deployment as much as possible. Iversen ea (2008) suggest that the psychological impact of deployment might be lessened by factors such as good unit morale, leadership, and preparation of soldiers for their role in war theatre.

It is important to bear in mind that psychotherapies with research-based efficacy for PTSD are not widely available.(Gilbertson ea, 2008, p. 476) *Debriefing does not work for everyone and it has the potential to some cases worse, especially if it is used too early.* Debriefing remains a controversial subject with arguments for and against.(Wessely & Deahl, 2003; Sijbrandij, 2006) In a meta-analysis, van Emmerik ea (2002) found that single session critical incident stress debriefing (CISD) and non-CISD interventions did not improve on natural recovery from psychological trauma. Brief-series CBT started 2-4 weeks after impact in high-risk cases may have efficacy (Litz ea, 2002), a finding supported by meta-analysis.(Roberts ea, 2009) Gist & Devilly (2002) are highly critical of debriefing. They find that PTSD criteria for stressor and duration have broadened to include non-traumatic cases, that we really know little about the variable courses and outcomes among individuals who have been traumatised, and that debriefing has been taken

¹⁷⁰⁸ The Japanese, who value the group over individual autonomy, may fear that their activity (blushing, eye-to-eye contact, body odour, etc) will offend others (*Taijin kyofusho*).

over by the poorly informed. Single session CBT has been used with effect to treat earthquake survivors, as has behavioural intervention with an earthquake simulator.(Basoglu, 2004) Brief CBT may speed up relief of symptoms of acute PTSD without affecting long-term outcome.(Sijbrandij ea, 2007) Cognitive therapy was effective for PTSD related to terrorism and other civil conflict in Northern Ireland.(Duffy ea, 2007) Excessive fear responses to fear-eliciting stimuli¹⁷⁰⁹ may be important in limiting response to CBT.(Bryant ea, 2008a)

The Royal Air Force offers more than simple debriefing, e.g. prolonged residential introduction and group integration, problem-solving training, involvement of the family, and a year long follow-up. Treatment embraces the various forms of psychotherapy. Flooding in imagination has been employed. Flooding was deemed to be better than counselling by Vietnam War veterans.¹⁷¹⁰ Image habituation training involves the patient listening to his audiotaped description of a traumatic event.

A self-help booklet failed to help trauma victims in a study by Turpin ea.(2005)

Antidepressants are useful in about 70% of cases and serotonergic agents may have an advantage.

Symptoms such as recurrent, distressing recollections or nightmares may respond¹⁷¹¹ better to TCAs or SSRIs whereas symptoms like avoidance, lack of interest, or restricted affect require psychotherapy and, perhaps, SSRIs. According to some sources, phenelzine is useful for combat PTSD whereas fluoxetine is good for non-combatant PTSD but is ineffective for combat PTSD. Fluoxetine, in doses of up to 60 mgs./day, has been shown to be superior to placebo in civilians with PTSD. Fluoxetine reduces PTSD symptoms and prevents relapse for at least the first 6 months of treatment.(Martenyi ea, 2002) A systematic review and meta-analysis (Mooney ea, 2004) supports the use of sertraline for PTSD. Alprazolam is no better than placebo in reducing symptoms of PTSD; in fact, benzodiazepines may exacerbate PTSD or increase the likelihood of its occurrence.(Gelpin ea, 1996) Venlafaxine was effective and well tolerated in a 6-month randomised controlled trial (Davidson ea, 2006) and mirtazapine was as efficacious as sertraline in another randomised, controlled trial.(Chung ea, 2004)

NMDA channel and specific peptide receptor blocking agents inhibit the physiological and behavioural corollaries of PTSD in animals. The NMDA receptor or the beta-adrenoreceptor¹⁷¹² may prove suitable drug targets in humans. It has been suggested that drug treatment in PTSD may be too late to prevent brain traces underlying the disorder being laid down, but that reactivation of memories followed quickly by drug therapy may be helpful. How much damage to other memories would follow such controversial interventions is unknown.(Morrison ea, 2002)

Eye-movement desensitisation and reprocessing¹⁷¹³ (EMDR)

Therapy for PTSD (Coetzee & Regel, 2005)

Patient mentally visualises image of traumatic event

While he thinks of some phrase which represents how he feels about it (e.g. 'have no control'), bilateral saccadic eye movements are induced by following the therapist's rapidly moving (side to side across visual field) index finger (held about 35 cm from patient's face: 2 waves/second for total of 24 waves)

An important part of the procedure is replacing the negative belief statement with a preferred one, such as 'I have control'

While the patient repeats this statement to himself, saccadic eye movements are again induced

This 're-processing' procedure is repeated for all memories which are causing anxiety, until no anxiety is evident

It is unclear how essential are the eye movements (e.g. Seidler & Wagner, 2006)

EMDR may be no more effective than exposure therapy (e.g. Taylor ea, 2003) or trauma-focused CBT (Seidler & Wagner, 2006)

¹⁷⁰⁹ The authors used fearful and neutral faces to elicit responses in 14 PTSD cases. Treatment was with CBT. Imaging was with fMRI. Amygdala and ventral anterior cingulate activation predicted treatment response to cognitive behaviour therapy.

¹⁷¹⁰ Flooding, however, has generally become less popular as a treatment because of the intense discomfort associated with it.

¹⁷¹¹ The alpha-1 adrenergic antagonist prazosin may help for PTSD-related nightmares.

¹⁷¹² In one study of cardiac surgery cases (Krauseneck ea, 2010) adrenaline (beta-stimulation) enhanced memory for adverse experiences in men but not women whereas the beta-blocking drug metoprolol decreased memory for post-operative adverse events and PTSD symptoms in females only.

¹⁷¹³ Francine Shapiro PhD (Palo Alto, California) noticed that whilst looking intently at tree leaves moving in the wind one's mind turns from unpleasant thoughts.

EMDR and trauma-focused CBT are first-line psychological therapies for PTSD according to systematic review (Bisson ea, 2007a)

Most positive studies are flawed and value is unclear (Marshall ea, 2008, p. 605)

Ten daily sessions of repetitive transcranial magnetic stimulation (rTMS) applied over the right dorsolateral prefrontal cortex at a frequency of 10 Hz may help some patients.(Cohen ea, 2004)

A flexible, client-centred approach is likely to give the best results. According to Bowman,(1999) evidence from a number of studies suggests that an approach aimed at solving problems may be superior to one based on emotional display.

Disaster management – some principles (after Bisson ea, 2007b)

Have an agreed plan that includes psychosocial intervention

Non-mental health professionals:

Supply emotional support and information

Verbal and written information on normal responses and their tendency to subside over the short term

Advice to avoid excess drugs and alcohol

Avoid structured interventions

Do not force ventilation of feelings but listen to those who wish to ventilate

Advice to contact GP if symptoms persistent or severe

Mental health professionals:

Co-ordinate response

Support and supervision of non-mental health professionals

Deal with complicated cases, e.g. overwhelming anxiety or psychosis

About 30-50% of PTSD cases recover within 12 months.(e.g. Yule ea, 2000) Up to a third still have PTSD even many years later.(Kessler ea, 1995) Strong social supports, adherence with treatment, use of evidence-based treatments, and no comorbid disorders suggest a good outlook, the opposite being suggested by social isolation, drug abuse, poor cognitive ability, and many childhood traumas.

Management of torture victims¹⁷¹⁴

Physicians should not be directly or indirectly (advice, monitoring, etc) involved in torture (Marks, 2008)

Integrated, flexible, client-centred approach using a variety of techniques

Help patient feel accepted

Acknowledged fact that torture occurred

Security for the self and for friends left behind

Psychiatric help, e.g. treating depression

Help with psychological working through

Retelling the story of the trauma may be used to create a statement of testimony against torture

Cognitive-behavioural strategies, marital or family therapy to reduce the impact on relatives

Techniques to increase social support and reduce post-captivity depression and anxiety

Prior knowledge of what to expect, strong commitment to a cause, immunisation as a result of repeated exposure, and strong social supports may protect against PTSD in torture survivors

Physical therapies, e.g. analgesics for pain (see Mayou & Bryant, 2002)

Phobias

¹⁷¹⁴ There has in practice been little progress in impacting the suffering of **torture** victims.(Başoğlu, 2007) Torture in forms other than physical (psychological manipulation, humiliation, forced stress positions) causes just as much suffering and similar mental outcomes to classic torture.(Başoğlu ea, 2007) Traumatic head injury (prefrontal and temporal) in Vietnamese ex-political detainees was found to be associated severity of depression.(Mollica ea, 2009) Unfortunately, medical professionals have been (e.g. Nazi Germany, Guantanamo Bay) and still are involved in what amounts to torture in some parts of the world (genital mutilation, testing for homosexual activity or virginity, and withholding treatments for 'self-induced' problems).(Anonymous, 2010)

A phobia must fulfil the following criteria: a fear that is out of proportion to the stimulus; involuntary; refractory to logical argument; and leads to avoidance of the feared stimulus. The aetiology of phobias are most likely complex and different factors may weigh differently in their contribution to individual cases. (Ollendick *et al.*, 2004) Research in twins suggests that the fear conditioning process is moderately heritable, in the 35-45% range. (Hettema *et al.*, 2003) It may be that people who inherit a worrying or autonomically reactive temperament may be prone to develop phobic disorders. (Ollendick *et al.*, 2004) Psychoanalysts explain phobias as resulting from unresolved childhood conflicts, with displacement and avoidance as defences against castration anxiety. Put another way, the phobic situation is a symbolic representation of an inner conflict that the sufferer wants to avoid, the anxiety being displaced from the conflict onto a more readily available external object or situation. Phobias may start by the pairing of fear with a stimulus (Pavlov's classical conditioning) and be maintained by the reduction in anxiety associated with the avoidance of the same stimulus (Skinner's operant conditioning)¹⁷¹⁵. Other possibilities are the observation of others showing fear in the presence of an object or situation or being informed that such things should provoke fear by the media. Rachman (1977) suggested three pathways to fear acquisition: direct classical conditioning, vicarious conditioning (seeing others show fear), and information/instruction (being told fear-inducing stories).

Another putative mechanism is 'preparedness' or 'prepotency', i.e. things that were dangerous for our primitive ancestors, such as heights, are more likely to lead to phobias than are relatively harmless objects such as flowers. (Marks, 1969) The most successful exposure therapies for phobic disorders tend to be prolonged, given in a real life setting, and are regularly practiced with self-exposure homework tasks. (Stern, 1998)

People with phobic disorders are much less likely to seek help than, say, people with panic disorder. (Kessler & Walters, 1998) There are three major groups of phobia:

Specific (simple) phobia. An example is the fear of various animals such as furry animals¹⁷¹⁶ or spiders. Early during the twentieth century, Watson and Rayner (1920) induced animal phobia in a boy using classical conditioning. The kind of things we become phobic for (e.g. heights) and those that we do not develop phobias for (e.g. motor cars) suggests a survival function among our ancient ancestors. Genetic input into specific phobia appears to work mainly via temperamental inhibition (shyness). In practice, whilst some people relate experiencing an unpleasant event to which they attribute their phobia, this is by no means universally true.

Specific phobia

Usually starts in childhood, but can commence later (usually following a stressful event)

Adult onset cases have a better prognosis than do cases persisting from childhood

Among adults, the DSM-III-R lifetime prevalence rate has been estimated as 13% for women and 4% for men (Simonoff *et al.*, 1997)

Virginia twin study (8-16 year olds) reported prevalences (per 1000) of 212 and 108 for specific phobia and overanxious disorder respectively; 21% were functionally impaired, contrasting with overanxious disorder (41%) and major depression (93%); Functional impairment was associated with comorbidity

National Epidemiologic Survey on Alcohol and Related Conditions (Stinson *et al.*, 2007): 12-month and lifetime prevalences of DSM-IV specific phobia were 7.1% and 9.4% respectively; mean onset at 9.7 years; mean episode duration of 20.1 years; 8% received specific treatment; mostly multiple fears, and the more fears the greater disability, treatment seeking and comorbidity (axes I and II)

There is a good outlook, at least in the short term¹⁷¹⁷, with behaviour therapy. Modelling involves the therapist in demonstrating the lack of real danger in performing some act. Severe cases may persist into adult life.

¹⁷¹⁵ This idea stems from the American psychologist Orval Hobart Mowrer (1907-82).

¹⁷¹⁶ May generalise to include any furry or soft object.

¹⁷¹⁷ A 10-18 year follow up of 28 people who were treated for specific phobia found that 40% had clinically significant symptoms whilst 62% of 'responders' were practicing avoidance or suffering whilst continuing to expose themselves to dreaded stimuli. (Lipsitz *et al.*, 1999)

Needle phobia is seen in people subjected to repeated venepuncture or hypodermic injections. Blood-injection-injury phobia (Page, 1994) encompasses a wider array of fears than needle phobia: injections, mutilation, medical equipment, etc. Patients may avoid essential procedures. They faint if exposed to blood or injury; there is a biphasic response with hypertension and tachycardia followed by hypotension and bradycardia, i.e. vasovagal syncope. Management includes exposure or graded desensitisation (lying down at first). The patient can be taught *applied tension*: tense the hands and arms before and during exposure to prevent hypotension (it is the exposure that is therapeutic). (Öst & Sterner, 1987)

Phobia for chemotherapy or radiotherapy is a conditioned response in which anticipatory anxiety and nausea and vomiting leads to treatment avoidance. It has been treated with antiemetics¹⁷¹⁸, short term BZDs, and systematic desensitisation.

<i>Examples of names for phobias</i>

¹⁷¹⁸ E.g. the 5-HT₃ antagonists ondansetron and granisetron.

Acro-phobia (a fear of) heights
 Agora- open places
 Ailuro- cats
 Algo- pain
 Amatho- dust
 Astra- thunder and lightning (syn. Bronto-)
 Aviato-, flying^
 Claustro- confined spaces*
 Coito- sexual intercourse
 Cyno- cats (syn. Felino-)
 Dento- dentists
 Entomo- insects (Api-, of bees; Arachno-, of spiders; Motte-, moths)
 Frigo- cold weather
 Hoplo- , firearms
 Iatro- doctors
 Kerauno- thunder
 Myso- dirt
 Nebula- fog
 Noso- disease/suffering**
 Nycto- night/dark***
 Odyne- pain
 Ophidio- snakes
 Phono- loud voices
 Pyro- fire
 Tapho- being buried alive
 Toko- a morbid fear of childbirth in a woman, despite a wish to have a baby
 Topo- stage fright
 Triskaideka- number 13

^ see <http://www.fearofflyinghelp.com>. *Marks and Mataix-Cols (2004) refer to the agoraphobic cluster of situations, e.g. shopping, leaving home alone, etc. This may include claustrophobia. However, if claustrophobia is the single fear, these authors would classify it as a specific phobia. 'The more situations that are feared from the agoraphobic cluster, the more the problem can be called agoraphobic'. In other words, these categories are artificial with 'no sharp dividing line'. **Marks and Mataix-Cols (2004) suggests that worrying about one illness constitutes a specific illness phobia; if the fear is of many illnesses the diagnosis is hypochondriasis; the authors do admit that boundaries are not always clear. ***Achluophobia refers specifically to fear of darkness.

Social phobia. ('wall-flower' of the dancehall; social anxiety disorder) This is not mere shyness.(Stein & Stein, 2008) Social phobia is characterised by fear of being scrutinised by others, a fear of what others may think. We often feel some level of anxiety on social occasions, but the socially phobic experiences such a high degree of anxiety as to disrupt their lives. Sufferers may fear being tremulous, sweaty, blushing, vomiting in public, looking stupid, etc. Life becomes restricted, as when the person only ventures outdoors in darkness. People with this problem may avoid consultation because they do not view it as an illness or because they fear what the professional may think about them. This disabling and underdiagnosed condition has a mean age of onset in the mid-teens or earlier¹⁷¹⁹. It may affect up to 10% of people; the one year prevalence in the US has been estimated as 9% for women and 7% for men. Subthreshold cases that fail to meet diagnostic criteria are very common. Lifetime prevalence rates vary from 2.4-16%. The National Comorbidity Survey (Kessler et al, 1994) estimated lifetime and twelve-month prevalences of social anxiety disorder at over 13% and 7.6% respectively (12.1% and 7.1% respectively in a replication study: Ruscio et al, 2008). The only commoner psychiatric disorders were major depression and alcohol abuse/dependence. Social phobia is often divided into generalised/diffuse (2 out of 3 cases) and specific/focal¹⁷²⁰ types, the former being more severe and potentially disabling.(Kessler et al, 1998) It has been suggested that public-speaking fears should be included with the social phobias. This generally comes on in the teens, but later onset, in the present author's experience, should prompt a search for some other disorder, such as depression. According to Marks and Mataix-Cols,(2004) marked shyness in childhood may persist into adulthood but most focal social phobias commence in young adulthood. 'Shy bladder syndrome'¹⁷²¹ and fear of speaking

¹⁷¹⁹ 50% onset by age 11 years and 80% onset by age 20 years.(Stein & Stein, 2008)

¹⁷²⁰ Circumscribed fears such as public speaking or urination.

¹⁷²¹ Fear of urinating in a public toilet.

to a date may also be included among the phobias. Fear of urinating/defecating in public toilets or of being incontinent when a toilet is not available are sometimes called 'sphincteric phobia'. Marks and Mataix-Cols (2004) point out that sphincteric phobias are free of other social phobias.

There is an increased risk for later depression and alcoholism/substance abuse.(Stein & Stein, 2008) Akiskal and Perugi (2004) argued for an association between bipolar affective disorder and social phobia, arguing that social phobia usually precedes hypomanic episodes and disappears when the hypomania supervenes. However, this 'social phobia' could be a manifestation of depression in bipolar II disorder. Functional neuroimaging suggests increased activity in amygdala and insula in social phobia.(Stein & Stein, 2008)

Social phobia (social anxiety disorder)¹⁷²² must be distinguished from:

Separation anxiety

GAD

PTSD - avoidance based on trauma

Specific phobia

Panic disorder with agoraphobia - fear of having a panic attack

OCD - avoidance related to, say, dirt/contamination

Performance anxiety

Social inadequacy with shyness

Avoidant¹⁷²³ and schizoid personality disorders

Schizophrenia - avoidance based on delusions

Similar symptoms in depression - may outlast depression for some time

Parental psychopathology (especially social phobia and depression) and perceived parental style (overprotection or rejection) seem to be associated with the development of social phobia in offspring.(see Knappe ea, 2008) Social phobia seems to be more common in close relatives of autistic children and in girls with fragile X syndrome.(Oosterheld ea, 2003, p. 335) Dopamine may be involved in social phobia because mice bred to be timid have a low dopamine brain concentration.

A PET study (Furmark ea, 2004) found that patients with social phobia who possessed 1 or 2 copies of short allele of the 5-HTT gene had much greater trait and state anxiety and increased right amygdala activation while speaking publically compared with socially phobic patients who were homozygous for the long allele. In one study (Goldin ea, 2009), compared to controls, patients with social anxiety disorder had exaggerated negative emotional reactions and reduced neural activity related to cognitive regulation on fMRI following socially threatening stimuli.

Treatment may be ineffective for 30-40% of cases.(Stein & Stein, 2008) While psychological treatments help adults with social anxiety disorder they may not be particularly effective in more severe cases (meeting DSM criteria) and in studies that used placebo or usual care rather than waiting list controls!(Acarturk ea, 2009) Systematic desensitisation is not very effective. Exposure¹⁷²⁴, social skills training (SST: the evidence for SST is mixed: Ponniah & Hollon, 2008) and cognitive therapy may be offered as a package. Exposure, if tolerated and completed, has long lasting benefit. Assertiveness training may be tried. Role-playing may be of benefit in social phobias, and this might include, for example, talking to an opposite-sexed partner on a date. CBT (exposure and anxiety management) appears to be superior to both placebo and to exposure alone, but perhaps inferior to phenelzine in terms of quality of response (but patients are more likely to relapse when the drug is stopped than when CBT ceases). Exposure has been seen as the key component of CBT in this disorder (Barlow ea, 2004, p. 190; Ponniah & Hollon, 2008) but the whole CBT package may be best.(Hofmann, 2004) MAOIs are effective¹⁷²⁵, as are venlafaxine¹⁷²⁶, the

¹⁷²² Fear of being judged by others and/or embarrassing oneself in public.

¹⁷²³ Some authorities, such as Marks and Mataix-Cols,(2004, p. 22) and Torres (2005) equate this with social phobia and some see it as commonly comorbid with social phobia, others such as Rettew (2000) place avoidant personality disorder, generalised social phobia, and shyness on a continuum. According to Reichborn-Kjennerud ea (2007), a common genetic vulnerability underlies both disorders in female twin pairs with differing life events determining final expression (common environmental effects could not be ruled out).

¹⁷²⁴ Extinction is blocked by by antagonism of the NMDA receptor and D-cycloserine (given an hour before exposure), a partial agonist at this receptor, facilitates extinction of conditioned fear.(Campbell-Sills & Stein, 2008, p. 568)

¹⁷²⁵ Phenelzine plus CBT group therapy was better than placebo and either treatment on its own in one RCT.(Blanco ea, 2010)

SSRIs paroxetine (Stein ea, 2002), fluoxetine, (Davidson ea, 2004), escitalopram (Kasper ea, 2005) and the other SSRIs as well. An adequate SSRI trial is at least three months and relapse is a significant risk if responsive patients are switched to placebo. Whether moclobemide (Manerix) is effective has been strongly debated. (Hollander & Simeon, 2003, p. 577; Cowen, 2005) There is some evidence for efficacy with mirtazepine and for Pregabalin. Beta-blockers are ineffective for generalised social anxiety¹⁷²⁷. BZDs, especially clonazepam, give relief but carry their own problems and are less effective than the SSRIs. Venlafaxine, (Kelsey, 1995) bupropion, and gabapentin may be worth trying in resistant cases. Many patients remain symptomatic despite treatment responses that are superior to placebo. (Davidson ea, 2004) Alcohol, despite common belief, is no better than placebo for social anxiety¹⁷²⁸; however, a person who mistakenly thinks that he imbibed alcohol might experience relief! (Himle ea, 1999)

Agoraphobia.¹⁷²⁹ This affects young women in particular, who may become house bound¹⁷³⁰. If patients venture out, they will bring a friend, a spouse, or a dog. They are poor clinic attenders. DSM-III-R one-year prevalence has been reported as 3.8% for women and 1.7% for men. There is a normal class and education distribution. The partner or the child¹⁷³¹ may be kept at home as well. It may start as a panic attack in the street, in church, or in a supermarket. Psychoanalysts have explained agoraphobia as stemming from early maternal deprivation or traumatic separations in early life. It is often chronic and subject to exacerbations. McGennis ea (1977) divided agoraphobia into primary ('an abnormal fear of going out unaccompanied') and secondary (depression or schizophrenia) cases. However, the core fear may be of being separated from a source of security. Some authors stress the fear of a second panic attack leading to agoraphobic behaviour and write that agoraphobia without a history of panic disorder is very rare in clinical practice. Each case should be subjected to careful assessment with collateral information gathering. Brief episodes of depression during the course of chronic agoraphobia may prompt a visit to the doctor.

'Out and About'¹⁷³² is a national self-help association for Irish agoraphobics.

Behaviour therapy is effective for specific phobias. Desensitisation (i.e. systematic desensitisation) involves gradual increases in exposure to the feared stimulus. Flooding involves sudden and sustained exposure. Ghosh ea (1988) found that, when treating phobias, self-exposure (to the feared stimulus) treatment was equally effective if a psychiatrist, a computer, or a book was used by the patient, and all held the same effect at six-months follow-up.

Serotonin-reuptake inhibitors (SRIs) such as clomipramine and the SSRIs are the drug treatments of choice, although other antidepressants (MAOIs, SNRIs, TCAs, reboxetine) and benzodiazepines (clonazepam, alprazolam) may help individual cases. (Schatzberg ea, 2005, p. 23)

It may have the worst prognosis among the phobias. It may be complicated by drug or alcohol abuse.¹⁷³³

Space phobia is a fear of falling made worse by the absence of any immediate source of support and is especially common in open spaces. It has a later age of onset than agoraphobia, with a mean onset at 55 years of age, and it does not respond to behaviour therapy. It is often accompanied by evidence of neurological or cardiovascular disorder.

Chronic fatigue syndrome¹⁷³⁴ (CFS)

This is an idiopathic disorder (Prins ea, 2006; Baker & Shaw, 2007) that affects women more than men. (Evengård ea, 2005; Sullivan ea, 2005a)

CFS was said to be uncommon in children (Chalder ea, 2003) but Farmer ea (2004) found that children aged more than eleven years might not differ significantly from adults in terms of prevalence, symptoms, gender distribution, severity and comorbid depression.¹⁷³⁵ Crawley ea (2009) found that separation anxiety and social phobia were prominent in paediatric CFS.

¹⁷²⁶ Lower doses may be as effective as higher doses. (Campbell-Sills & Stein, 2008, p. 569)

¹⁷²⁷ However, beta-blockers like atenolol decrease performance anxiety in normal people.

¹⁷²⁸ Or anxiety symptoms in general for that matter.

¹⁷²⁹ 'Fear of the market place'. Westphal originally defined agoraphobia in 1872.

¹⁷³⁰ Initially being housebound may be a source of annoyance to a partner. However, the housebound person may take on extra household chores so that the rest of the household becomes discommoded when treatment is aimed at helping the patient break out of this mould.

¹⁷³¹ Part of the differential diagnosis of school refusal.

¹⁷³² St. John's House, Seafield Road, Clontarf, Dublin 3. Founded by Mortimer Murrihy, a psychiatric nurse, in May 1974.

¹⁷³³ The present author's experience has taught him that secret alcoholism can sometimes present as agoraphobia.

¹⁷³⁴ Epidemic neuromyasthenia, myalgic encephalomyelitis (ME), Royal Free Hospital disease, Iceland disease, Yuppie flu.

¹⁷³⁵ However, the latter study was conducted over the telephone with parents and there was a problem with validating the interview questions.

CFS is probably not as new as its modern names suggest. Doctors dislike self-diagnosis among their patients, a practice that may be encouraged by groups for ME patients as well as Internet sites.(Page & Wessely, 2007, p. 138) The diagnosis is less common in primary care in Brazil than in Britain but Brazilian doctors are just as likely as their British colleagues to record the symptoms of CFS.(Cho ea, 2009) It serves no purpose to disbelieve what is often a very handicapped patient.(White ea, 2007)

Risk factors for CFS have still to find application in clinical practice.(Hempel ea, 2008) Very few patients who complain of 'fatigue' in primary care settings are referred to hospital specialists. Most people with chronic fatigue do not have CFS. The criteria for CFS are wider¹⁷³⁶ than the original ME criteria. Some authors have suggested that CFS is more or less identical with neurasthenia¹⁷³⁷, is culturally sanctioned, will disappear like neurasthenia, and may be better classified under some other psychiatric label or as a psychophysiological reaction. Sullivan ea (2005b) obtained data from twins by telephone and concluded that CFS is a complex trait resulting from both environmental and genetic sources. Harvey ea (2008) found that people with psychiatric illness between the ages of 15 and 36 years had an increased likelihood of later reporting CFS and depression and anxiety in particular were common before CFS. Roy-Byrne ea (2002), using data from a highly selected small twin sample, suggest that chronic fatigue may more closely resemble atypical, anxious forms of depression than 'classic' depression. CFS patients do better than major depressives and worse than healthy controls on cognitive tests and their maximum voluntary contraction improves less than that of than major depressives during the day whereas the strength of contraction in the depressives improves more than in healthy controls.(Lawrie ea, 2000) Others wonder if it is primarily a sleep-related problem. Other workers have found CFS patients to be fitter than controls,(Bazelmans ea, 2001) although Viner and Hotopf (2004) found that sedentary behaviour increases the risk for CSF. Like CFS patients themselves, the partners of these patients are more likely to see the symptoms as having a somatic basis.(Butler ea, 2001) The commonest reason given by lay people for this complaint is a psychosocial problem, only a small minority (1.4% in one English sample) attributing it (excessive tiredness) to CFS.(Pawlikowska ea, 1994) Fatigue is distributed as a continuous variable in the community. Indian women with chronic fatigue were found to have an excess of poor mental health and gender disadvantage, notably sexual violence by the husband.(Patel ea, 2005)

A population-based study (Heim ea, 2006, 2009) found an excess of self-reported childhood adversity (sexual, physical, and emotional abuse as well as emotional and physical neglect) in cases of CFS; such adversity was also associated with more severe CFS and with symptoms of depression, anxiety, and PTSD; also, patients with a history of such childhood trauma, but not those lacking such a history, have decreased salivary cortisol after awakening. A prospective study (Kato ea, 2006) found that premorbid stress was a risk factor for CSF, as was emotional instability assessed 25 years earlier; genetic factors appeared to influence the effects of these predictors. Excess life events, particularly the dilemma of having to choose between undesirable options, are reported in a minority of cases before the onset of CFS.(Hatcher & House, 2003)

An estimated prevalence¹⁷³⁸ of 0.04% of the Australian population had CFS in 1990, women slightly outnumbering men, and with a mean age of onset of about 39 years. In general, estimates of prevalence tend to range from 0.3% to 1.5%. There may be little pathological basis for calling it an encephalomyelitis or a myopathy. It has been suggested that patients might have an abnormal perception of effort. Fatigue before an infection tends to be associated with post-infection fatigue. Indeed, a study in primary care found that people who complained of fatigue for more than six months following an infection were more likely to be fatigued prior to the infection.(Wessely ea, 1995)

Symptoms are chronic, and non-specific, and include fatigue, weakness, myalgia, memory loss and concentration difficulties¹⁷³⁹, and depression. Patients may be severely incapacitated, often missing school or work. Some take to wheelchairs. Laboratory findings, including CSF, are normal.

¹⁷³⁶ With 'hazy' boundaries.(Musser & Schiffer, 2003, p. 1196)

¹⁷³⁷ Others suggest that most cases of neurasthenia suffer from anxiety or depression. Neurasthenia, known in China as *shenjing shuairuo*, has become a less popular diagnosis, particularly in urban areas, and the Chinese classification system of mental disorders (CCMD-3) describes it as a diagnosis of exclusion.(Lee, 2001)

¹⁷³⁸ There were 'outbreaks' in a Los Angeles hospital in 1934 of 'epidemic neuromyasthenia' (paralysis) and at London's Royal Free Hospital in 1955.

¹⁷³⁹ **Cognition in CFS:** Dickson ea (2009), on the basis of a study comparing healthy people and patients with autoimmune thyroid disease with CFS sufferers, suggest that impaired attention may be a primary cognitive problem in CFS. Cockshell and Mathias (2010) performed a meta-analysis and found mainly problems with attention, memory, and reaction time.

Fatigue states can follow infectious disorders (postviral fatigue syndrome¹⁷⁴⁰), such as infectious mononucleosis, and physical and psychiatric disorders often co-exist. It has been that CFS is due to chronic cytokine (e.g. interferon) release from lymphocytes during viral infection. Coxsackie B and Epstein-Barr viruses do not seem responsible for CFS. There has been a report of enteroviral RNA in muscle biopsy specimens in postviral fatigue. Lombardi *et al.* (2009) detected a retrovirus, XMRV, in the blood cells of a significant proportion of patients with CFS¹⁷⁴¹ but this finding has since been refuted in a number of studies. (McClure & Wessely, 2010) Chia and Chia (2007)¹⁷⁴² state that most CFS cases have persistent or intermittent GIT symptoms and that on gastric biopsy they viral capsid protein 1 (VP1) in 82% and 20% of CFS patient and control parietal cells respectively, suggesting chronic enterovirus infection of the stomach. Lyme disease can cause fatigue. The widely held belief that antibiotics cause fatigue was not upheld in a double blind, randomised crossover trial in healthy volunteers of amoxycillin v placebo. (Bergmann *et al.*, 1993) MRI and standardised cognitive tests failed to support an organic aetiology (e.g. postviral) for CFS in a study by Cope *et al.* (1995)

Okada *et al.* (2004), in a voxel-based morphometric study of CFS, found bilateral reduction in prefrontal cortical grey matter volume, the decrease correlating with fatigue.

Suggestions of increased brain serotonin levels are difficult to interpret; they could be primary or due to prolonged inactivity, disturbed sleep pattern, or some other variable; there is some evidence for increased activity of presynaptic 5-HT neurones. These observations, as well as suggestions of reduced hypothalamic-pituitary-adrenal axis function or reduced baseline cortisol levels, could be causing CSF or resulting from CSF. (Parker *et al.*, 2001) Van Den Eede *et al.* (2008) reported reduced cortisol responses in the combined dexamethasone/CRF test in CFS cases *without* a history of early-life stress. Cortisol levels return to normal following behavioural intervention. (Cleare, 2003)

In a neurological hospital, Wessely and Powell (1989) found major depression in half of cases of chronic postviral fatigue, no psychiatric disorder in almost a quarter, somatisation in 13%, minor depression in 6%, anxiety disorder in 4%, phobia in 2%, and conversion disorder in 2%.

Among patients attending an infectious diseases clinic with idiopathic fatigue, many improve spontaneously but functional impairment is associated with belief in a viral cause, reduction in exercise, avoidance of alcohol, a change in job, quitting work, belonging to a self-help group, or having a current emotional disorder on follow up. (Sharpe *et al.*, 1992) Of course, these characteristics could denote consequences or aetiological contributions to fatigue. Darbishire *et al.* (2005) found that meeting the criteria for CFS was the most powerful predictor of poor outcome. A shorter history of fatigue and an absent history of anxiety or depression may favour a better prognosis for CFS, as may the absence of a primary psychiatric diagnosis at follow up or the lack of a belief in the explanatory power of a physical diathesis for one's symptoms. Diagnostic uncertainty on the part of the physician and the provision of a sick note may be unwitting contributors to an adverse outcome. Most patients get better¹⁷⁴³ but a significant minority is functionally impaired. Psychological factors are more important predictors of outcome than immunological¹⁷⁴⁴ or demographic variables. (Wilson *et al.*, 1994; Skapinakis *et al.*, 2003) Bentall *et al.* (2002) found a poor outcome in the psychological treatment of CFS to be associated with resistance to accepting therapeutic rationale, poor motivation to adhere to the treatment and secondary gains from illness. People in support groups, those currently emotionally distressed, receipt of sickness benefits and an exclusive belief in a physical aetiology were associated with adverse outcomes.

Various treatments have enjoyed transient period of popularity such as magnesium supplementation. Iron supplementation for unexplained fatigue in the absence of anaemia only seems beneficial if the patient has low or borderline serum ferritin concentration. (Verdon *et al.*, 2003) Controlled trials of antidepressants have been disappointing, although some cases are helped. The anticholinergic side effects of TCAs may be difficult to tolerate. Low doses of TCAs may however alleviate insomnia and pain. SSRIs only help if the patient is depressed. Mirtazapine following CBT was found helpful by Stubhaug *et al.* (2008) Doctors should

¹⁷⁴⁰ An Australian study (Hickie *et al.*, 2006) found that post-infective fatigue (disabling tiredness, musculoskeletal pain, neurocognitive problems, and disturbed mood) was largely predicted by severity of acute illness and not by demography, psychology, or microbiology.

¹⁷⁴¹ Retroviruses include HIV. XMRV = xenotropic murine leukemia virus.

¹⁷⁴² Chia JK-S, Chia AY. 'Chronic fatigue syndrome is associated with chronic enterovirus infection of the stomach'. *J Clin Pathology* September 2007: <http://press.psprings.co.uk/jcp/september/cp50054.pdf>.

¹⁷⁴³ Including CFS children when followed to adulthood.

¹⁷⁴⁴ Lyall *et al.* (2003) could find no consistent evidence for an immune disorder in CFS in their systematic review.

encourage 'fatigued' patients to deal with their psychosocial problems and discourage prolonged rest. Wessely *et al.* (1988) reported an improvement in myalgic encephalomyelitis using a combination of cognitive-behavioural methods and graded exercise. They suggested that instead of resting after influenza one should start taking regular gentle exercises to get going again. Brief courses of graded exercise therapy may be inadequate. (Ridsdale *et al.*, 2004)

An effective treatment package might consist of CBT¹⁷⁴⁵, (Stulemeijer *et al.*, 2005) reassurance that the disorder is non-organic¹⁷⁴⁶, a diagnosis of CFS, and advice to increase activity levels in a graded manner. (McCrone *et al.*, 2004) Graded rehabilitative exercises should be based on present and not past ability. These should be started without delay. (Powell *et al.*, 2004)

Smith *et al.* (2006) found no excess for all-cause mortality or suicide in a cohort of CFS cases.

Neuroses: general considerations

Those without personality disorder may be more likely to respond to psychological treatment methods, whereas those with personality disorder may respond better to medication, particularly antidepressants. However, the literature has not been uniform in this regard.

Neurotic states are relatively common in the elderly. They are often not seen by doctors and may be missed or misdiagnosed, or simply put down to advanced age or somatic illness. Alternatively somatic disorders may be misclassified as neuroticism. The clinical picture may be complicated by alcohol abuse or by dependence on or side effects from therapeutic drugs. Hysterical disorders may arise as a result of missed physical illness or they may be due to the release of dissociative tendencies in vulnerable people by organic brain disease or functional psychiatric illnesses. (Lindesay, 1997)

Recovered memories

The 'false memory syndrome' implies that people falsely recall being victims of CSA because it has been suggested to them that it did occur. Some patients 'recall' murders. Many experts doubt the possibility that one can develop dissociative amnesia for traumatic events and warn us to outrule organic causes like head injury or intoxication. Various forms of backlash against 'recovered memories' have occurred on both sides of the Atlantic, both by those who say they have been falsely accused by these recollections and by insurance companies who refuse to pay therapists who harvest them. (O'Shea, 2000a)

Factitious disorders

Factitious disorders have probably always been with us and they occur throughout the globe. (McDermott *et al.*, 2008, p. 643) It took years before Munchausen syndrome ceased to be viewed in a purely exotic medico-surgical way instead of the psychosocial problem it represents. (O'Shea *et al.*, 1984; O'Shea, 2003; Eisendrath & Young, 2005)¹⁷⁴⁷ These patients repeatedly seek admission to hospital with plausible but consciously faked or exaggerated histories to support complaints of a physical or psychiatric nature. They submit to potentially hazardous investigations and treatments, and discharge themselves against medical advice if challenged when tests or observation negate their complaints. Many cases over-reported and many are missed. Factitious disorder was diagnosed in 10 or 0.8% of 1,288 consecutive inpatient referrals in one Canadian hospital. (Sutherland & Rodin, 1990) In a Scottish 10-year study of thyrotoxic patients presenting to Edinburgh's Royal Infirmary, 0.2% of cases were diagnosed as factitious hyperthyroidism¹⁷⁴⁸. (Strachan & Walker, 2006, p. 746) Bhugra (1988) reported that 0.5% of psychiatric admissions had Munchausen's syndrome.

¹⁷⁴⁵ Unskilled practitioners may not deliver CBT effectively. (Huibers *et al.*, 2004) Low cortisol levels may be associated with poor response to CBT in CFS. (Roberts *et al.*, 2010)

¹⁷⁴⁶ Although a physiological 'explanation' often helps. Two patients challenged NICE Guidelines (CBT and graded exercise) in the High Court in London in 2009 stating that NICE should have used a biomedical model rather than a psychosocial approach. The challenge was rejected. (Dyer 2009)

¹⁷⁴⁷ Although such cases were known to doctors for many years, (e.g. Claudius Galen [c. 129 AD-c. 216 AD], Roman physician in Feldman, 2004, pp. 18-32; Gavin, 1838) Richard Asher (1912-69: see Turner & Reid, 2002) published his classic description of the presentation of the disorder with an emphasis on presenting physical signs in 1951. Galen wrote on feigned disease. Hector Gavin (1815-1855) was the first to use 'factitious disease'. He wrote about soldiers who mimicked of induced illness in themselves and women who 'assume the semblance of disease'. He belied the Irish were the best fabricators, followed the Lowland Scots! Gavin died of an accidental pistol wound in the abdomen in the Crimea. (Spriggs, 1984)

¹⁷⁴⁸ Exogenous T4 suppresses TSH as well as iodine uptake, serum thyroglobulin, and endogenous thyroid hormone release. In thyrotoxicosis the T4/T3 ratio is 30:1 but is > 70:1 in factitious cases. Negligible iodine uptake + high T4/T3 ratio + low/undetectable thyroglobulin = factitious.

The author recognises a *nuclear or classic factitious syndrome*¹⁷⁴⁹, more common in males, with extensive careers, costing an enormous amount of money to the exchequer over numerous admissions. The IQ, in this author's experience is often in the borderline range. *Non-nuclear cases* (90% of cases) may be more common in women who are mostly socially conforming, of a higher socioeconomic status than the peregrinating, alias-using nuclear group, and may be intelligent and educated, and are frequently employed in a medically related field. (Reich & Gottfried, 1983) *Munchausen/factitious disorder by proxy* (*frabricated/induced illness by carers, paediatric condition falsification, abnormal illness by proxy, vide infra*) perpetrators, on the other hand, are mostly female (Makar & Squier, 1990; Feldman & Eisendrath, 1996): Schreier and Libow (1993) could identify eleven reports out of nearly 200 where the father was the perpetrator. Mothers in such cases may give histories of insecure attachment in their own childhood. (Adshead & Bluglass, 2005)

The clinical features tend to include dramatic presentations, inconsistencies in their histories, complaint may be supported by congenital, static, or induced signs, there may be many operative scars, and almost any bodily system may be the focus of attention. The patient may be ingratiating and 'helpful' initially, profuse in thanks, but later becoming clinging and demanding. Staff may experience splitting due to identification and countertransference. An apparent high pain threshold may be accompanied by demands for opiate analgesia. Great ingenuity is shown in simulating illness. *Pseudologia phantastica* (pathological lying) refers to a free and effortless flow of lies that are immediately plausible. There is often a forensic history. The psychiatric subtype can include such varied complaints as PTSD following an non-existent military exploit or an exaggerated dependence on drugs. The F-K ('lie scale') on the MMPI is classically greatly elevated. Aetiology is obscure¹⁷⁵⁰ but there is evidence that it may stem from learning in childhood and may be continuous with MBP. However, pathological lying may be associated with a deficiency of prefrontal grey matter relative to prefrontal white matter. (Yang ea, 2005; Spence, 2005) The only pathognomonic sign is when the doctor sees the dye from last IVU leaving the bladder as dye from index IVU enters the kidney!¹⁷⁵¹

A high index of suspicion and knowledge of the profile described in bare outline above are required for a working diagnosis. Inexplicable laboratory results may prompt consideration of factitious disorder. (Krahn ea, 2003) Both ICD-10 and DSM-IV recognise absence of external incentives (economic gain, imprisonment, etc – malingering) in factitious disorders and motivation is *assumed* to be the adoption of the sick role. DSM-IV states that 'factitious disorders are distinguished from...malingering... (in that the malingeringer) has a goal that is obviously recognisable when the environmental circumstances are known'. Criteria include intentional production or feigning of physical or psychological symptoms, motivation is to assume sick role, and external incentives are absent. Presentation can be 'predominantly psychological signs and symptoms', 'predominantly physical signs and symptoms', 'combined psychological and physical signs and symptoms', or 'factitious disorder not otherwise specified'¹⁷⁵². Modern examples of feigned disorders include factitious disorders include diarrhoea¹⁷⁵³, hypoglycaemia¹⁷⁵⁴, 'arrhythmias' produced by manipulating ECG leads, HIV/AIDS (Craven ea, 1994), Guillain-Barré syndrome, bereavement, amnesia (Doherty & Sheehan, 2010), psychosis, and altered electronic records. Patients may manipulate real treatments for real disorders, may have real plus feigned disorders, or may develop real disorders as a result of treatment¹⁷⁵⁵ or attempts at inducing/simulating illness. They may present to physicians or online in chat rooms on the internet.

Almost any condition can be simulated, e.g. phaeochromocytoma due to ingestion of vanilla extract. ICD-10 talks about the intentional production or feigning of symptoms or disabilities, either physical or psychological [factitious disorder] where there are no confirmed physical or mental disorder, there is

¹⁷⁴⁹ *Munchausen's syndrome* in Asher's sense, perhaps 10% of all factitious cases. (Reich & Gottfried, 1983)

¹⁷⁵⁰ The DSM-IV-TR statement that factitious disorder patients wish only to assume the sick role may be too simple. Such cases may have multiple, mixed, changeable or unknown motivations. They may have Axis I (e.g. drug abuse) or II (e.g. borderline personality disorder) diagnoses. They may also, at times, malingering.

¹⁷⁵¹ In one study of renal calculi, 3.5% of the stones were non-physiological! (Gault ea, 1988)

¹⁷⁵² E.g. MBP = intentional production or feigning of physical or psychological signs or symptoms in another person who is under another's care in order to indirectly assume sick role.

¹⁷⁵³ Test the urine for phenolphthalein.

¹⁷⁵⁴ Use of exogenous insulin results in low C-peptide levels; oral hypoglycaemic drug use may raise C-peptide levels (mimicking insulinoma) by stimulating beta islet cells; oral hypoglycaemic drugs lead to measurable glibenclamide (glyburide in US) in urine.

¹⁷⁵⁵ A patient may accept prescribed medication without telling his clinician that he has had an adverse reaction to it in the past.

repeated and consistent feigning of, there may be self-cutting or abrading to induce bleeding, the use of toxins to simulate internal disorders, many investigations and operations at numerous centres despite negative tests, a presumed disorder of illness behaviour and the sick role, and signs of severe personality and interpersonal abnormalities.

The differential diagnosis is broad but includes pathological lying in hypoglycaemia, GPI, Ganser's syndrome, Korsakoff's confabulation, intellectual disability, bizarre histories in schizophrenia, hospital addiction¹⁷⁵⁶, malingering¹⁷⁵⁷, the gaslight phenomenon¹⁷⁵⁸, drug abuse¹⁷⁵⁹, psychoses,¹⁷⁶⁰ and hysteria¹⁷⁶¹. Some cases are difficult to classify.¹⁷⁶²

Contrasting behaviours¹⁷⁶³

	Behaviour evident + admitted	Behaviour under voluntary control	Behaviour directed towards obvious goal
Factitious	No	Yes	No
DSH*	Usually	Yes	Sometimes
Hysteria	No	No	Yes
Malingering	No	Yes	Yes

*Deliberate self-harm

MBP/FDP (Meadow's syndrome; Meadow, 1977, 1984, 1993; O'Shea, 1987; McGuire & Feldman, 1989), was first described in 1977. The mother may be a nurse¹⁷⁶⁴ or work in an occupation involved with touching, e.g. manicurist. The parents give false histories or fabricate signs in the child. The child may die as a result of such interference. (Wood, 2004) Fabrication may include feigned psychiatric or behavioural problems. (Schreier, 2000) The pregnant perpetrator may deliberately infect the amniotic fluid. (Porter et al., 1994) There is an absence of aspects of illness when the mother absent is absent; otherwise mother is in constant attendance.

Review of 451 cases of MBP (Sheridan, 2003)

Typical victim 4 or less years old, M = F, 6% end fatally

Mean of almost 22 months pass between start of symptoms and making of diagnosis

Over 60% of siblings suffer similar illnesses as do the index case

One-quarter of victims known siblings are dead

¹⁷⁵⁶ Looking for food and shelter, staying put, feigning illness or its exacerbation in order to stay in hospital.

¹⁷⁵⁷ These cases avoid dangerous procedures, have definite goals such as getting out of a war zone – 'Malingering is behaviour and not a diagnosis'. (Bass & May, 2002)

¹⁷⁵⁸ Make another person appear sick so as to have him/her committed to mental hospital - seen in marriage, nursing home, etc.

¹⁷⁵⁹ Munchausen patients use drug needs as a ruse and will leave hospital after confrontation despite offer of drugs.

¹⁷⁶⁰ Some simulators of psychoses have become psychotic eventually.

¹⁷⁶¹ True conversion is rarely found in Munchausen's syndrome.

¹⁷⁶² Other conditions that must be considered include **SHAFT syndrome** (patients who manipulate plastic surgeons into performing surgery, described as *sad, hostile, anxious, frustrating, and tenacious*: Kasdan et al., 1998), **multiple amputation seekers** ('*Mania operativa passiva*' or '*amputee identity disorder*' – very rare as when someone seeks removal of a healthy limb or places a leg in front of an oncoming train), the **masquerade syndrome** (presentation of school refusal as abdominal pain, headache, etc) **dermatitis artefacta**, people who have their **appearance altered to resemble an animal** such as a tiger, **simulated patients** (models used in training), and **pseudopatients** (journalists posing as psychiatric patients who were admitted in the US after complaining that they heard sounds such as 'thud' and who behaved normally thereafter; 11 of 12 cases were diagnosed with schizophrenia, the remaining case was given the label of manic-depressive psychosis; patients were more likely than staff to realise that the journalists were imposters, probably because they observed them more: Rosenhan, 1973).

One patient demanded admission because of Munchausen syndrome but his abdominal scars were washed off by staff! (Gurwith & Langston, 1980) An adolescent contaminated his urine in order to have pathology he believed to be present detected by investigation. (Reich et al., 1977) The first case was probably a true factitious disorder, whilst the other case most likely developed from concerns dating to surgery for hypospadias in early childhood.

¹⁷⁶³ In real life such distinctions are very difficult to make. Indeed real patients often change from somatisation to factitious and malingering over time. (Eisendrath & McNiel, 2002)

¹⁷⁶⁴ It is essential to avoid miscarriages of justice, e.g. the Dutch nurse Lucia de Berk was jailed for 7 murders in 2003 but had her conviction quashed in 2010.

Poor prognostic factors in MBP, according to Bass and Adshead, (2007) are where there is harm done to the child, the child is sexually/physically abused/developmentally delayed/injured/somatising, sadism, previous child deaths, harm to animals, problems with the parent (denial/uncooperativeness, personality disorder¹⁷⁶⁵, somatisation, alcohol/substance abuse, personal history of unresolved child abuse) or parenting (disordered attachment, lacks empathy for child, selfish) or family (conflict/violence, including across generations), professional difficulties) under-resourced, ignorant, prejudiced), and socio-environmental (violent neighbourhood that offers no support, involvement in false allegation network).

Extended forms of MBP include cases of abuse of elders, the intellectually disabled, and pet animals.

Prolonged psychotherapy and behaviour modification may help some cases of adult factitious disorder.(O'Shea & McGennis, 1982) Open acknowledgement of vulnerability of therapy to manipulation is helpful. Developing a therapeutic alliance offers best chance of enacting real change.

Management of MBP may involve multidisciplinary meetings, careful observation, laboratory evidence, police notification, court, psychotherapy, supervision, removal, etc. A high level of awareness and communication with all persons involved facilitates early diagnosis. The Royal College of Paediatrics and Child Health in the UK suggest in 2009 that a single responsible paediatric consultant should be the clinical lead and take responsibility for all decisions about the health care of the child.¹⁷⁶⁶ Expert opinions on MBP cases received much (sometimes adverse) publicity in Britain.(Anonymous, 2004; Dyer, 2005, 2006)

Dermatitis artefacta

Cotterill(1992) wrote that the skin is 'an organ of communication and patients with artefact dermatitis are very poor communicators...the only way that they can signal the rest of the world that they are angry or miserable is by developing simulated skin disease'.

*Pseudoseizures*¹⁷⁶⁷

These can occur in people varying from malingerers to true conversion cases.

Some potential features of pseudoseizures

Mimicking dramatic forms of epilepsy, e.g. tonic-clonic (often with changing motor activity, including non-synchronous or prolonged thrashing activity, during the 'ictus' in pseudoseizures)

Start at an older age than do true seizures (22 v 12 years)

Longer episodes of status

Closed eyes, resistance to attempted eye opening by examiner, or eye deviation to the ground when patient is turned on her side (the patient may still turn her eyes to the ground when turned to the opposite side); if eyes are open, convergence of eyes when a mirror is held up to the face

Observed attempts to control patient's hand held over the subject's face by the clinician

Ability to remember events despite bilateral convulsive movements

Prolonged non-responsiveness with full recovery

'Attacks' when under observation, e.g. in front of healthcare staff at a clinic

Uncontrolled cases with no early childhood onset and normal brains

History of overdose or self-injury, or other unexplained neurological disorders and abdominal pains

Retained pupillary and gag reflexes, a negative Babinski test

Incontinence, tongue¹⁷⁶⁸ or other injuries, and cyanosis are poor at differentiating pseudoseizures from legitimate cases. There is no rise or only a modest increase in prolactin above baseline¹⁷⁶⁹. Prolactin may not rise during true epileptic status.(Fink, 2000) Neurone-specific enolase, a marker of neuronal damage, rises after status, peaking 24-48 hours later.(DeGiorgio ea, 1999) Pseudoseizure cases are nearly always female. Pseudoseizures should be differentiated from *psychogenic seizures* that are evoked (deliberately or

¹⁷⁶⁵ Ford (2008b, p. 415) makes the point that severely narcissistic mothers may view the maltreated child as an object rather than as a person with all that that entails.

¹⁷⁶⁶ www.rpach.ac.uk.

¹⁷⁶⁷ AKA: dissociative seizures, functional seizures, non-epileptic attack disorder/seizures/events, psychogenic epilepsy, pseudo-epilepsy.

¹⁷⁶⁸ Epileptics usually bite the side of the tongue whereas people with pseudoseizures may bite the tip of the tongue, the cheek, or a lip. If the tongue is badly scarred, however, the cause is more likely to be true epilepsy.

¹⁷⁶⁹ Only 72% of seizures show a rise in prolactin; false-negatives can arise with non-generalised fits; prolactin can rise after non-epileptic seizures; neuroleptics and the contraceptive pill increase prolactin.

not) by specific mental activity, e.g. arithmetic. *Déjà vu* is most often due to anxiety, and it lacks the vividness and repetitiveness of a temporal lobe epilepsy aura.

A history of child sexual abuse is common cases with conversion non-epileptic seizures¹⁷⁷⁰.

Videotelemetry is the most important test: a normal EEG during and just after an apparently generalised seizure favours a diagnosis of pseudoseizure. An observer may record an attack on a mobile 'phone.

Malingering

'The doctor-patient relationship is understood sacredly as a fiduciary relationship, a relationship based on trust'. (Dyer & Miller, 2003, p. 1635)

'Compensable injuries are highly resistant to treatment'. (Clarke ea, 2007, p. 226)

'Malingering is not a medical diagnosis but it does exist as an unwelcome shadow at the periphery of our discipline'. (Spence, 2010)

Malingering, which is by no means rare, (Rogers & Shuman, 2000) involves the intentional production of symptoms with a goal (external incentive) that is obvious when environmental circumstances are known, e.g. to escape from any intolerable circumstance, to avoid combat, receive compensation (e.g. combat veterans: Gold & Frueh, 1999), collect insurance, evade prosecution, obtain drugs¹⁷⁷¹, or to influence an interpersonal relationship. Antisocial personality disorder is over-represented in this area, particularly so in prison. *Adaptive malingering* includes survival tactics during such life-threatening circumstances as hostage-taking or being a prisoner of war. *Malingering by proxy* (Cassar ea, 1996) refers to circumstances where illness is fabricated in another person (e.g. a child) in order to achieve some external incentive (e.g. monetary assistance benefit or as 'evidence' in litigation proceedings: see Stutts ea, 2003), as distinct from factitious disorder by proxy wherein the motivation is thought to be achievement of the sick role by proxy. Malingering may be suggested by medico-legal context (referral by legal advisor), discrepancies between subjective complaints and objective findings, non-compliance with elements of diagnostics or management, or evidence of dissociality. Even hallucinations may be malingered¹⁷⁷². Estimates of the prevalence of malingering on neuropsychological testing varies from 33-64%. (Rao & Swanson, 2003, p. 27) A person should score better on easier test items than on more difficult ones and one a person exceeds his/her level of ability subsequent answers should be correct or false by chance. This idea is utilised in the *Validity Indicator Profile* (Frederick, 1997), i.e. there will be a disparity between expected and actual performance curves.

Dysmorphophobia (body dysmorphic disorder [BDD])

This chronic disorder (Oshea, 2000b; Phillips ea, 2006) had a mean age of onset in one study of circa 17 years and a mean duration of 9 years. There is a preoccupation with some real or imagined minor bodily defect¹⁷⁷³ that the patient feels is conspicuous. There is no true phobia and most cases have an overvalued idea, albeit expressed vaguely. Some cases reach delusional proportions. Non-delusional cases appear under hypochondriacal disorder in ICD-10 and delusional cases are recorded as delusional disorder, somatic type in DSM-IV. Insight may change and so redefine the phenomena from obsessional preoccupation through overvalued idea to frank delusion. There is no disorder of perception. Whilst the patient may be defining himself through his appearance (Veale, 2007)¹⁷⁷⁴ compliments about appearance have no ameliorating effect. Most common areas of concern are the overall appearance, face, hair, nose, genitalia, legs, skin, and multiple areas. Picking at skin is common, sometimes with secondary infection or scar formation. Concerns tend to shift from one body part to another. Some cases repeatedly check their appearance in mirrors whilst others avoid mirrors and cover up supposed defects with wigs or cosmetics. BDD must be distinguished from normal adolescent concerns about appearance, schizophrenia, delusional disorder, depression, nihilistic delusions, OCD, and anorexia nervosa.¹⁷⁷⁵ Cerebral blood flow studies suggest that these patients may have increased thalamic perfusion bilaterally as well as increased blood

¹⁷⁷⁰ Espc. with deep penetration and closely related perpetrator.

¹⁷⁷¹ E.g. a person malingers a history of narcolepsy in order to obtain a prescription for stimulants

¹⁷⁷² E.g. 'I saw a crowd of swans in monochrome', 'As soon as I lifted the blind I saw green men on the lawn', or the person's thinking or actions are inconsistent with experiencing hallucinations.

¹⁷⁷³ Or smell according to Marks & Mataix-Cols. (2004, p. 25) Patients with olfactory reference syndrome may try to disguise the 'smell', e.g. with perfume, deodorants, changes of apparel, frequent baths.

¹⁷⁷⁴ Veale (2007) suggests that Freud's Wolf Man may have had dysmorphophobia (a later analyst, Brunswick, described preoccupation with the nose associated with mirror gazing and constant powdering).

¹⁷⁷⁵ Life however is complicated, e.g. this author has seen a patient with dysmorphophobia, schizoaffective disorder and anorexia nervosa!

flow through the right pallidum and putamen. Abnormal asymmetry of the caudate and increased total white matter was shown on MRI.(Rauch ea, 2003) There is evidence from fMRI of abnormal visual processing and frontostriatal systems in BDD (Feusner ea, 2010) when patients respond to faces of various spatial frequencies. Case reports of BDD associated with fronto-temporal inflammation or chronic abuse of ciproheptadine (5-HT antagonist) and exacerbation with tryptophan depletion are listed by Perugi and Frare.(2005, p. 206) BDD is not uncommon in cosmetic surgery and dermatology clinic populations. Surgical correction of alleged defects is generally ineffective for the underlying dysmorphophobia. The patient may transfer his preoccupation to another body part after surgery. Rare cases may operate on themselves if turned down for cosmetic surgery¹⁷⁷⁶. CBT may help some cases, although its specificity awaits demonstration. Mild cases (and those also on medication) appear to make up most of the CBT literature and long-term maintenance may be needed.(Perugi & Frare, 2005, pp. 213-4) Clomipramine and the SSRIs are often effective as long as they are taken and have rarely been combined for resistant cases.(Veale, 2007) Antipsychotic are often given for psychotic states, although there are reports of such cases responding to antidepressants (SSRIs or clomipramine) given alone (e.g. Phillips ea, 2002) and pimozide added to fluoxetine was not more effective than placebo added to fluoxetine in a placebo-controlled study.(Phillips, 2005) However, this does not mean that antipsychotic drugs have no role.(e.g. Filteau ea, 1992)

Muscle dysmorphia (Hitzeroth ea, 2001)

Type of BDD where the person is unreasonably dissatisfied with their musculature/frame

Much more common in males

Excess working out, preoccupied with diet, abuse of steroids

Common in amateur body builders

May have other body dysmorphic preoccupations

Trichotillomania

Trichotillomania¹⁷⁷⁷ consists of ‘compulsive’¹⁷⁷⁸ hair pulling, from any part of the body, as single hairs or tufts.(Mansueto ea, 2007a,b) Various patterns are described: transient, episodic, and continuous. The hair may be collected or swallowed. The hair follicles show a characteristic change known as trichomalacia¹⁷⁷⁹. Some cases, particularly children, may also pull hair from other people or from pet animals. Females predominate. It may be related to stress, or at least exacerbated by stress. It has been described in a variety of circumstances and in a number of different psychiatric disorders¹⁷⁸⁰ and I.Q. levels. It usually presents in adolescence, but sometimes in childhood. It is a difficult disorder to manage. Trichobezoar¹⁷⁸¹ is an uncommon complication. Attempts may be made to cover up bald areas (wigs, hairstyles, colouring pencils, etc). MRI suggests structural grey matter changes in circuits¹⁷⁸² involved in habit learning, cognition, and affect regulation.(Chamberlain ea, 2008) A variety of psychological and physical (e.g. chlorpromazine) treatments have been advocated. Clomipramine and (to a lesser extent) SSRIs (serotonergic) seem to be more efficacious than desipramine (adrenergic), as they also do in OCD and other ‘habitual behavioural disorders’ such as kleptomania. N-acetylcysteine¹⁷⁸³, an amino acid and glutamate modulator (perhaps increasing extracellular glutamate in the nucleus accumbens), was significantly more efficacious compared to placebo in an American study.(Grant ea, 2009)

¹⁷⁷⁶ DIY cases include those who glue their ears back or use a hot iron for facial wrinkles! The patient should be asked to draw himself before and after surgery. Even if the patient is satisfied with the operation it is unlikely to alter the underlying disorder.

¹⁷⁷⁷ Term introduced by Francois Hallopeau, a French dermatologist, 1889. Gk *trich* (hair), *tillo* (pulling) and *mania* (morbid).

¹⁷⁷⁸ In fact some people do it whilst relaxed and, e.g., watching TV. Trichotillomania Learning Center, Inc at 303 Potrero Street, Suite 51, Santa Cruz, CA 95060, USA (831-457-1004 or www.trich.org) is a useful resource.

¹⁷⁷⁹ Punch biopsy shows increased catagen hairs. The upper follicles and infundibulum show melanin casts and granules.

¹⁷⁸⁰ Comorbidity is common: mood and anxiety (including panic, GAD, and simple phobic) disorders, OCD (syndromal and sub-syndromal), eating disorders, and drug abuse.(Keuthen ea, 1998)

¹⁷⁸¹ **Trichobezoar** (hair ball) may lead to malabsorption, anaemia, peritonitis, pancreatitis, acute appendicitis, and perforation of small or large bowel.

¹⁷⁸² Increased density of grey matter in left striatum, left amygdalo-hippocampal formation, and multiple bilateral areas.

¹⁷⁸³ N-acetyl cysteine has also been used in schizophrenia.(Berk ea, 2008)

Behavioural approaches include habit reversal (use an incompatible competing response such as clenching fists when entering high risk situation), stimulus control (wearing gloves, hats, and so on to block pulling), and stress management (breathing control, deep muscle relaxation, or CBT). Outlook is better for young children than for adults. Some patients are so ashamed and in fear of ridicule that they withdraw from social interaction.

Personality and its disorders

Brian O'Shea

'The few specialist services for patients with personality disorder operate mainly at the tertiary referral level, often in conditions of security'. (Coid, 2003)

'Greater public appreciation of the differences between behavioral disorders and pure "diseases" might help the public see the role of clinical treatment in a more appropriate light'. (Cohen, 2003, p. 70)

'Diagnostic criteria for [antisocial personality disorder] are little more than a catalogue of disruptive behaviours which, it has been suggested, merely medicalises "evil"'. (Mullen & Sullivan, 2007, p. 495)

Personality¹⁷⁸⁴

'The field of personology reflects the complexity of human nature'. (Akiskal & Akiskal, 2005, p. 495)

Maturity

Attributes:

Objective self-perception

Flexibility in face of change

Tendency to make own decisions/plans

Objective view of the world

Integration - aware of own attributes and determining psychological processes

Competence to express own abilities/needs without clashing significantly with prevailing culture

Cloninger (2002): individual differences in maturity defined by 3 characterological dimensions:

Self-directed e.g. responsible for own acts v blaming others

Co-operative e.g. reasonable v prejudiced

Self-transcendent e.g. insightful v superficial

Temperament

Emotional core of the personality – thought to be largely genetic – Kagan (1994) described two distinct temperaments (inhibited and uninhibited¹⁷⁸⁵) in infancy that describe the fearfulness associated with novel situations; another approach (e.g. Clark & Watson, 1999) opines three basic temperaments (positive or negative emotionality, and constraint¹⁷⁸⁶); Goldsmith et al (1987) listed four ways in which infants express temperament, i.e. activity with effects on the environment, reactivity to the effects of the environment, emotionality (e.g. intensity of emotion and time taken to calm down), and sociability (causing and responding to social interactions); Chess and Thomas (1986) wrote of ten infant temperament categories (activity level, rhythmicity of biological rhythms, approach-withdrawal, adaptability, threshold of responsiveness, intensity of emotional response, quality of emotional response, distractibility, ability to finish a task, attention span/persistence) from which three topographical characteristics are derived (easy, difficult, slow to adapt)

Character

Conceptual core of personality

¹⁷⁸⁴ Latin, *persona*, a mask – how others perceive us.

¹⁷⁸⁵ 15% of infants are *inhibited* (low spontaneity, quiet/vigilant, low social interactivity), 15% are *uninhibited* (interactive talkers), and at least half remain so into the second decade of life.

¹⁷⁸⁶ *Negative emotionality* (subservied by a behaviour inhibition system and noradrenaline) is associated with fear of a hostile universe whereas confidence characterises *positive emotionality* (subservied by a behaviour activation system and dopamine). *Constraint* (possibly subserved by serotonin) refers to the tendency to take the longterm view rather than simply reacting to emotions.

Character is less heritable and more easily influenced by society and culture than is temperament (Cools & Ellenbroek, 2002) – best seen as formed by environmental effects on temperament

Personality (various definitions)

‘Those characteristic patterns of behaviour *and* modes of thinking determining a person's adjustment to the environment’

‘Lifelong style¹⁷⁸⁷ of relating, coping, behaving, thinking, and feeling’

‘The relatively stable differences between people in those aspects of their emotional and interpersonal behaviour, motives and drives which determine their adjustment to social and other environmental situations’

Trait

Any persistent aspect of personality

Nomothetic perspective

Compares aspects of personality between individuals to discover group norms

Defines personality in terms of deviation from such *norms*

Idiographic perspective

Recognises rich complexity and uniqueness of the *individual*

Individual-centred

Non-specific

Personality disorder

Enduring behaviour patterns, of developmental origin, causing inflexible responses to many personal and social situations

Appears in childhood or adolescence and persist into adulthood

Not due to another disorder

Not to be diagnosed on a cross-sectional basis¹⁷⁸⁸

Personality change

Acquired

Secondary to brain insult, severe mental illness or extreme environmental deprivation

The inflexibility or rigidity of traits and their inappropriate exhibition foster ‘vicious circles that perpetuate and intensify already present difficulties’. (see Millon & Davis, 2000) As exceptions to the rule, passive-aggressive (negativistic) and borderline personality disorder patients do not have rigid coping styles – they are openly ambivalent and unable to find a direction for their behaviour; they vacillate all over the place. DSM-IV criteria for personality disorder are given in the table.

Certain assumptions are often made in life cycle studies. According to the epigenesis approach, development occurs in successive, clearly defined stages. Each stage follows the previous one, and each must be negotiated successfully in order for development to proceed smoothly. Should a stage not be resolved, all subsequent stages reflect that failure in the guise of physical, cognitive, emotional or social maladjustment. In crisis points theory, on the other hand, each stage is characterised by a crisis point that must be successfully negotiated. Crises require adaptation. Each stage has at least one crisis point that differs from those of other stages.

Many factors interact in a complex way to produce our eventual personality: genes, experiences, culture, parents, other people, the environment, etc. Many different theories have been put forward to explain personality development. Illness, disease or dysfunction does not arise *in vacuo* but in a person with a personality. The disorder may be within the personality itself, or the personality's reaction to illness may colour or modify presentation of a disorder. Other factors are also important in modifying the clinical appearance of illness, e.g. culture and drugs. The latter are prescribed by licensed professionals, the self, lay acquaintances, or illicitly. Genes have an important influence on personality¹⁷⁸⁹. Also, in the context of environmental adversity, genetics become more important in the causation of ‘externalising disorders’ such as antisocial behaviour and substance use. (Hicks et al., 2009)

¹⁷⁸⁷ In reality certain ‘personality disorders’ may come on early (e.g. cluster B) and abate early whereas others (clusters A and C) may have a somewhat later onset and be more persistent. The diagnosis is relatively unstable over time and many clinicians are either extremely reluctant to make it or view it as a working diagnosis. (See Tyrer, 2010)

¹⁷⁸⁸ Cross-sectional assessment only tells us about personality functioning around the time of assessment.

¹⁷⁸⁹ E.g. MZ twins separated from birth have similar personality profiles.

Harari and Jackson (2007, p. 269) are critical of the fact that a person's response to discrimination or disadvantage may attract a psychiatric diagnosis, including one of personality disorder. Learning problems and psychological difficulties are common in any population of epileptics. Medication, especially the barbiturates, contributed to the so-called 'epileptic personality'. The *Mental Health Act 1983* (England and Wales) defined 'psychopathic disorder' as a persistent of disorder of mind (regardless of IQ) resulting in abnormal aggressiveness or seriously irresponsible conduct.

DSM-IV criteria for personality disorder

- (a) Enduring pattern (EP) of inner experience and behaviour that deviates markedly from the expectations of the individual's culture and is manifested in at least 2 of the following areas:
 - 1. cognition – ways of perceiving/interpreting self/others/events
 - 2. affectivity – range/intensity/lability/appropriateness of emotional response
 - 3. interpersonal functioning
 - 4. impulse control (this does not include 'impulse control disorders not otherwise specified' like gambling – Q.V. infra)
 - (b) The EP is inflexible/pervasive across broad range of personal/social situations
 - (c) The EP leads to clinically significant distress/impairment in social/occupation/other important areas of functioning
 - (d) The pattern is stable/long duration and onset dates at least to adolescence/early adulthood
 - (e) The EP is not better accounted for by another mental disorder/drug of abuse or medication/general medical disorder such as head injury
-

Hippocratic theory, of historical interest, is based on the four temperaments (see box).

Hippocrates and temperament

<i>Temperament</i>	<i>Body humour</i>	<i>Characteristic</i>
Melancholic	Black bile	Pessimistic
Sanguine	Blood	Over-optimistic
Choleric	Yellow bile	Irritable
Phlegmatic	Phlegm	Apathetic

Trait theory is basically an attempt at taxonomy. Introversion-extraversion¹⁷⁹⁰, body build types, and so on, are all based on the assumption that we, as people, occupy some point along some line(s) which are called trait(s).¹⁷⁹¹

Trait

An enduring, distinguishing, or idiosyncratic feature of personality

Factor analysis

A statistical technique used to determine the minimum number of items that explain observed differences/similarities between individuals over many different tests

Problems include poor predictive powers in many instances and the rather simplistic practice of 'explaining' traits by inference from what tends to vary over time, i.e. from behaviour.¹⁷⁹²

In 1936 Kretschmer described three personality types: pyknic, athletic and leptosomatic. Sheldon produced a similar classification (endomorphy, etc) in 1940. In 1942 he rated personality on three dimensions: viscerotonia - relaxed, enjoys comfort; somatotonia - assertive, energetic; and cerebrotonia - very controlled, not inclined to overt action, expresses himself symbolically. These are all attempts at classifying people according to somatotype (body-build), a practice that had some grain of truth in extreme cases.

¹⁷⁹⁰ Depending on whether our basic orientation is directed inwardly toward the self or outwardly toward the world at large.

¹⁷⁹¹ E.g. passive-assertive, confident-shy, and anxious-calm.

¹⁷⁹² Baca-Garcia et al (2007) found that the temporal consistency of mental disorders was poor, better for schizophrenia than for specific personality disorders, best for in-patient diagnoses and least for out-patient diagnoses.

Eysenck's theory: The most important input is from genes. Genes determine differences in reaction between individuals to the same environmental situation. Personality traits select the situation – situations do not determine conduct. Family environment (read 'genetic') is more important than wider (environmental) influences (e.g. school). There are three main traits (*vide supra*): E, extraversion – (ambiversion) – introversion; N, neuroticism – stability; and P, psychoticism – ego control. Stress + vulnerability = illness. He is highly critical of modern psychiatric taxonomies, seeing that as politically compromised committee resolutions, and recommends the dimensional over the categorical approach to diagnosis.¹⁷⁹³

Cramer (1994) interprets Eysenck's 'neuroticism' as reflecting emotional instability and his 'psychoticism' as meaning a lack of caring. Green and Smith (2010, p. 279) interpret Eysenck's 'neuroticism' as reflecting high levels of anxiety and depression but not necessarily attracting a diagnosis within the neurotic spectrum; they suggest that 'psychoticism' refers to eccentricity or un-socialised rather than psychosis as such.

Robert Cloninger (Cloninger, 1987, 2002)

Dimensions preferable to categories (supported by Morey *et al.*, 2007)

Temperament is the emotional (limbic, hypothalamic) and character is the higher cognitive (mental self-government; thalamocortical, frontal cortex) aspects of personality respectively

Four temperamental dimensions: harm avoidance (anxious *v* daring), novelty seeking (exploring/impulsive/irritable/aggressive *v* frugal/stoical), reward dependence (social sensitivity attachment *v* insensitive/alooof), and persistence (industrious/determined *v* underachiever)

Character traits include self-directedness (purposeful/resourceful *v* aimless/helpless), cooperativeness (helpful/principled *v* hostile/opportunistic), and self-transcendence (inventive/insightful *v* unimaginative/undiscerning)

People with personality disorders have immature characters and show low self-directedness and low-cooperativeness

Cools and Ellenbroek (2002) detect some correspondence between Cloninger's temperaments and the ancient Greek humors as well as with basic emotions (anger, fear, love, tenacity).

Five-Factor Model (Wiggins, 1997)

First used to describe 'normal' people

Applied later to describe personality disorder

Clinicians may find it more difficult to apply than the categories of DSM-IV (Rottman *et al.*, 2009)

Five dimensions:

Neuroticism (unstable emotion, negative affect)

Extraversion (energy, sociable)

Agreeableness (non-confrontation, warm)

Conscientiousness (responsible, organised)

Openness (to new ideas, not rigidly traditional)

These dimensions are composed of lower order *facet traits*¹⁷⁹⁴, e.g. extraversion contains assertiveness, warmth, positive affect, and a wish to experience excitement (briefly, these are gregarious people)

Dimensional Assessment of Personality Pathology (Livesley *et al.*, 1989):

Mainly concerned with lower level traits

Later simplified into four broad factors (neuroticism, disagreeableness, introversion, and compulsivity), so bringing it close to the Five-Factor Model (Livesley *et al.*, 1998)

¹⁷⁹³ He draws parallels between the ancient Greek temperaments (melancholic, choleric, phlegmatic, and sanguine) and his dimensions (unstable *v* stable and introverted *v* extraverted) so that rigidity (twixt introverted and unstable: melancholic), reliability (twixt introverted and stable: phlegmatic), easy-going (between stable and extraverted: sanguine), and impulsive (between extraverted and unstable: choleric) can be neatly plotted on a diagram. It is possible that these insights owe more to the similar meanings of words from different languages than to any revelations about what makes people tick.

¹⁷⁹⁴ For Morey *et al.*, (2007) five-factor facets did not improve on validity of higher-order factors upon cross-validation.

Categorical and dimensional schools in psychiatry are uneasy bedfellows, with, classically, psychiatrists generally belonging to the first camp and psychologists favouring dimensions. (Marcus et al., 2006) In truth, we do not know which is most valid and both approaches have a role to play: categories for describing clinical disorders and dimensions to structurally assess personality. (Ansell & Grilo, 2007, p. 635) Many psychiatrists view both the neuroses and the disorders of personality dimensionally as exaggerations of normal. Kendell et al. (2004, p. 255) prefer a dimensional approach for personality disorder. Likewise, Schneider (1950) decried categorisation because he felt that personality, which he believed was genetically endowed, was too rich and complex to be described so narrowly. He advocated a description of the personality rather than a label. Community studies tend to support a dimensional approach, personality disorder being on a continuum with 'normal' personality. (Livesley & Jang, 2000) Livesley (2005) does not accept that discrete categories of personality disorder exist: 'features of personality disorder merge with normal variation and with each other'.

Skodol and Bender (2009) discussed the possible approaches to describing personality disorders in DSM-V. They point out the deficiencies of categories: overlap, heterogeneity within categories, vague boundaries with 'normals', and the fact that the 'not otherwise specified' category is the most heavily populated! Clinicians are most familiar with categories. Approaches centred on variables measure how they describe an individual patient whereas those centred on the patient look for closeness of (dimensional) match between a prototype and the patient. Trait-based dimensional approaches include many continuous variables on which all of us vary.

Tyrer's (2007) personality diathesis model suggests that personality disorder carries a vulnerability to an Axis I disorder that may or may not be manifest. He points out that personality disorder does not disappear when an Axis I condition erupts. Vulnerability is more a dimensional than a categorical notion.

Freudian analytical theory recognised certain psychosexual stages in personality development with some variation in their timing.

Oral stage

First year of extrauterine life

Everything revolves about the mouth

Results of excesses of gratification or deprivation at this stage: optimism, pessimism, self-love, demanding nature, dependence, ingratiating, jealousy and envy

Anal stage

Centres round the anus and toilet training

Derived pathological traits: orderliness, obstinacy, stubbornness, frugality, parsimony, ambivalence, defiance, sadomasochism and rage

Anal defensiveness is classically found in obsessive/compulsive neurosis

Urethral stage

Non-Freudian transitional phase

Shame resulting from inappropriate urination causes ambition and competitiveness as compensatory devices

Phallic phase

Child is focused on his genitals

Masturbates and imagines having sexual relations (oedipal¹⁷⁹⁵)

Experiences anxieties

Resolution of **oedipal conflict** allows development of superego by identification with influential others and externalisation of drive impulses towards constructive ends

Latent stage

Sexual impulses are quiescent (this is controversial)

Child plays mainly with same-sexed partners and learns many living skills

Child may develop excessive or absent inner controls

Genital (adolescent) stage

Intensified libidinal drives

Old conflicts reopened and must be resolved to achieve mature sexual and adult identity

¹⁷⁹⁵ *Oedipus, a character in a play by Sophocles.*

Adult psychosexual problems (Erikson's identity diffusion) may result from non-resolution of this phase

Abraham suggested that arrest at the oral, anal, and phallic phases respectively led to dependent, obsessive-compulsive, and hysterical character types. Later theorists have put greater emphasis on the shaping influences of extra-psychic factors, such as interpersonal relationships, and socio-cultural influences.

Main 'regulatory (defence?) mechanisms' (according to Millon and Davis, 1996) of personality disorders as they appeared in various versions of DSM

schizoid – intellectualisation
 avoidant - fantasy
 depressive – asceticism
 dependent – introjection
 histrionic – dissociation
 narcissistic – rationalisation
 antisocial - acting-out
 sadistic – isolation
 compulsive - reaction
 formation
 negativistic (passive
 aggressive) – displacement
 masochistic – exaggeration
 schizotypal – undoing
 borderline – regression
 paranoid - projection

Object relations theory¹⁷⁹⁶ concerns the relation between subject and object (another person) as unconsciously perceived by the subject. Internal representations of people are not necessarily realistic. Personality is shaped by early relationships with parents. For example, parental deprivation causes dependency, struggles with parents leads to obsessive-compulsive traits, and parental eroticisation and competition contribute to hysterical traits.

Social learning theory looks at the behaviours that we acquire in our attempts at coping with life. The environment we live in and the situations we experience are emphasised. We learn by direct reinforcement (we like rewards) and by mimicry. (Bandura & Walters, 1963) We discriminate between behaviours depending on how they are received and responded to by others and by the environment. Cognition is more important in determining behaviour than are instincts. 'Basic trust' was described by Erickson: children who receive satisfactory parenting at an early age and who have not been exposed to traumatic separations, and who have learned gradually to cope with normal separations, enter adult with a sense of 'basic trust' and self-confidence. This results from being able to draw on a 'mental representation' or internal image of reliable parental figures¹⁷⁹⁷. Harlow demonstrated that monkeys separated at birth from their mothers become behaviourally disturbed, impaired sexually, poor socialisers, and rejecting of, and aggressive towards, any offspring that they may bear. Early learning occurs at a presymbolic level and cannot be recalled or unlearned. In most cases of personality disorder it is probably true that problem behaviours accrue gradually through repetitive learning experiences and, contrary to popular experiences, single experiences only account for a small percentage of cases.

In the case of borderline personality disorder it has been argued that it may arise from the lack of constants like customs and values in modern society. Adults then reflect the contradictory and changing customs and beliefs of contemporary society and are left without a feeling for a 'core' to their being: 'the great unrequited'.

Evolutionary necessity theory states that personality disorder depends on context, i.e. excessive aggression or timidity may be adaptive under certain (e.g. harsh) circumstances and at certain times and that great diversity may be necessary for the survival of the species. (e.g. Allman, 1994, Weiner, 1999)

Situationist theory stresses the importance of environment in behaviour determination, e.g. if one randomly assign students to a guard role or a prisoner role the former may quickly act brutally toward the latter, as shown by Hanley's experiments during the 1970s.

Phenomenologists stress how different people perceive and interpret events.

Humanists emphasise positive attributes. Everyone has a unique life experience and personality can only be understood from knowledge of that experience (idiographic). The American psychologist Abraham Maslow (1908-1970) believed that we strive to reach the highest level of personal functioning and he wrote about climbing a pyramid of personal integration. Carl Rogers (1902-1987), an American psychologist and clergyman's son, believed that we innately tended to move in the direction of growth, maturity and positive change. Personality was a reflection of self-image and interactions with other people and the environment. Reflecting back what has been said by the patient by the therapist allows recognition of alternative views of perceived problems. Important themes in the patient's experience are sought. The therapist's role involves providing unconditional positive regard for the client and reacting in a warm, empathic and genuine way. Giving of advice is not central. Rather the therapist helps the client to heal himself. Kohlberg (1980) has subdivided moral development into three levels. The pre-conventional level (up to 6-7 years) is one of self-interest and obedience aimed only at avoiding punishment or receiving a reward. The conventional level (starts at about 6 years) is characterised by an appreciation of the importance of conforming to rules,

¹⁷⁹⁶ While Ronald Fairbairn (1889-1964) coined the term 'object relations', Melanie Klein (1882-1960) is the person most associated with the 'theory'. Other pioneers included D W Winnicott (1896-1971) and Harry Guntrip (1901-1975).

¹⁷⁹⁷ John Bowlby (1907-90) observed the effects on British children being separated from parents and evacuated into the countryside to evade the Nazi blitz. He believed that insecure attachments formed early in childhood left a person vulnerable to develop psychopathology, even a disorder of personality. A child who is emotionally deprived or abused in some way may employ defences that are meant to fix or stabilise, but end up inducing dysfunction. Donald Winnicott (1896-1971) wrote of the *false self*: the child who has unempathic, traumatising parents has to accommodate to such an environment. Such traumatising may be multi-generational. The capacity to survive in the physical absence of the mother is developed by the 4-7-year-old by relying on the internalised caregiver, itself a product of *good enough* parenting. Heinz Kohut (1923-81) stated that healthy development flowed from internalising empathic parenting in order to be capable of self-soothing.

obligations, and a consideration of the views of others. This type of reasoning has been seen as important in adolescence and as the most common type of reasoning in adults. In the post-conventional level, said to be the highest form of moral reasoning, one understands the complexity (shades of grey) of values and rules and appreciated ethical principles.

'Self' concepts include the ideas, perceptions and values that typify 'I' and 'Me'. How one sees the 'Self' affects the way we perceive other things. We act in accord with our self-image and repress feelings that are not in keeping with this. The perceived distance between the self and the ideal self, if wide, causes anxiety.

Type A behaviour¹⁷⁹⁸ is reminiscent of the executive, who is always on schedule, works extremely hard, is competitive and aggressive. It is said to be associated with coronary artery disease. An interesting phenomenon in psychiatry is seen when two men go on strike from work: the busy, enthusiastic worker becomes anxious or depressed whilst the lazy man relaxes. Similarly, the breaking of a leg means more to a national cycling champion than to a loafer. It may be that type A individuals are highly defended and that work allows them to avoid neurotic problems.

Genetics: Most measurable aspects of personality appear to be at least moderately heritable. The human 5-HT transporter (5-HTT – necessary for fine-tuning serotonin transmission) gene is encoded by a single gene (SLC6A4) on chromosome 17q12. A small percentage of inherited variance (7-9%) and of total variation (3-4%) in anxiety-related personality traits appears to be related to 5-HTT gene polymorphism. Proposed linkage between D4 dopamine receptor gene alleles and novelty-seeking has yielded mixed results. (Kluger et al, 2002)

Panic attacks in adolescence may be a marker for any personality disorder during young adulthood. (Goodwin et al, 2005)

A Norwegian multivariate twin study (Kendler et al, 2008) found that genetic risk factors for DSM-IV personality disorders were not supportive of the notion of clusters A, B, and C in the DSM. Instead, one genetic factor reflected broad vulnerability to personality disorder pathology and/or negative emotionality. The two other genetic factors more specifically reflected high impulsivity/low agreeableness and introversion. Interestingly, the DSM clusters were well reflected in the structure of environmental risk factors. In other words, the tendency to clustering may be due to environmental experiences.

Personality of psychiatrists: There is some evidence that the personality and social attitudes of psychiatrists may, at least in part, influence their choice of treatment modalities, e.g. conservatives may incline toward physical treatments with radicals opting for psychotherapy.

Locus of control¹⁷⁹⁹: People, on this basis, are divided into internals ('my own efforts count') who seem to cope well and externals (attributing everything to fate, luck, other people, etc.) who cope less well.

*Burnout*¹⁸⁰⁰

Burnout is a major problem in modern human services. Some occupations may be at greater risk than others, e.g. deliverers of health care. (Evans et al, 2006) Persistently elevated occupational stress, coupled with lack of peer support and idealistic rather than realistic expectations of self and others, may lead to demoralisation, emotional exhaustion, and cynicism.

Features of burnout

Loss of humour
Persistent sense of failure
Anger, irritability
Marital conflict
Clock watching
Increasing resistance to go to work each day
Reluctance to see patients
Increased use of psychotropic drugs
Sleep disorders
Accident proneness
Minor ailments

¹⁷⁹⁸ Described originally in 1974 by Friedman and Rosenman.

¹⁷⁹⁹ Rotter introduced this concept in 1966.

¹⁸⁰⁰ The term was coined by HJ Freudenberger in 1974.

Increasing thoughts of leaving work
Rigid thinking
Suspiciousness
Dehumanisation of clients

Therapeutic interventions

'Detached concern' for clients
Appreciation of small gains rather than demand for cures
Adequate support peer support and sharing of work load and responsibilities
Development of interests unrelated to work

Italian community mental health staff study (Lasalvia et al, 2009)

Almost 2 of 3 staff experienced severe job stress
1 in 5 had burnout
Highest risk of burnout in psychiatrists and social workers
Lowest risk of burnout in support workers and psychologists
Burnout predictors = high frequency of face-to-face interaction with users, longer time in mental healthcare, poor work group cohesion, and perceived unfairness

The most dedicated and enthusiastic are consistently found to be at risk. One instrument used by researchers is the *Maslach Burnout Inventory*.

Notes on personality tests¹⁸⁰¹

¹⁸⁰¹ Modern **tests of personality and behaviour** are often divided into *objective* (responses are objectively scored and interpreted according to normative data) and *projective* (asked to give meaning to unstructured test stimuli [e.g. pictures of people, incomplete sentences, and inkblots], the theory being that the patient projects unconscious elements) groups. The most famous personality test is the MMPI-2 which was originally (1943) developed by a psychologist and a psychiatrist, Starke Hathaway and Charley McKinley, at the University of Minnesota. The MMPI-2 and MMPI-A (adolescents) are very Axis I oriented.

The *Lubin checklist of psychopathology* looks for feeling tone - various adjectives are ticked off. Kane's *self-description questionnaire* or the HOQ (*hystero-obsessoid questionnaire*) have been used, for example, in anorexia nervosa and in overdosers; the latter failed to support the notion of hysterical traits in young female parasuicides. The HDHQ (*hostility and direction of hostility questionnaire*) has been employed with groups such as alcoholics to determine their extrapunitive-intrapunitive status. Questionnaires are best used with an intelligent group because the questions are often difficult to decipher.

The *Firo-B* (Schultz) looks at characteristic ways of interacting with people, such as whether we move toward or away from them. Each of these tests is accompanied by manuals, which supply normal scores. The SSI (*symptom-sign inventory*) attempts to differentiate psychotic from neurotic and to tell the type of disorder present. The DPI (*dynamic personality inventory*) is analytically orientated and deals with Freud's developmental staging of personality development. Cattell's *16 PF* (personality factors) looks at traits (factor means trait). The *Personality Disorder Questionnaire Revised* is a self-report questionnaire.

The *Millon Clinical Multiaxial Inventory - III* (MCMI-III) is a 175-item self-report questionnaire in true/false format. It searches for personality disorders and for Axis I disorders. The MCMI-III has much item overlap in the scales which poses problems in interpretation and the Inventory may best be viewed as measuring Millon's own views on personality rather than DSM-IV-TR diagnostic criteria. (Clarkin et al, 2008, p. 81) The *Personality Assessment Interview* has 344 items and a 4-point response format ('false' to 'very true') that are used to form 22 scales containing items that do not overlap. Included are 4, 11, 5, and 2 validity, clinical, treatment, and 2 interpersonal scales respectively. It can be scored by computer. The *Millon Adolescent Clinical Inventory* has a greater focus on Axis II disorders than has the MMPI.

Projective tests: An ambiguous stimulus is presented which is open to the client's own interpretation. The person is all that he brings to mind at that moment. Examples of such tests are the *Rotter*, the *Bernventor incomplete sentences*, e.g. 'I want to know.....' (complete this), the TAT (*thematic apperception test* - Henry Murray, Harvard psychologist, developed this test in 1943 - look at a picture and tell a story about that has a start, a middle and an end and that describes how the people in it are thinking and feeling), and the CAT (*children's apperception test*). One looks at pictures and says what is happening now and what might occur in the future. The *Rorschach* (Hermann Rorschach, Swiss psychiatrist, published his test in 1921) consists of ten cards - the famous ink blots. What do you see in them? Marking this test can be quite complicated, e.g. Exner's Comprehensive system. (Exner, 2002) Other tests include the interpretation by the tester of drawings (e.g. a man, a tree, a house, etc), and *Blacky's pictograms* which were developed to see who would benefit from open versus closed prisons (e.g. if they put drawings inside given squares they were safe in open prisons). These tests, like all other tests, should never be interpreted in isolation from an appraisal of the whole case by the clinician. Eysenck (1994) believes that projective tests lack validity, that there are too many possible reasons for each choice of response, and that these tests attempt the impossible, i.e. they argue backwards.

Diagnosis of personality disorder is risky when based on hospital observation of an ill individual, although suspicions may be noted. Corroborative information should be sought from a reliable informant. The patient should be observed when clinically recovered from any 'Axis I' diagnosis. Personality tests may measure aspects that are of marginal or no clinical significance. Also, self-report instruments and interviews for personality disorders may show little agreement in terms of the patients they classify as disordered.

Examples of instruments used to diagnose personality disorders are *Structured Clinical Interview for DSM-IV Axis II Personality Disorders*¹⁸⁰², *Structured Interview for DSM-IV Personality Disorders* (Pfohl ea, 1997)¹⁸⁰³, and *International Personality Disorders Examination* (Loranger ea, 1994)¹⁸⁰⁴.

A longitudinal perspective is essential when diagnosing personality disorder. Cross-sectional observations offer the opportunity to develop hypotheses which can be tested in the firmament of time. How does the patient function in diverse life areas, such as with peers and authority figures, in affairs of the heart, or in occupational or educational settings? Are there recurrent themes, as when the patient meets with disappointment? Is he exploitative or callous?

Relationship with psychiatric illness

The relationship between specific personality disorders and specific psychiatric illnesses is not now held to be as strong as was previously believed. It is still recognised that having a personality disorder renders a person more vulnerable to developing a psychiatric illness. However, personality disorder may render a psychosis more difficult manage and schizophrenia appears to damage the personality (particularly if it develops early in life).

Epidemiology and definitions of personality disorder

According to various authors (Weissman, 1993; Samuels ea, 2002) the prevalence of personality disorder is 4.4-18%¹⁸⁰⁵ of the general population (2-3%, mostly males, with antisocial personality disorder, and perhaps 2%, mostly females, with borderline personality disorder), the precise figure depending on the cut-off point used.

The WHO Mental Health Surveys (Huang ea, 2009) looked at DSM-IV personality disorders in 13 countries. Personality disorder was found more often in males and in the poorly educated. Cluster C disorders were more common in the previously married and the unemployed while young people were overrepresented in clusters A and B. Other results are shown in the following box. Personality disorders are highly comorbid with Axis I disorders but comorbidity does not account fully for the degree of impairment found in these subjects.

Estimated prevalences: DSM-IV Personality disorders in WHO Mental Health Surveys (Huang ea, 2009)

Any personality disorder – 6.1%

Cluster A – 3.6%

Cluster B – 1.5%

Cluster C – 2.7%

There are many definitions of personality disorder. Schneider, in the 1950s, stressed personal or community suffering as a result of psychopathy (i.e. abnormal personality). Walton and Presly, in the 1970s, stated that personality is manifest in a person's social relationships, and can be regarded as consisting of what people actually do in social contexts. Personality disorder has been seen as an enduring pejorative judgement rather than a clinical diagnosis and there have been calls to abandon its use. To diagnose personality disorder the clinician is called upon to explore by clinical interview the person's pattern of relationships with other people including his behaviour with the interviewer himself. Personality disorders manifest

¹⁸⁰² SCID-II, a semi-structured clinical interview (119 sets of questions), assesses DSM-IV personality disorders as categories or dimensions. A screening version is available. Associated with Michael B First (who was Editor, Text and Criteria, for DSM-IV) and co-workers.

¹⁸⁰³ SIDP-IV, a semi-structured clinical interview (2 versions: 107 questions concerning specific disorders, and 101 questions in thematic version), assesses DSM-IV and ICD-10 personality disorders as categories or dimensions.

¹⁸⁰⁴ IPDE, a semi-structured clinical interview (99 sets of questions in ICD-10 version, 67 sets of questions in DSM-IV version) assesses personality disorders as categories or dimensions. A screening version is available.

¹⁸⁰⁵ Coid ea (2006) surveyed British households and used the Structured Clinical Interview for DSM-IV axis II disorders: weighted prevalence of personality disorder was 4.4%.

themselves across a broad range of situations, rather than in only one specific ‘triggering’ situation or in response to a particular stimulus - as with separation anxiety or morbid jealousy. In order to distinguish them from personality *changes*, ICD-10 described personality disorders as developmental conditions that appear in childhood or adolescence and persist in adulthood.

ICD-10 and personality disorders

Deeply ingrained and enduring patterns

Manifested as inflexible responses to a broad range of personal and social situations

Represent extreme/significant deviations from the way an average individual in a given culture perceives, thinks, feels, and particularly relates to others

These behaviour patterns tend to be stable and to encompass multiple domains of behaviour and psychological functioning

Often associated with various degrees of subjective distress and problems in social functioning and performance

Are not secondary to another mental disorder or brain disease, although they may precede or accompany other disorders

Not mutually exclusive and overlap in some of their characteristics

Divided in accord with trait clusters corresponding to the most frequent/conspicuous behavioural manifestations

Assessment should be based on as many sources of information as possible

The ICD-10, DSM-IV, and Tyrer and Johnson (1996) classifications are summarised in the box. DSM-IV divides personality disorders into three clusters: eccentric, dramatic, and anxious. The diagnosis is unlikely to be appropriate before 16-17 years of age. At least three of the traits or behaviours described in the clinical description in ICD-10 are needed for a diagnosis. The absence of narcissistic personality in ICD-10 was interpreted (tongue-in-cheek) by Millon & Davis (1996) as reflecting lifestyle differences between the US and Eurasia! In fact, as they acknowledge, some of the features of ICD-10 histrionic personality disorder suggest that the WHO may have sneaked narcissism in by the side door. Millon described 60 subtypes of personality disorder¹⁸⁰⁶. (Millon & Davis, 1996)

Personality disorder

(a) ICD-10 personality disorders (p.d.), F60-69

Paranoid p.d. – excessive sensitivity to setbacks/rebuffs, bears grudges, suspicious/misconstrues actions of others, excessive sense of personal rights, excessively suspicious of fidelity of spouse/partner, excessive sense of self-importance, and preoccupied with conspiratorial interpretations of events, personal and at large

Schizoid p.d. – gets pleasure from no/few activities, emotionally cold/distant, finds difficulty in expressing feelings towards other people, no reaction to praise/criticism, no need for a sexual relationship, prefers solitary activities, lives an introspective existence/dwells on fantasies, little or no close/confiding relationships and doesn’t desire them, and insensitive to social norms/conventions

Dissocial p.d. (syn. amoral, antisocial, psychopathic, sociopathic etc) – callous unconcern for feelings of others, irresponsible/no regard for social norms/rules/obligations, able to start but not maintain relationships, low frustration tolerance/easily becomes aggressive/violent, can’t experience guilt or learn from experience (especially punishment), and blaming of others/rationalisation/antisocial behaviour

Emotionally unstable p.d. – marked tendency to act impulsively, does not consider consequences, and affective instability; two variants: *impulsive type/explosive p.d.* (emotional instability, lack of impulse control, and outbursts of violence or threatening behaviour (especially if criticised), and *borderline type* (syn. borderline p.d., see below)

Histrionic (hysterical or psychoinfantile) p.d. – self-dramatisation, theatrical, exaggerates emotions, suggestible, shallow/labile affect, looking constantly for excitement/approval/attention, inappropriate seductiveness, over-concern with physical appearance

Anakastic (obsessional or obsessive-compulsive) p.d. – excess doubting/caution, preoccupation with detail, perfectionism that thwarts completion of tasks, excess conscientiousness/scruples, preoccupation with productivity to exclusion of pleasure and interpersonal relationships, pedantic, excess adherence to social convention, rigid, stubborn, wants others to do things his way, and unwelcome thoughts/impulses intrude into consciousness

Anxious (avoidant) p.d. – persistent tension/apprehension, poor self-image, preoccupied with being criticized/rejected socially (leads to avoidance), must be sure of acceptance before becoming involved, and restricts lifestyle to ensure physical safety

¹⁸⁰⁶ Reflecting the artificiality of the classification.

Dependent (asthenic, inadequate, passive, self-defeating) p.d. – leaves important decisions to others, undue compliance/subordination, unwilling to make reasonable demands, uncomfortable/helpless when alone – feels he cannot cope for himself, fears abandonment by close others and having to fend, and requires much advice/reassurance before making simple decisions

Other specific p.d. – eccentric, immature, narcissistic, passive-aggressive, etc

Unspecified p.d.

Mixed and other p.d. – mixtures of above or ‘troublesome personality changes’ due to co-existing affective or anxiety disorder

(b) DSM-IV p.d.

Paranoid – distrustful, suspicious, motives of others seen as malevolent

Schizoid – detached from people, limited range of emotional expression

Antisocial – disregards and violates rights of others

Borderline – unstable interpersonal relationships, self-image, and moods; impulsive

Schizotypal – social/interpersonal deficits (acute discomfort with, and reduced capacity for, close relationships), cognitive or perceptual distortions, eccentricities of behaviour

Narcissistic – grandiosity, need for admiration, and lack of empathy

Histrionic – attention seeking, excess emotionality

Avoidant – socially inhibited, inadequate, hypersensitive to negative evaluations

Dependent – submissive, clinging and needs to be cared for

Obsessive-compulsive – preoccupied with orderliness, perfection and control

Others, e.g. depressive/passive aggressive

(c) Tyrer and Johnson classification of personality (simplified)

Level	Classification	Description
0	No p.d.	Good capacity to form relationships; reasonable personal resources to help in adversity
1	Personality difficulty	Enduring behaviour patterns interfere with social function only if stressed
2	Simple p.d.	Particular & persistent abnormalities create major problems in many life areas
3	Diffuse p.d.	Fulfils criteria for a number of p.d.s (In fact most cases of p.d. fulfil criteria for multiple p.d.s – Millon & Davis, 1996; 3.5 diagnoses of p.d. per patient in Chisea & Fonagy, 2000; Tyrer (2008, p. 137) calls this phenomenon ‘the other multiple personality disorder’)

Reactions of professionals

These may take the form of hate, anger, avoidance, abandonment, over protectiveness, side taking¹⁸⁰⁷, anger against supervisors¹⁸⁰⁸, excess concern, over-investigation, etc. The management of staff splitting¹⁸⁰⁹ includes helping staff to ventilate and discussing how their feelings help to understand the patient. They should be helped to relax, to develop a sense of control, to be consistent, and to set limits for the patient without recourse to anger. (Fogel & Stoudemire, 2000) Personality disordered subjects utilise a disproportionate amount of mental health resources. There are no quick fixes for personality disorders (Silk, 2010) and clinicians should not confuse short- (e.g. relief of depression or substance detoxification) and long-term (personal maturation and survival) goals.

¹⁸⁰⁷ E.g. with patient against family or other staff.

¹⁸⁰⁸ Because feeling powerless or incompetent.

¹⁸⁰⁹ This may reflect psychic splitting on the patient’s part into ‘all good’ and ‘all bad’ staff.

*Individual disorders of personality*¹⁸¹⁰

'By their nature personality disorders cannot be cured but some individuals can be helped to make necessary changes so that their behaviour is less distressing to themselves or other people'. (Lloyd, 1991)

'Personality disorder may explain, but never excuse'. (Ferguson & Milton, 2000)

Antisocial personality disorder and the history of psychopathy

According to Derek Raymond in *The Hidden Files* of 1992, 'The psychopath is the furnace that gives no heat'. In psychopathological terms it is the polar opposite of obsessional personality disorder: superego agenesis v hypertrophy.

Some definitions of psychopathy

Alexander (1930): *psychoneurosis* (repressed impulses cause anxiety, depression, obsessive-compulsive and hysterical symptoms) and character neurosis (same repressed drives lead to apparently purposeless and self-defeating antisocial behaviour)

Scott¹⁸¹¹ (1960): no other cause for the behaviour can be found; starts at an early age; abnormal aggressiveness or inadequacy with serious antisocial or asocial tendencies; and society feels it necessary to intervene

Craft (1966): psychopath differs from ordinary criminal because antisocial acts are often self-defeating, motivation is obscure, and abnormal conduct extends into many interpersonal areas

The term psychopathy may refer to a zone between lunacy and normality or to 'antisocial personality disorder'. The term personality disorder in general and the narrower concept of psychopathy are intermingled historically. There is some overlap with the neuroses, although it has been said that most neurotics do not have a personality disorder. (Tyrer et al, 1983) Gunn, a forensic psychiatrist, gave a different opinion during the 1970s: psychopaths are neurotics who handle problems antisocially. He later warned that since everyone except psychiatrists thought psychopaths required help we might be turned into jailers by the authorities. (Gunn, 2000) In a study of the extent to which normal personality variation accounts for comorbidity of a number of common psychiatric and substance use disorders, Khan et al (2005) found that, whilst novelty seeking was modestly contributory to comorbidity between externalising disorders, neuroticism seemed to be a broad vulnerability factor for comorbid psychiatric disorders. Porter, (2001, pp. 296-7) a social historian, believed that earlier psychiatrists painted themselves into a corner by labelling 'vice, sin and crime' as mental disorder. The real truth is that the boundary between psychiatry and public opinion is too transparent.

History

1801, Pinel: people with sanguine fury and blind tendency to violent acts but who knew they were doing wrong - non-confusional mania or *manie sans délire*

1812, Benjamin Rush: morally deranged individuals; aggressive, irresponsible, callous, and shameless from early youth; possibly born with these tendencies

¹⁸¹⁰ Personality disorder categories are rarely discrete, most patients fitting the descriptions of a number of them. Also, personality disorder comes in all degrees of severity. A rounded picture of a patient's personality can be got from interviews from the patient, informants who know the patient well, and from tests of personality such as the *Personality Disorder Examination*. Multiple sources are superior to single sources. However, the information given by each may not be identical. (Riso et al, 1994) A study of treatment of major depression showed that comorbid personality disorder predicted poor social functioning and residual symptoms of depression. (Shea et al, 1990)

¹⁸¹¹ a forensic psychiatrist

1835, Prichard¹⁸¹²: *moral insanity* - devoid of cognitive or floridly psychotic features but with perverted impulses, feelings, morality, inclinations, etc: 'morbid perversion of the feelings, affections, and active powers, without any illusion or erroneous conviction impressed upon the understanding'
Moral imbecility: combination of mental handicap and moral insanity
 Henry Maudsley, borrowing the Morelian concept of degeneracy,¹⁸¹³ believed that some temperaments, occasionally inherited, while not psychotic under normal situations of stress, might readily become mad as a result of intrapsychic or environmental strain; he wondered if doctors were responsible for dreaming up the concept of moral insanity unjustifiably (i.e. such people were criminals)
 1888, Julius Ludwig August Koch (1841-1908) of Württemberg: *psychopathic inferiority* fell short of mental disorder
 Emil Kraepelin failed to satisfactorily classify psychopathy
 Analysts indict early rejection as the root cause of psychopathy - Rutter and Giller (1983) found evidence that parental divorce/separation were strongly associated with delinquency, whereas parental death bore only a weak association, i.e. discord seems to be key (Luntz & Widom, 1994) - weak attachments with caregivers, as in institutions, have long been seen as leading to poor development of internal controls
 Schneider's *affectionless psychopath*: conceptually close to modern idea of psychopathy
 1939, D. K. Henderson: 3 types of psychopath - *aggressive, inadequate* (passive¹⁸¹⁴) and *creative* - creative psychopath¹⁸¹⁵ is individualistic, carves a way through life, suffers no obstruction, and may become driven leaders
 Donald Winnicott (1896-1971), a British psychoanalyst, wrote that antisocial proclivities were due to a child being able to attribute deprivation to external forces (self-attribution leads to depression) and thereafter annoying others in order to get them to fill a void
 Cleckley (1964) divided psychopathy into *primary* (cold, aggressive and never upset), *secondary* (suffers more, high tension levels, low self esteem, hidden guilt or regret), and a possible third (*secondary to psychoneurosis*) types
 Cloninger (2005, p. 126) - two groups of impulsive, antisocial personality psychopaths: *primary* (cold, callous, without remorse) and *secondary or neurotic* (DSM-IV borderline personality disorder and ICD-10 emotionally unstable personality disorder, the latter being divided into impulsive and borderline subtypes)
 Marcus ea, (2006) using taxometric analysis, looked at male offenders in state prisons or court-ordered to residential drug treatment, and concluded that antisocial personality disorder exists on a *continuum* (i.e. best measured dimensionally) and that its origins are *multifactorial*

Distinguishing between subtypes can be difficult in practice. The present author prefers to distinguish between *primary* (recognisable to friends and family) and *subcultural* (normal antisociality within a locality) types. In the DSM system, the division of delinquency into socialised and under-socialised aggression has lost unfortunately favour and has been replaced by onset in childhood or adolescence and scoring as mild, moderate or severe. It is important that the normal (and transient) risk-taking and group effects found in adolescence are not labelled as being pathological.

Dolan (1994) lists possible causes of psychopathy as cortical immaturity (excess theta waves¹⁸¹⁶), chronic under-arousal (low autonomic arousal¹⁸¹⁷ and low electrodermal orienting¹⁸¹⁸)(Scarpa & Raine, 2002) leading to sensation-seeking¹⁸¹⁹, psychosocial deprivation, brain dysfunction¹⁸²⁰, heredity¹⁸²¹, and impulsivity¹⁸²².

¹⁸¹² James Cowles Prichard (1786-1848), English Quaker.

¹⁸¹³ Mental handicap, psychoses, epilepsy and criminality.

¹⁸¹⁴ It was suggested at the time that he was describing neurosis.

¹⁸¹⁵ Henderson suggested Joan of Arc, Napoleon and Lawrence of Arabia as examples of creative cases.

¹⁸¹⁶ But 15% of people have abnormal EEGs yet are not psychopaths.

¹⁸¹⁷ Low resting heart rate correlates with later criminality.

¹⁸¹⁸ People with antisocial personality disorder show reduced skin conductance during a social stressor.

¹⁸¹⁹ Less capacity for anxiety.

¹⁸²⁰ Pseudo-psychopathic states follow head trauma or cerebral disease involving in some but not all cases the fronto-temporal areas; association with ADHD; possible limited dominant hemisphere resources for processing verbal information.

¹⁸²¹ Some evidence from twin and adoption studies.(Christianson, 1970; Crowe, 1974; Cadoret ea, 1995) There seems to be a complex input from genes and environment in antisocial behaviour.(Silberg ea, 2007)

¹⁸²² 5-HIAA and platelet MAO may act as markers; reduced catecholamine output in response to stress; low MAO A activity may interact with adverse childhood to produce conduct disorder.(Foley ea, 2004) Antisocial personality may involve problems with not

The term psychopath should probably be confined to a personality type (dissocial, sociopathic) and not to personality disorders as a whole as was variably the case in the past. For instance, the obsessional personality and the criminal psychopath are not natural bedfellows. Psychopathy is often used professionally in a pejorative fashion.¹⁸²³

Many psychopaths learn from experience to avoid punishment in borstals and prisons yet find it difficult to stop getting into trouble despite knowledge of the probable consequences. Children with psychopathic traits may have a reduced ability to avoid frustration and this may relate to abnormal ventromedial prefrontal cortical function.(Finger ea, 2008)

Posterior temporal slowing of the EEG was found to be common in the young psychopath, although this is probably simply a reflection of immaturity rather than pathology. MRI work suggests an 11% reduction in prefrontal gray matter¹⁸²⁴. This could account for low arousal, poor fear conditioning, lack of conscience, and decision-making deficits. The amygdala is important in aversive conditioning, instrumental learning, and in responding to emotionally laden facial expressions¹⁸²⁵. MRI studies have also reported reduced amygdaloid volume (+/- surface deformations: Yang ea, 2009) in people with high levels of psychopathy¹⁸²⁶. fMRI revealed reduced amygdala response in the higher scoring (on PCL-R) group during processing of words of negative valence.¹⁸²⁷ fMRI also showed that psychopaths failed to significantly activate the limbic-prefrontal circuit¹⁸²⁸ during fear conditioning,(Birbaumer ea, 2005) leading the authors to suggest that dissociation of emotional and cognitive processing may underlie lack of anticipation of aversive events in criminal psychopaths. Disruptive youths with callous-unemotional traits fail to activate the amygdala when processing fearful expressions.(Marsh ea, 2008) The corpus callosum may be abnormal in psychopathy.(Raine ea, 2003)

Some, but not all, cases of maternal deprivation (Gao ea, 2010) and early institutionalisation show psychopathic tendencies later on. Maternal nutritional deprivation during early pregnancy in wartime Holland has been associated with antisocial personality disorder in young adult offspring.(Neugebauer ea, 1999) Schulsinger, in a 1972 Danish adoption study, found an excess of psychopathy among biological relatives of psychopathic adoptees over that of adoptive relatives. Adoptive parents may show negative parenting when the parents of their children had antisocial proclivities, possibly reacting to some inherited trait in the children.(Thapar & O'Donovan, 2002) Some people, again a minority, with an XYY sex chromosome constitution, have been associated with criminality; they also tend to be tall. However, most experts believe that the association is spurious. Novelty seeking may be associated with the type 4 dopamine receptor (but this was not so in a meta-analysis: Kluger ea, 2002) and the type 1 cannabinoid receptor. According to Fu ea, (2002) who studied male twin pairs who served in Vietnam, shared risks between antisocial personality disorder, major depression and marijuana dependence may be explicable as stemming from the antisocial personality disorder. It does appear that parenting style can moderate the

doing something despite negative consequences, and this tendency is found in animals who have a dysfunctional septo-hippocampal system. The neuronal isoforms of nitric oxide synthase may be involved in modifying various behaviours, including aggression, and deficits in neuronal signalling via nitric oxide in moderating prefrontal circuitry may be important in the origin of impulsiveness.(Reif ea, 2009)

¹⁸²³ 'He's only a PD!' Barbara Wootton (Baroness Wootton of Abinger, 1897-1988), British sociologist and criminologist, has called it a circular diagnosis: mental illness is inferred from antisocial conduct, and this term is then used to explain why he acts the way he does.

¹⁸²⁴ Cortical thinning in inferior mesial frontal cortices.(Narayan ea, 2007) Others report left posterior cingulate and right dorsal anterior cingulate gray matter concentrations as potential endophenotypes for psychopathic traits, with heritability estimates of 46% and 37% respectively.(Rijsdijk ea, 2010)

¹⁸²⁵ Criminal psychopaths differ from controls on MRI patterns when responding to various facial emotional expressions.(Deeley ea, 2006)

¹⁸²⁶ On *Hare's Psychopathy Checklist – Revised*: PCL-R. The screening version contains interpersonal/affective (superficial, grandiose, manipulative, lacking remorse, no empathy, doesn't accept responsibility) and social deviance (impulsive, poor control of behaviour, lacking goals, irresponsible, antisocial as adolescent and adult) factors. **Psychopathy is a narrower concept than antisocial personality disorder, insofar as the former may not have broken overt rules or have been caught doing so.**(Hart ea, 1995) Employing the *Hare's Psychopathy Checklist-Youth Version* (PCL-YY) and adjusting for associated conduct problems Fowler ea (2009) found that in children with ADHD total psychopathy scores were associated with maternal smoking during pregnancy, emotional dysfunction (callous, lacking affect, etc) scores were associated with birth complications, and neither was associated with family adversity.

¹⁸²⁷ For a review see Blair.(2003)

¹⁸²⁸ Amygdala, orbitofrontal cortex, insula, and anterior cingulate.

genotype of offspring, e.g. parental negativity and low warmth predicting antisocial behaviour.(Feinberg ea, 2007)

Wood and Park (2002) compared the results of a neuropsychological test battery in DSM-IV antisocial personality patients and controls. The former had impairments on dorsolateral prefrontal cortical executive function tasks of planning ability and set shifting. They were also impaired in ventromedial prefrontal cortical function.¹⁸²⁹ Boys with pure conduct disorder differ from normal boys and boys with pure ADHD on fMRI during a task measuring inhibitory control, with reduced activation in bilateral temporal-parietal regions in the former group.(Rubia ea, 2008) An fMRI study by the same group (Rubia ea, 2009) of male (aged 9-16 years) pure ADHD, pure conduct disorder, and healthy subjects found a process-related prefrontal dysfunction in both disorders: attention-related dysfunction in ventrolateral prefrontal cortex in ADHD and reward-related dysfunction in orbitofrontal cortex in conduct disorder.

Antisocial personality disorder is nearly always preceded by conduct disorder (see box) in childhood.(Hill, 2003; Simonoff ea, 2004) One study (Robins, 1978) found that only 40% of antisocial children became antisocial adults, but it was rare to find an antisocial adult who hadn't been an antisocial child. A 40 year follow-up of conduct-disordered adolescents (Colman ea, 2009) found that they were likely to leave school without any qualifications and to experience many social and health problems that had adverse effects on them, their families, and society. Children who have early feeding, washing, or dressing problems, who cry loudly, who protest at novelty, and who have tantrums may later be over-represented among the ranks of psychopathy. The earlier the onset of conduct disorder in childhood and the more pervasive it is the more likely is antisocial personality disorder to be present in adulthood.(Zoccolillo ea, 1992) Inequality of income may bear a stronger relationship to antisocial behaviour than does absolute wealth. Also, environmental deprivation is more closely linked to antisocial behaviour than is social class. A reduced resting heart rate has often been reported in studies of conduct disorder: a combination of relative bradycardia, reduced skin conductance, lesser amygdala¹⁸³⁰ response to fearful faces, and increased EEG slow wave activity suggests autonomic hypoarousal – all suggesting a reduced ability to become anxious or afraid. An fMRI study of males aged 16-21 years (Passamonti ea, 2010) whilst viewing different facial expressions found that those with conduct disorder had reduced responses in areas associated with antisocial behaviour: there was increased amygdala response to neutral but not angry faces; conduct disorder emerging in childhood was associated with relatively reduced amygdala response to sad compared to neutral faces and to sadness compared to adolescent-onset cases and control subjects. Some findings suggest a dysregulation of the hypothalamico-pituitary-adrenal axis¹⁸³¹ in conduct disorder and antisocial personality disorder.

Conduct disorder

Not an entity in itself

Various forms of unacceptable behaviour

Different levels of severity

Prevalence: 1% - 10%

M > F, but females may be catching up¹⁸³²

Reading disorder in one-third

Family (e.g. unstable home with absent/alcoholic father), socioeconomic (classically poor), and environment important in majority of cases¹⁸³³, but some come from 'good' homes; the combination of antisocial personality disorder symptoms and depression in mothers strongly increased the risk for children's antisocial behaviour in Kim-Cohen ea (2005); a broad range of externalising psychopathology in late-adolescent offspring is associated with alcohol and illicit drug dependence in their parents (Marmorstein ea, 2009).

Comorbidity includes affective disorder (espc. bipolar disorder: Arrendondo & Butler, 1994; Spencer ea, 2001), substance abuse (some evidence of role for chromosome 9q34: Stallings ea, 2005), ADHD, intellectual disability, psychoses, brain impairment

¹⁸²⁹ Go/No Go tasks and visual memory tasks.

¹⁸³⁰ Right amygdala responsivity in an fMRI study of callous, unemotional, conduct disordered boys.(Jones ea, 2009)

¹⁸³¹ E.g. low morning plasma cortisol levels.

¹⁸³² Girls' antisocial behaviour may differ from that of boys, e.g. malicious rumours are more likely to emanate from females!

¹⁸³³ Rutter (1990) holds that a positive relationship with a parental figure (at any point up to adolescence) is important in preventing conduct disorder. Childhood adversity associated with maladaptive family functioning is a strong predictor of chronic functional impairment.(McLaughlin ea, 2010)

DSM-IV diagnoses ADHD plus conduct disorder as comorbidity; ICD-10 would label the combination as hyperkinetic conduct disorder

Early (childhood v adolescent) onset (M > F) is more often associated with violence, ADHD, history of oppositional defiant disorder¹⁸³⁴, and adult antisocial personality disorder

Most cases of oppositional defiant disorder do develop conduct disorder

Caspi et al (2002) theorised that conduct grew out of early physical abuse but only if the person had a polymorphism of the MAO-A gene conferring low levels of MAO-A; those with higher levels were better protected against developing conduct disorder (see also Prom-Wormley et al, 2009)

Heritability of conduct disorder may be weaker in girls with earlier menarche (Burt et al, 2006)

Conduct disorder should be distinguished from 'subcultural' cases who 'adapt' to neglect, disadvantage, and antisocial peer group¹⁸³⁵

Management should aim at environmental change, especially education of parents¹⁸³⁶ (Scott, 2008)

'Multisystemic' therapy, an expensive intervention, utilises available systems in the child's environment (school, friends, family, etc) and tries to maximise positive interactions and outcomes

Management of psychopaths includes longterm support, counselling, insight-orientation, limit setting, and a multidisciplinary therapeutic set-up. CBT did not improve outcomes for aggressive community-living antisocial adult males (N = 52) with antisocial personality disorder. (Davidson et al, 2009) Other interventions have included therapeutic communities where psychopaths exert some controlling influence over one another, penal disposal, and drugs such as clopenthixol to reduce aggression, benperidol¹⁸³⁷ to reduce libido, disulfiram to prevent alcohol intake, and methadone maintenance programmes to keep the patient from illicit drug-seeking.

The outlook tends towards improved social behaviour with time (Paris, 2002) but there remains the possibility of domestic violence thereafter. Problems, ranging from illness to early demise, may result from accidents, drug and alcohol abuse, fighting etc. HIV infection is more likely in drug abusers if the abuser has an antisocial personality disorder. Maturation of the EEG might be a good prognostic sign. Many, if not the majority, of psychiatrists, hold that there is no legitimate treatment for personality disorder in general and psychopathic personality disorder in general.

Pseudologia phantastica (pathological lying)¹⁸³⁸

- Stories told are distinguishable from other types of lying in a number of ways
- Not entirely improbable and often built upon a matrix of truth
- Stories are enduring, unlike confabulation
- Not told for personal profit
- Non-delusional (when confronted with the facts acknowledgement of falsehoods can be elicited)

Pseudologues have an equal sex distribution¹⁸³⁹

I.Q. varies

At least 40% may have evidence of CNS damage/dysfunction

¹⁸³⁴ **Oppositional defiant disorder** (ODD) usually starts before a child is eight years old and may affect 2-16% of children. There is persistent defiance toward authority (teachers and other adults) characterised by hostility, resentment, and argumentativeness. The syndrome is more common in young boys than young girls but it affects the sexes equally by adolescence. Symptoms are more often displayed in front of people familiar to the child and may not be revealed to the clinician. A diagnosis of conduct disorder (vandalism, cruelty, larceny, etc) trumps that of ODD. Perhaps 25% of preschool ODD cases progress to conduct disorder and about 30% of conduct-disordered adolescents progress to antisocial personality disorder. Early onset, aggression, poverty, and parental drug abuse favour the development of conduct disorder. Female adolescent conduct disorder may progress to antisocial personality disorder and somatoform disorder, depression and other 'internalizing' conditions.

¹⁸³⁵ **Conduct disorder** is often divided into those with onset in childhood (boys > girls, neuropsychological impairment, prolonged course, and high risk of adult antisocial personality disorder) and those commencing in adolescence (little sex difference, no neuropsychological problems, and low risk [10%] of adult antisocial personality disorder). Social problems, especially deviant peers, are significant factors in the genesis of adolescent-onset cases, i.e. they are close to what are sometimes known as 'sub-cultural psychopaths' and are less likely to be viewed as deviant within their own neighbourhood than is the case with childhood-onset conduct disorder. The author is aware of inner urban dwellers who had no moral qualms about stealing from 'outsiders' but who were outraged if one of their peers stole from a neighbour! This may be a product of 'outsiders' being seen as 'haves' and the subculture/neighbourhood as 'have not's'.

¹⁸³⁶ **Parent education:** promote play and organise child's day, improve relationship with child, reward desired behaviour and consequences for unwanted behaviour should be calmly delivered and consistent, and give clear directions/rules. (Scott, 2008)

¹⁸³⁷ Evidence of effect is lacking and EPSEs are likely.

¹⁸³⁸ Originally described by Delbruck in 1891.

¹⁸³⁹ The inclusion of peregrination (wandering about from place to place) artificially raises male numbers.

Structural MRI suggest that excess prefrontal white matter distinguishes pathological liars from normals and antisocials (Yang ea, 2007)

Functional MRI (Fullam ea, 2009) showed enhanced activation of ventrolateral prefrontal cortex during a deception paradigm

Emotionally unstable personality disorder (ICD-10). Such people act on impulse without considering the consequences of their actions. There is affective instability, minimal planning and frequent angry outbursts, with violent and explosive behaviour. ICD-10 divides this group into:

(a) Impulsive type

Uncommonly seen in clinical practice, such people are emotionally unstable, lack impulse control, have outbursts of violence or threatening behaviour, and are particularly likely to 'blow' if criticised. Such cases tend to behave within normal limits for most of the time. They may use the fear they engender in others for exploitative purposes.

(b) Borderline type/personality disorder (BPD)

BPD¹⁸⁴⁰ does not 'border' on anything. BPD has been seen as being in danger of becoming synonymous with personality disorder in general. (Tyrer, 1999) American psychiatrists described these patients as being disruptive at interview, sarcastic, argumentative, angry, and uncooperative. Such patients blame others for their problems and are self-centred. Borderlines recall less parental care than do non-borderlines, especially from the mothers. They are lonely, lacking in emotional tone, anhedonic, and have a low stress tolerance. Depersonalisation and derealisation were commonly observed. They show a lack of discernment despite normal intelligence. Regression and transient psychosis often occur during psychotherapy – thoughtless attempts to 'probe the emotional depths' of these patients may exacerbate the situation. (Nemiah, 1999) Other features include alcohol and drug abuse, self-injury¹⁸⁴¹, parasuicide, masochism, labile mood, criminality, and binge eating. Comorbidity with somatisation disorder, panic, GAD, and major depression¹⁸⁴² is said to be common, but the link with depression has been described as weak and non-specific (Gunderson and Phillips, 1991) and the association with bipolar disorder I and II as 'modest'. (Gunderson ea, 2006) Criteria for BPD are an admixture of symptoms (state characteristics) and traits. This fact and complications¹⁸⁴³ may account for suggested relationships with schizophrenia and affective disorders. (see, e.g. Livesley, 2005; Clarkin, 2005) Stone (2005b) suggests that there is no relationship to schizophrenia and some connection to affective disorders, especially bipolar II disorder. Early-onset bipolar affective disorder may be a risk factor for BPD. (Goldberg & Garino, 2009) There may be 'brief psychotic episodes'¹⁸⁴⁴ that tend to be stress-related, reversible, transient, ego alien, and unsystematised.

Adult prevalence varies from 0.7% in Norway to 1.8% in the USA, with 70% of cases being female. (Lieb ea, 2004) However, it has been suggested that whilst clinical samples demonstrate a female excess the sex distribution may be closer to equality in community samples. (e.g. Torgersen ea, 2001) Perhaps females are more likely to look for or be referred for treatment. Patients may show some or all of the features defined in the box.

Features of borderline personality disorder¹⁸⁴⁵

¹⁸⁴⁰ The modern concept of BPD dates to Adolf Stern in 1938 ('borderline group of neuroses'), entered DSM III under the editorship of Robert Spitzer, and received its name from Gunderson and Singer in 1975. (Stone, 2005a) The term 'labile personality disorder' has been suggested by Millon. (Millon & Davis, 1996)

¹⁸⁴¹ Even though depression may deepen prior to an act of self-harm, suicidal behaviour may more accurately be predicted by unstable emotions. (Yen ea, 2004)

¹⁸⁴² Gelder ea (1996) suggest that GPs treat uncomplicated depression and refer depression 'complicated by abnormal personality traits or disorders' to psychiatrists.

¹⁸⁴³ As distinct from 'comorbidity'.

¹⁸⁴⁴ The present author's experience suggests that careful observation of the patient is required before diagnosing 'psychosis' in such cases. The term 'quasi-psychotic' is sometimes applied. Pope ea (1985) diagnosed 'factitious psychosis' in two of their cases, both of whom also had factitious neurological symptoms. The term factitious is problematic in such cases because it has been variably defined as 'subconscious' or 'simply seeking (inappropriate) medical care'. Psychosis in borderline personality disorder may be associated with drugs or mood disorder. (Zanarini ea, 1990)

¹⁸⁴⁵ Relationships are stormy and self-centred. Overcompensation for inferiority feelings is obvious. They cannot bear being alone. Davies (1987) defines this personality disorder thus: 'A diagnosis of borderline personality disorder may be made when a patient with longstanding difficulties in his relationships reports symptoms that though not clearly psychotic suggest disordered mental

Identity diffusion – no consistent sense of identity

Projective identification – unconscious attempt to force others, including therapists, to act out a particular type of behaviour

Splitting – sees others as all good or all bad, frequent shifts of allegiance; adept at getting some carers to take sides against other carers¹⁸⁴⁶

Chronic feelings of emptiness, impulsive self-mutilation, brief psychotic episodes, manipulative self-harm, very demanding in interpersonal relationships

Increased incidence of major depression

Commonly give a history of CSA – evidence suggests that this does not cause BPD but is part of a general parental neglect syndrome (e.g. Zanarini et al, 1997; Fossati et al, 1999)

There may be nothing specific about BPD that would separate it from personality disorders in general as regards being a trauma-associated spectrum disorder or PTSD variant, (Goller et al, 2003) although the PTSD-BPD relationship is still a subject of much research (e.g. Axelrod et al, 2005)

Likely to meet DSM-IV criteria for other personality disorders, especially histrionic, dependent, antisocial, passive-aggressive, and schizotypal (Links et al, 1998)

PET suggests that metabolism is abnormal in frontal areas (Goyer et al, 1994)

fMRI suggests that specific frontolimbic neural substrates are associated with emotional and behavioural dyscontrol (Silbersweig et al, 2007)

According to Benjamin, (1996) a chaotic family, traumatic abandonment, a family that does not allow autonomy or the expression of happiness but encourages misery and dependence, or one that offers nurturance only if the individual is miserable, may breed BPD. Crandell et al (2003) noted intrusively insensitive interactions between mothers with BPD¹⁸⁴⁷ and two-month-old infants. Hobson et al (2009) found that mothers with BPD usually demonstrated disrupted affective communication with their infants during a separation-reunion episode and they tended to be frightened and disoriented.

Family studies suggest that BPD is not related to schizophrenia. Because of a finding of shortened REM latency in BPD it has been suggested that BPD might be due to an underlying affective disorder. A high frequency of EEG abnormalities has been reported, including non-focal spike or sharp wave activity, and, sometimes, posterior temporal spike-wave discharges. MRI has shown reduced hippocampal volumes in female (males not tested) BPD and as yet it is unclear if this reflects early traumatic experiences.

Orbitofrontal cortex dysfunction may contribute to some core features of BPD, especially impulsivity. (Berlin et al, 2005)

Distel et al (2008) examined data (mailed self-report on BPD features) from twin samples in three countries and calculated that 42% and 58% of variation were heritable and unique environmental in origin respectively.

ICD-10 states:

Patient's self-image, aims and internal preferences (including sexual) are often unclear or disturbed

There are chronic feelings of emptiness

There is a liability to develop intense and unstable relationships with repeated emotional crises and excessive efforts to avoid abandonment

functioning'. Lynch (2008) discussed Linehan's 'biosocial' theory in relation to borderlines: emotional vulnerability (high sensitivity and reactivity and slow return to baseline), environmental invalidation (being told that one is wrong – this is associated with autonomic hyperactivity as shown by the galvanic skin response) and problems with regulating emotions interact. The person is hyperresponsive to environmental cues/triggers that lead to emotional dysregulation (Fertuck et al [2009] found that borderlines have an enhanced sensitivity to the mental states of others.). Patients feel estranged because they have no one to call on when troubled. Therapists need a 'consultation team' to call on for support because patients may dysregulate the therapist. Borderlines are better than controls at assessing facial expressions for all emotions. Treatment aims to prevent the self-cutting response and replace it with problem-solving.

Spitzer et al (1979) gave the following diagnostic criteria for BPD: abnormal self-concept, intense and chaotic relationships, excessive anger, self-injury, underachievement, unstable mood, unhappy and unsatisfied, poor tolerance for being alone, and requiring long-term support.

¹⁸⁴⁶ There may be alternating idealisation and demonising of others. This leads to brief and rocky relationships. Finally, when separation threatens, psychic decompensation follows with increasing levels of harm to the self.

¹⁸⁴⁷ N = 8; normal controls = 12.

Brief periods of inpatient care may be necessary from time to time. Outpatient care tends to extend over years. The whole gamut of psychotherapies has been advocated.(e.g. Stevenson ea, 2005) Drugs are also used although the risk of abuse is increased; some authors eschew treatment of ‘secondary’ problems like mood problems or ‘voices’, suggesting that they improve once control over impulsiveness and anger is achieved. There is some evidence that SSRIs may reduce suicidality and impulsiveness. There is some evidence that increasing age may ameliorate BPD. The suicide rate has been estimated at a low of 3% and as high as 10%. Comorbid depression is said to increase the suicide risk. In the present author’s experience, a patient may appear to be doing very well between psychotherapy sessions and suddenly kill themselves because of an event outside the therapist’s control, e.g. being jilted overnight. There is some evidence that dialectical behaviour therapy (DBT) may give positive results, especially in reducing self-mutilation. Improvement may occur with the passage of time¹⁸⁴⁸; in a 6-year follow-up study, Zanarini ea (2003) found that impulsive symptoms resolved the most quickly, cognitive and interpersonal symptoms had an intermediate outlook, and affective symptoms were the most persistent features of BPD.

McMain ea (2009) compared DBT with ‘general psychiatric management’ (psychodynamic informed therapy and APA guideline-derived symptom-targeted pharmacotherapy) in a single blind study and found them to equally efficacious. Meares (2005) also employs a psychodynamic approach for borderline patients. There are moments during treatment when sense of self is disrupted by traumatic memories. Therapist empathy with the patient and reflections help the patient to think about and gain understanding of what is happening within the self and between therapist/others and the self (*mentalisation* or *reflective function*). According to Bateman & Fonagy (2008, 2009) mentalisation therapy has long-term beneficial effects, although Choi-Kain and Gunderson (2008), who see mentalisation as excessively broad and multi-faceted, are sceptical.

Zanarini (2005a) has presented follow-up evidence suggesting that both symptomatic remission and attainment of good psychosocial functioning are common among even very disturbed cases, remarking that they ‘get well, as if they are growing up out of this disorder’. She also points out that optimism, humour, an ‘iron constitution’, and common sense are important attributes of the clinician who works with BPD cases.(Zanarini, 2005b) Gunderson ea (2006) found that a greater number of DSM-IV criteria for BPD and a history of childhood trauma predicted a poor outcome at two-year follow-up. Zanarini ea (2006) found a better prognosis at 6 years in younger cases, no history of child sexual abuse, no family history of drug abuse, no anxious cluster personality disorder, less neuroticism, and greater agreeableness.

The use of attachment theory research (insecure attachment) in family therapy in an attempt to prevent BPD is still at an early stage of development.(Byng-Hall, 2002)

NICE (2009)¹⁸⁴⁹ produced a set of guidelines for treatment and management of BPD patients. The guidelines emphasise access to services in spite of diagnoses or self-harm, ensuring active involvement by the patient in finding solutions and considering choices, options and consequences; developing a relationship that is optimistic and trusting and non-rejecting; careful management of changes in or ending of treatment, e.g. preparing patients for a change of service provider; and care in its various stages should be the responsibility of community mental health services. The guidelines suggest that medication should not be used specifically for BPD or its symptomatic or behavioural manifestations, including transient psychotic symptoms. Drugs may be used during a crisis if indicated with an eye to dependence and overdose potential. Twice weekly psychotherapy sessions are to be considered by therapists. Local services should develop specific teams to look after personality disordered patients. A crisis plan should be in place and consulted when needed: be calm and non-threatening, look at the event from the patient’s viewpoint, use open and empathic questions, validate the patient’s experiences (do not minimise their reasons), promote reflection on potential solutions, wait until you understand the problem fully before suggesting answers, consider alternatives to admission (e.g. home care), and offer appropriate follow-up at a mutually

¹⁸⁴⁸ In a 10-year follow-up study 88% of of 290 inpatients cases remitted; of these, 39.3% by the second year, another 22.3% by 4 years, an additional 21.9% by 6 years, 12.8% by 8 years, and a final 3.7% by the tenth year.(Zanarini ea, 2006)

¹⁸⁴⁹ National Institute for Clinical Excellence (NICE) in UK. Download at www.nice.org.uk/CG78. There are quick reference and the complete guidelines.

agreed time. Admission is only for situations carrying significant risk to self or others or where involuntary treatment is indicated. The aims and duration of admission should be discussed and agreed beforehand. A Cochrane systematic review and meta-analysis of RCTs (Lieb *et al.*, 2010) found that while drug treatment, especially with mood stabilisers and second-generation antipsychotics, may be useful in treating some core symptoms of BPD and associated psychopathology, it doesn't have much effect on the overall severity of BPD; SSRIs do not yet have a strong evidence base; and the authors suggest that medication be used for targeted specific symptoms.

Schizoid personality disorder. This disorder is not as closely associated with schizophrenia as suggested by Kretschmer in 1936. However, what goes under this heading changed dramatically over the years, leading McKenna (2007, p. 445) to wonder if it had not become synonymous with Asperger's syndrome!

DSM-IV divided 'schizoid' patients into

Schizoid - cold, anhedonic, solitary, insensitive, robotic, and mechanical

Schizotypal (see below)

Avoidant - hypersensitive, socially withdrawn, yet craving acceptance, passively detached

Differential diagnosis includes avoidant and schizotypal personality disorders and Asperger's syndrome. Schizoid patients have an intrinsic defect in the capacity to form social relationships. They prefer isolative hobbies: philately, gadgetry, computers, and pure math. Because these people fail to manifest the overt instability or eccentricity of schizotypal patients they are relatively uncommon in clinical populations (O'Flynn *et al.*, 2003, p. 81) and may be over-represented among the homeless. (Rouff, 2000)

Schizotypal¹⁸⁵⁰ (personality) disorder. This heterogeneous disorder¹⁸⁵¹ (Miller *et al.*, 2002) seems to be more closely related to schizophrenia (as reflected in ICD-10)¹⁸⁵² than is schizoid personality disorder. DSM-IV schizotypy is characterised by odd behaviour, thinking, perception and speech, with unusual beliefs, and ideas of reference. Such people, who often view themselves as non-conforming and creative, may drift toward fringe groups that support their odd thinking and beliefs. Therapists should take a formal stance, avoiding forays into humour.

Schizotypal disorder

Anxious, uncomfortable and inept in company¹⁸⁵³

Find it difficult to form relationships

Lack friends/confidants¹⁸⁵⁴

See themselves as different/outsidiers

Suspicious, ideas of reference

Odd beliefs, magical thinking¹⁸⁵⁵

Aware of a 'presence' that others would not experience

Hallucination-like experiences

Unusual way of speaking, digressive, vague, odd

Constricted affect

Eccentric¹⁸⁵⁶

¹⁸⁵⁰ It was once called 'borderline' (i.e. borderline schizophrenia), not to be confused with BPD.

¹⁸⁵¹ The present author agrees with McKenna (2007, p. 447) that 'the existing diagnostic criteria do not seem to capture what is being described very well'.

¹⁸⁵² Although isolated schizotypal symptoms are seldom precursors of impending onset of schizophrenia, the risk being greatest when a combination of symptoms or signs are present. (Miller *et al.*, 2002)

¹⁸⁵³ Low-dose antipsychotic cover may be helpful when a patient cannot avoid others, as when starting work in an office or commencing an educational course.

¹⁸⁵⁴ Interestingly, prolonged early maternal separation in children whose mothers reported early angry emotional behaviour was found to correlate with increased schizotypal personality disorder symptoms. (Anglin *et al.*, 2008)

¹⁸⁵⁵ E.g. they may believe in telepathy and clairvoyance.

¹⁸⁵⁶ Mannerisms; socially unconventional; odd attire; awkward in company; talk to self in public.

Schizotypal personality disorder appears to be found more often than by chance in females with fragile X syndrome.

Avoidant (anxious in ICD-10) personality disorder ('born worriers'). Such actively detached people have the capacity and desire to relate socially, but fearing humiliation and disapproval they distance themselves from others. They are shy, courteous, restrained, introverted, and timid. To complicate matters, this is what most psychoanalysts mean by 'schizoid'!

Differentiation (Millon & Davis, 2000)

Paranoid - believes he is the object of a conspiracy

Avoidant - sees himself as ridiculous (but may interpret routine questions as criticism)

Schizoid - derives little from interpersonal relationships

Avoidants - interpersonal relationships are punishing; prefers advance notice of what others expect

Avoidant cases may have been very submissive when growing up¹⁸⁵⁷, or they may have had a longterm physical illness. Separation anxiety disorder may have occurred in childhood. Therapists may be milked for constant reassurance, especially that he/she will not desert the patient. In fact, the patient may resist progress to avoid ending treatment. The therapist must not exploit or encourage submissiveness, or to reject a clingy client. There is a very high comorbidity rate between avoidant personality disorder and social phobia (Pigott & Lac, 2002) leading some authorities to suggest that they are synonymous. They may share a common genetic basis.(Reichborn ea, 2007) Persons with either disorder have similarly elevated familial risk for social phobia.(Tillfors ea, 2001) CBT may be beneficial.(Emmelkamp ea, 2006) Long term use of buspirone (withdrawn 2009) is acceptable in these patients.(Tyrer ea, 1997)

Histrionic personality disorder ('social butterfly')

Uncommon¹⁸⁵⁸

Slightly more common in females

Egocentric and often unaware of true feelings

Theatricality, attention-seeking, dramatic reactions to events, tantrums, excitability, dependency, emotional shallowness and lability, empty seductiveness, and suggestibility

Relationships rapidly formed and poorly sustained

Borderline personality traits are common (Stone, 2005b)

Males may abuse substances

Women may complain of physical symptoms with no cause found (Coid, 2003)

Narcissistic¹⁸⁵⁹ personality disorder

More common in males

Commonly encountered in forensic circles (Coid, 2003)

May be mistaken for hypomania

Not every narcissistic adolescent develops it

Explanations of its origins have varied depending on sex of patient

Female develops superficial sexuality because of perceived paternal expectations (father saw her as a beautiful doll)

Male responded to doting mother

Alternatively

- *primary group* - bred to believe they were superior to others

¹⁸⁵⁷ Psychoanalysts have suggested that avoidant people are fixed at a developmental stage where it 'was' acceptable to be very shy and fear strangers. Many people are shy right up into adolescence and it may be erroneous to regard them as having avoidant personality disorder.

¹⁸⁵⁸ Cultures differ in what is considered to be histrionic. There is considerable overlap between 'personality disorders' in real life, e.g. borderline and histrionic.

¹⁸⁵⁹ Ovid's (Publius Ovidius Naso, 43 BC-17 AD) poem has **Narcissus** in love with his reflection and then killing himself when he realises that this reflection is an illusion and not a true person. The term 'narcissism' was introduced by the English sexologist Henry Havelock Ellis (1859-1939) in 1898. Freud used the term to mean love of self or self-absorption. Psychoanalysts then used the term to describe a reaction to damaged self-esteem: 'narcissistic injury'. The term was applied to a personality type during the 1980s.

- *compensating group* - told they were failures
- *combined group* - told that they were both

Some cases do not conform to the classical arrogant picture but are, instead, outwardly humble and self-sacrificing but inwardly harbour a belief that they are better than others

Heinz Kohut (1913-1981) viewed the road to narcissism as developing via a grandiose-exhibitionistic self or mirror transference and an idealised parental imago (the object's representation out of conscious awareness) or idealising transference

Dependent personality disorder (DPD; 'passive-dependent' in DSM-I). Whilst there is little support linking orality, as suggested by Abraham, and DPD, parenting styles (e.g. discouragement of independence) may influence development of this disorder. These patients are submissive and appeasing in relationships and inhibit negative responses for fear of destroying a relationship. Whilst DPD patients may present with problems secondary to real or threatened loss of a relationship upon which the person depended, there does not seem to be a direct relationship between this personality disorder and adult separation anxiety disorder. (Manicavasagar *et al.*, 1997) A psychiatrist with such tendencies may unconsciously seek nurturance and excessive gratitude from his patient, with predictable results! Transient dependence secondary to axis I or medical disorders do not qualify for a diagnosis of DPD. Group therapy may encourage efforts at autonomy by practicing alternative coping styles in a safe setting. CBT may help through promoting assertiveness. Role-playing techniques may also be beneficial. Families must be won over so that any changes in the patient are not met with negative responses. Depression may follow failure of clingy or autonomous behaviour.

Paranoid personality disorder (PPD). One theory is that people with this personality disorder were the victims of excessive rage and humiliation in childhood. Interestingly, the incidence of PPD in the offspring of parents with schizophrenia was not increased in a study conducted by Hans *et al.* (2004) unlike the incidence of schizotypal personality disorder and, intriguingly, avoidant personality disorder. The incidence of PPD in first-degree relatives of patients with delusional disorder is increased. PPD may be more closely linked to this disorder than to schizophrenia.

Paranoid personality disorder

Self-important

Suspicious, mistrustful, sensitive¹⁸⁶⁰

Resentful, bears grudges

Jealous

Obsessive-compulsive (anankastic in ICD-10) personality disorder. Freud, in 1913, distinguished between what is now called OCD (a neurosis) and obsessive-compulsive personality disorder (OCPD). In OCD there were the symptoms of a breakdown in a person's efforts to repress impulses and thoughts. In OCPD, the antithesis of antisocial personality disorder, one had a character style reflecting successful repressions with supplementary reaction formations and sublimations. OCD patients are distressed by their symptoms (ego dystonic) and while OCPD patients may be worriers they view their symptoms as being adaptive (ego syntonic). Millon & Davis (2000) described thinking in OCPD as a 'paralysis of analysis'! Self-righteousness and a polarised view of the world are typical. There is an unwillingness to accommodate the views and methods of other people. In therapy OCPD patients talk so much that it is difficult to interject. However, once interrupted they may view the therapist as unhelpful or unprofessional. The association between OCPD and depression is sometimes said to no longer be as strong as it once was held to be, although this is open to dispute (Costa *et al.*, 2005, p. 418) and there is some evidence for a connection with bipolar disorder (Rossi *et al.*, 2001). Also, the present author is struck by how many 'house proud' depressives he has encountered. It is often stated that OCPD does not seem to increase the likelihood of developing OCD and that most OCD patients do not have OCPD, but, perhaps due to 'differences in conceptualization and diagnostic criteria' (Costa *et al.*, 2005, p. 416) and associated 'shame and secrecy', (Rothenberg, 2005) the literature is somewhat contradictory on these points (Black & Noyes,

¹⁸⁶⁰ This makes treatment and research difficult as PPD patients suspect hidden motives. An essential first step is to develop a (tentative and often brittle) trusting relationship.

1997; Samuels et al., 2000; Gabbard, 2005). The OCP style is not so devoted to his labours that he neglects his dependants, whereas the OCPD may do so; OCPD patients make difficult co-workers but they may be successful in some roles. According to Costa et al., (2005, p. 416) the most frequently comorbid personality disorders associated with OCPD are avoidant, dependent, and passive-aggressive. OCPD is commonly associated with eating disorders. (Costa et al., 2005, p. 417) OCPD is also reported to be associated with paranoid personality disorder. (Stuart et al., 1998) Treatment is often avoided, unless pressure is exerted by third parties. (Gabbard, 2005) CBT may be helpful. When psychoanalytic psychotherapy is undertaken it is important for the therapist to take an active stance and to promote a focus on (avoided) feelings and the patient's need for control rather than engage in endless intellectualisation.

Passive-aggressive (negativistic in DSM-IV-TR) personality disorder

Included in the DSM as subject for research

'Passively' resists carrying out tasks

Sullen, argumentative, unfairly critical of authority, resentful of successful others

Complaining of how unfortunate and unappreciated they perceive themselves to be

When confronted they may exhibit contrition, only to become hostile and defiant shortly thereafter

It has been suggested that such people were spoiled early on but, for various reasons, are dethroned (say by a new sibling) and treated harshly

Lay term passive-aggressive refers to sabotage in the workplace

Depressive personality disorder. Another DSM subject for research, this category is characterised by gloom and doom, low self-worth (and often a negative view of others as well), brooding, worrying, pessimism, guilt, and remorse. It may overlap aetiologically with major depressive disorder but a twin study suggests that it is a distinct entity. (Ørstavik et al., 2007) However, some practitioners consider that depressive personality disorder is synonymous with dysthymia.

Personality change

ICD-10 bases this condition on the cause or antecedent of such change. Residual schizophrenia (F20.5) is excluded. F62 is called 'enduring personality changes, *not attributable to brain damage and disease*'.

There should not have been a previous personality disorder that explains current traits. The change is aetiologically traceable to a profound, existentially extreme experience. F62.0-9 includes enduring personality change after catastrophic experience/psychiatric illness/other/and unspecified. Examples include enduring personality change following torture or concentration camp experiences.

In practice, enduring personality change may follow trauma to or organic disease of the brain¹⁸⁶¹, severe mental disorders (particularly schizophrenia), and extreme stress such as hostage taking, concentration camp experiences, or torture. PTSD may coexist.

Enduring personality change due to catastrophic experience (ICD-10)

No prior personality disorder that explains current profile

Duration of 2 years or more

Permanently feels distrustful of a world that is viewed as hostile

Always feels changed/different

Constantly feels empty/hopeless

Feels threatened/on edge all of the time with no exogenous cause

Prognosis

With a general increase in longevity more people with personality disorders may reach old age than heretofore. (Mordekar & Spence, 2008) Age has various effects on personality. We often hear of the elderly that 'he became more like himself', i.e. an exaggeration of personality traits as age advanced. According to Pankratz and Kofoed (1988), 'Abstract judgement becomes more difficult with age... This phenomenon, known as hardening of the categories, results in overgeneralization and inflexibility'. Behaviours that lead to a diagnosis of personality disorder in youth may change expression so as to no longer meet the necessary

¹⁸⁶¹ 'Personality change due to a general medical condition' as found in DSM-IV, Axis I.

criteria for such a label, so-called 'heterotypical continuity'. Rosowsky and Gurian (1991) provide the example of prescribed medication misuse replacing earlier self-mutilation in borderlines. Also, what is maladaptive in youth may prove adaptive in old age, e.g. excess dependency may help one to accept nursing home care.

Stone (1993) reviewed long-term prognosis in the personality disordered. 10-25 year follow up of BPD showed a wide range of outcomes, from clinical recovery in at least half the cases to suicide in 3-9%. Certain factors, like artistic talent, were conducive to a better outcome, while others, such as parental cruelty, were associated with a poorer outlook. Prominent psychopathic traits are a bad sign in antisocials. Schizoids and schizotypals remain isolated and marginalised. Lenzenweger et al (2004) also found considerable variability in features of personality disorder over time.

Some forensic issues

'It seems clear ...that it is impossible at present to decide whether personality disorders are mental disorders or not, and that this will remain so until there is an agreed definition of mental disorder'. (Kendell, 2002)

A prison survey in England and Wales (Singleton et al, 1998) found antisocial personality disorder in 63% of remanded males, 49% of sentenced males, and 31% of females in both groups. The controversy surrounding the best approach to psychopathy continues. (Casey & Craven, 1999; Eastman, 1999) Most murderers do not have 'severe' mental illnesses or contact with mental health services. The commonest diagnoses among convicted murderers in this part of the world are personality disorder, alcohol misuse, and drug abuse. However, without assertive follow up, mentally ill ex-prisoners are prone to lose contact with services, to re-offend and end up back in custody.

Children of criminals or psychopaths adopted by 'normals' are more likely to show antisocial behaviour than the offspring of 'normals'. (e.g. Crowe, 1974)

The stealing of young children is a rare offence. Much data comes from prison cases. Most such children are quickly recovered since there may be no attempt to conceal them. They are usually well cared for. Personality disorder (ill defined with overlap of categories) or psychosis (usually schizophrenia) are common in perpetrators. The act may satisfy an emotional need, may be used to manipulate the environment, or may be impulsive and psychotic. It may arise from a custody dispute. A man may abduct a child for sexual purposes. Baby stealing has been described in association with pseudocyesis. (D'Orban, 1982)

In a series of women who killed their children, D'Orban (1979) found that 84% had some disorder, the commonest being a disorder of personality; 16% were psychotic.

In one study the great majority of those who assaulted their wives had a personality disorder. (Hart et al, 1993)

Firesetting (arson) in young people is often associated with conduct disorder, social deprivation, failure at school and family disharmony. Most cases are boys.

If the sole goal is to become sexually aroused, then sadism¹⁸⁶² should be placed among the paraphilias. It was in DSM-III-R as a proposed personality disorder requiring further study, but it was dropped for DSM-IV. Masochistic personality disorder was not in DSM-III, was sneaked into an appendix of DSM-III-R as 'self-defeating personality'¹⁸⁶³, was dropped for DSM-IV, and isn't in ICD-10. Objections included unfairness to the female sex (who may be victimised in relationships and end up with a label¹⁸⁶⁴) and possible confusion with depression. It has been suggested that people with masochistic personality disorder become hypochondriacal manipulators when they cannot obtain love and nurturance by other routes: an abusive attachment is better than no attachment. (Berliner, 1958) Freud, in the 1920s, distinguished 'moral masochism' (a guilty sadist wishes to suffer) from 'erotogenic masochism' (sexual perversion). His thinking from viewing masochism as part of a spectrum shared with sadism to one of Thanatos (the masochist wished for self-destruction).

¹⁸⁶² Kraft-Ebing introduced the terms sadism and masochism in 1882. Cesare Borgia is sometimes cited as a classic example of the sadist. In contrast to Freud, Horney, in the 1940s, believed that sadism wasn't necessarily sexual in origin - that is that personality-based attitudes were bound to manifest themselves at some stage through sexual activity. She felt that the central feature was a deep need to triumph vindictively.

¹⁸⁶³ What personality disorder isn't?

¹⁸⁶⁴ The objection is that the label implies that women 'were asking for it', i.e. the abuse!

Management principles

One can only help people to function better. They cannot be changed into a different person. Progress, if any, will be slow. Be clear about the aims of treatment. The aim should be change real life behaviour rather than simply look for change in the treatment setting. Anything treatable, such as depression, should be treated. Use techniques to modify the environment. It may be better to see patients briefly and relatively infrequently. Although rotation systems make it difficult, as far as possible the one therapist should continue to see the patient. A wide variety of approaches have been used, e.g. group and individual psychotherapies¹⁸⁶⁵, behavioural treatments (social skills training, CBT), and various drugs (antipsychotics, lithium, antidepressants, anticonvulsants, antiandrogens, disulfiram etc). Millon and Davis (2000) consider the psychotherapies just as good and just as bad as one another when applied to the personality disorders. Efficacy should be subject to ongoing scrutiny and spurious 'cures' should be studied critically. Treatment needs to be individually tailored. Development of a therapeutic alliance and acknowledgement of vulnerability to manipulation by therapists are important ingredients of any therapeutic approach. Overdose of drugs is common. The evidence-base for many drug-based 'treatments' for personality disorder is flimsy.

The *Dangerous People with Severe Personality Disorder Bill* was introduced in 2000 by the British Labour government with the aim of removing people who might commit future crimes from society. Dangerous and severe personality disorder (DSPD) involved increased risk of a personal with a significant personality disorder (and *because* of personality disorder) offending against others within 5 years leading to serious physical or psychological harm. The RCPsych came out against this, pointing out the difficulties involved in accurate prognostication. Anyway, 6 people would have to be detained to prevent 1 person acting violently. Certain prisons and special hospitals are assigned the role of detaining such individuals.

Pathological gambling

'Impulse control disorders not elsewhere classified' (DSM-IV-TR) are defined as failure to resist a drive to perform an act that is harmful to the practitioner or others, with or without conscious resistance or planning. The disorders involved are intermittent explosive disorder¹⁸⁶⁶ (aggression, assault), kleptomania (stealing¹⁸⁶⁷), pathological (compulsive) gambling (PG), pyromania¹⁸⁶⁸ (pathological fire-setting), and trichotillomania (hair-pulling). ICD-10 is very similar on this subject, using the umbrella term 'habit and impulse disorders' (F63). There is likely to be a genetic element in abnormal gambling in both sexes. (Slutske et al, 2010)

Tension or arousal increases before the event. There is a feeling of pleasure, gratification, or release at the time of the act, and the act is consonant with the immediate conscious wish of the person, i.e. it is ego-syntonic. Following the act there may or may not be feelings of regret, self-reproach, or guilt. The prevalence of PG in Britain has been estimated as 2-40/1,000 of the population. About 68% of the US adult population have gambled legally during the past year. (Lynch et al, 2004) It is more common in men,

¹⁸⁶⁵ *Mentalisation* (Bateman & Fonagy, 2004; Meares, 2005) tries to assist people to understand their reactions to others and the reactions of other people to their behaviour. Beliefs, feelings and desires are examined for this purpose. *Nidotherapy* (changing the person's environment rather than trying to change the person) and *transference-focused therapy* (dysfunctional relationships are examined within the transference and the patient is taught to reflect) are some other approaches.

¹⁸⁶⁶ DSM-IV-TR criteria for **intermittent explosive disorder** (IED) include several discrete episodes wherein the person fails to control aggressive impulses that lead to (verbal or physical) assault or property damage; aggression is grossly disproportionate to any precipitant ('provocation' is usually from a known person); and there is no other explanation for these episodes. Comorbidity with anxiety, mood, eating, substance, other impulse control, and personality disorders (especially borderline and antisocial) is common. However, IED may antedate many of these disorders. Whilst IED is not commonly diagnosed some authorities insist that it is common, although high comorbidity levels may cloud the issue.

¹⁸⁶⁷ **Kleptomania** refers to compulsive stealing with increased tension before the act that is released by the act; unwanted goods are returned or thrown away. Mullen and Sullivan (2007, p. 492) are sceptical about this being a real disorder. The lifetime prevalence of shoplifting in the US is 11.3%. It is associated with illegal money making, scams aimed at extracting money from others, and disorders involving poor impulse control such as antisocial personality disorder, drug abuse, pathological gambling, and bipolar disorder. (Blanco et al, 2008)

¹⁸⁶⁸ **Pyromania: *Monomanie incendiaire*** was described by a French psychiatrist, Charles Chretien Henry Marc (1771-1841), in 1833 and this was translated in English as pyromania. These rare people, males more than females, set fires deliberately. It cannot be explained by another disorder, impaired judgement (e.g. dementia), ideology, revenge, or criminality. Pyromaniacs are fascinated by fire, are fire-watchers, and, despite often not caring about the consequences of fires, may volunteer to help put out fires. Insight is poor, alcoholism is common, and patients often will not accept responsibility for their actions. Comorbid diagnoses include substance use disorder, ADHD, mood disorders, and pathological gambling.

prisoners, and the fathers of those with PG: modelling and identification are probably operative, although there may be some genetic input. Women may start gambling later than men, but there seems to be no significant difference between the sexes in terms of the age at presentation for treatment. Gambling increased significantly in the UK after the 1994 introduction of a national lottery, especially among those who could least afford it. Pathological gambling was increased in those living within 50 miles of a US casino.(Gould & Sanders, 2008, p. 310) Gambling is a more socially accepted outlet in some areas of society than in others. Women tend to gamble at different activities to men, e.g. bingo versus poker. Internet gambling is a novel problem.(Dineen, 2002) Only a minority of gambling is clinically pathological. Normal gambling is neither uncontrolled nor irresistible. It is abnormal if the gambler or his family view it as excessive; it is the sole relief from tension; the practitioner is preoccupied with it; there is loss of control over the amount gambled; and, if any important sphere of life (in gambler or dependants) is adversely affected. Viewed thus, it seems closely allied to alcoholism. Indeed, people with PG are at increased risk for alcoholism and other substance dependence.(Scherrer ea, 2005; Slutske ea, 2005) Adolescent-onset gambling may be particularly associated with present or later substance use disorders.(Lynch ea, 2004) Interruption in gambling leads to restlessness, irritability, and physical (e.g. alimentary) symptoms. Low mood and self-harm may follow depletion of family funds. Gambling offers a dissociative high that permits escape from mundane concerns. Pathological gambling might start when a (perhaps psychologically vulnerable) person observes others gambling and be maintained by variable ratio reinforcement scheduling. Addictive or impulsive behaviour in general may involve increased dopamine and noradrenaline activity and a reduction in serotonin¹⁸⁶⁹. Dopaminergic drugs (e.g. pramipexole) for Parkinson's disease and deep brain stimulation may trigger gambling activity¹⁸⁷⁰ that may respond, among other things,(Wong & Steiger, 2007) to a reduction in the dose of the offending agent or to risperidone.(Dineen, 2002)

Moran's (1975) classification of gamblers

Symptomatic - secondary to other psychiatric problems, especially depression – there is evidence for overlapping genetic factors for gambling and depression (Potenza ea, 2005)

Psychopathic - one part of an antisocial profile

Neurotic - secondary to stress, interpersonal or emotional difficulties

Impulsive - loss of control once a binge starts

Management ideally involves a full assessment of all aspects of the case by a multidisciplinary team. The spouse should be involved early. Discussion, advice, and treatment of any treatable disorder follow. Family support and/or therapy may be required. Psychotherapy (CBT) and a behavioural programme may be indicated. Desensitisation in imagination appears to be beneficial. The relaxed patient imagines a hierarchy of situations leading to gambling and then imagines leaving the scene without gambling. Controlled gambling is sometimes offered as an alternative strategy to abstinence, although, as with alcoholism, it is by no means certain how to predict who is likely to benefit. Motivational interviewing may help some people to quit. Combined imaginal desensitisation plus motivational interviewing may be successful, including for those who fail to respond to Gamblers Anonymous (GA).(Grant ea, 2009) SSRIs, naltrexone, and nalmefene (25 mg/day, an opioid antagonist: Grant ea, 2006) are other suggested methods of treatment. Gambling in people with 'bipolar spectrum disorders'¹⁸⁷¹ may be reduced with lithium (Hollander ea, 2005) or the anticonvulsants. There are many methodological problems to be considered in evaluating such research, particularly the small numbers involved.

GA¹⁸⁷² offers long-term support. Like Alcoholics Anonymous (AA), GA teaches an illness model and the necessity for abstinence; like AA, it employs public confession, peer pressure, and utilises reformed gamblers to help novices. GAM-ANON is for the relatives and friends of gamblers.

¹⁸⁶⁹ 5-HT is involved in initiating behaviour and behavioural disinhibition. Noradrenaline is important in being prepared for stimulation whereas dopamine is concerned with reward and reinforcement.

¹⁸⁷⁰ Pathological gambling in Parkinson's disease has a prevalence of 3.4%, rising to 7.2% in patients taking dopamine agonists.

Hypersexuality may also occur.

¹⁸⁷¹ I.e. subclinical or subthreshold cases.

¹⁸⁷² Founded: Los Angeles, 1957.

Ultimately, pathological gamblers must accept responsibility for debts. They should not have credit cards and it may be better if a responsible other handles their finances. Prognosis is often seen as poor, even with GA involvement, and there is a very high dropout rate from GA. Nevertheless, GA is a relatively strong force for change. Many give up gambling without any formal treatment. (Slutske, 2006) Prevention involves an unpopular strategy: reducing gambling outlets.

Eating disorders

Brian O'Shea

'We each day dig our graves with our teeth'. Samuel Smiles (1812-1904), 1880.

It appears most likely that eating disorders are triggered by socio-cultural and interpersonal stressors and may then be sustained by neural networks including those subserving homeostasis (brain stem/hypothalamus), drive (mesolimbic cortex/striatum), and self regulation (top-down control that views appetite in terms of the wider context of goals, values, and meaning). (Treasure ea, 2010) Individual symptoms, such as purging, are far more common than the disorders themselves, and there is a strong argument for a spectrum viewpoint rather than a collection of discrete conditions. Overlap syndromes and subtype changes over time in individual patients are common. (Milos ea, 2005) Patton ea (2008) found partial eating disorder syndromes (at least 2 DSM-IV criteria for anorexia or bulimia nervosa) in 9.4% of 15-to-17 year-old females and 1.4% of males in the community; few progressed to full syndromes but depressive and anxiety symptoms, substance abuse, and retention of low weight into the mid-20s were common. Many cases of anorexia nervosa graduate to bulimia nervosa, whereas movement in the opposite direction is less common. (Eddy ea, 2008) The DSM-IV diagnosis 'eating disorder not otherwise specified' is applied to almost one-half of eating disorder patients seen at tertiary care levels. (APA, 2002, p. 741; Palmer, 2004) ICD-10 (F50) recognises typical and atypical forms of bulimia nervosa and anorexia nervosa, overeating or vomiting associated with 'other psychological difficulties', and the usual ragbag categories ('other' and 'unspecified'¹⁸⁷³). Eating disorders (threshold and below) are not uncommon in adolescent females who have type I diabetes mellitus, and these patients are prone to omitting insulin in the hope of losing weight. (Jones ea, 2000) Lower birth weight and poorer weight gain in early childhood may augur negatively for psychological outcomes in both adolescence and adulthood. (Cheung ea, 2002)

Feeding disorder of infancy or early childhood

DSM-IV-TR diagnostic criteria for this disorder describe persistently inadequate food intake with resultant weight loss or failure to put on weight. There is no detectable medical or other psychiatric (e.g. rumination) explanation. Food is readily available. Onset is before age 6 years¹⁸⁷⁴. The child gags, does not open its mouth, or may eat excessively slowly. Older children may demonstrate interpersonal problems, developmental delay, mood and behaviour difficulties, strange food choices, or eat in odd ways. Foraging for food may be noted. Various explanations have been proffered: homeostatic dysregulation (autonomic instability), problems of attachment¹⁸⁷⁵, painful oral medical procedures, child abuse, or maternal/family psychopathology. Outcome ranges from full spontaneous recovery to death. Treatment approaches may include behavioural, cognitive and educational elements.

Psychological (psychosocial/deprivation) dwarfism (psychological/psychosocial/maternal deprivation, feeding disorder of poor care giver-infant reciprocity)
Described by Powell and others in 1967

¹⁸⁷³ EDNOS (atypical eating disorders) or 'eating disorder not otherwise specified' includes BED or binge eating disorder. EDNOS is the most common eating disorder diagnosis. (Shafran ea, 2008, p. 629)

¹⁸⁷⁴ Another classification is: **non-organic failure to thrive** if the condition commences before the third birthday, and, when it starts later, **deprivation dwarfism** or **psychosocial short stature syndrome**. Not all cases of non-organic failure to thrive become psychosocial dwarfs.

¹⁸⁷⁵ E.g. carer does not provide adequate emotional nurturance or a power struggle.

Can be due to pica¹⁸⁷⁶ or inadequate nourishment
 Low growth hormone levels
 Child is of short stature
 Unusual eating habits are common
 Lack of engagement with care giver during feeding, e.g. no babbling
 Retarded speech development
 Temper tantrums may be a problem
 Tend to come from disturbed families
 Domestic physical abuse is not uncommon
 Separation from family is followed by normalisation of pituitary function

Hyperphagic short stature syndrome (Skuse ea, 1996)

Aberrant, bizarre behaviours
 Adverse home environment
 Linear growth failure
 Simulation of hypopituitarism
 Clears up when the child is removed from the home environment
 Similar reports date to 1960s

Kaspar Hauser syndrome

Sobriquet covering psychosocial dwarfism, affect hunger, retarded growth, intellectual deficits etc (Money, 1992)

Kreigsneugeborene ('war infants': Lawrence, 2006, p. 263)

German infants experiencing starvation during WWI
 Underdeveloped
 Restless
 Automatic grasping

Prader-Willi syndrome (Holland ea, 2003)

1:28,000 births and 1:52,000 of population
 Absent of paternal genes at 15q – usually part of the chromosome but less often both chromosome 15s are of maternal origin – the latter, called maternal disomy, is associated with greater later risk of psychosis
 Main psychiatric disorder is atypical affective disorder +/- psychotic features, possibly related to maternal uniparental disomy (Soni ea, 2008)
 Hypotonic neonate, delayed milestones, short stature, small hands/feet, dysmorphic facies, hypogonadism (with risk of osteoporosis)
 Tantrums, OCD, stubborn/possessive, skin-picking
 Increased pain threshold and reduced likelihood of vomiting and unusual temperature regulation may lead to missed physical illness
 Hyperphagia, which may be fatal

WAGR syndrome

1:500,000-1,000,000 people
Wilm's tumour, aniridia, genitourinary problems, and mental retardation
 Deletions on chromosome 11p3
 Some cases have hyperphagia and obesity - BDNF haploinsufficiency is associated with low serum BDNF and childhood-onset obesity (Han ea, 2008)

The use of enteral feeding methods (NG tube, etc) in infants may increase resistance to taking food by mouth. It should be employed sparingly and an effort should be made to continue oral feeding.(Olson ea, 2008, p. 758)

¹⁸⁷⁶ Can be bizarre, e.g. eating garbage or drinking toilet water.

Rumination is usually a disorder of infancy (especially when alone) and the intellectually disabled (in whom it is more likely to persist), although it can occur in older children and adolescents in the absence of co-morbidity. Physical problems should be ruled out. The child voluntarily regurgitates its food into the mouth, as if chewing the cud. The food is then spat out or re-chewed and swallowed. The practice is most often enjoyable. Typical cases commence between 3 and 12 months of age and dies out by 36 months. Aetiological theories include self-pleasing¹⁸⁷⁷ and a method of catching the attention of caregivers. Weight loss, malnutrition, dehydration, aspiration, and even death may follow. Reactive parental distress may interfere with rearing. Diaphragmatic breathing should be encouraged as it disrupts ruminative behaviour. Putting a drop of lemon juice on the tongue each time the child regurgitates may reduce the incidence of this behaviour if the practice is maintained for long enough. Behavioural methods of treatment are popular, e.g. giving more attention or, in the case of very dangerous rumination in the intellectually disabled, mild shocks used in a contingent fashion. The domestic environment and child-caregiver interaction may need to be addressed. Psychopathology in the caregiver should be treated.

Pica: The ingestion of non-foods (inedibles) such as dirt, clips, cigarette butts, or paint carries a risk of poisoning, such as plumbism.(O'Shea, 2000) The child may be experiencing emotional stress. Intellectually disabled subjects are at high risk. Pica is common in children with sickle cell disease.(Ivascu ea, 2001) Pica can occur in pregnant women¹⁸⁷⁸. Pica is often associated with other behaviour problems and there is an excess of associated cerebral damage or intellectual disability. The latter patients include the most persistent cases of pica. Prevention is critical. In some developing countries soil (geophagia) may be eaten to curb diarrhoea or quench hunger. Some inner city folk who cannot get the type of soil they were used to in the countryside may eat laundry starch. Complications of pica include lead poisoning (e.g. paint) and parasitic infestation (faeces, soil). Intervention in pica is largely behavioural, e.g. limiting availability and response prevention.

Child stunting (linear growth failure secondary to pre- and post-natal poor nutrition and infection) in Indonesia is reduced by better parental education. Such parents are more likely to practice protective measures such as giving vitamin A, completing childhood immunisations, provide a cleaner environment, and use iodised salt.(Semba ea, 2008) Maternal education could mediate such protective practices via greater decision making power, higher IQ, and lower maternal depression levels, all interacting in a complex manner.(Wachs, 2008)

Food fads

These are only important if they become persistent and marked. The excesses of TV ('junk') meals eaten today may account for at least part of the disturbing increase in the incidence of obesity among teenagers.(Jain, 2004)

Obesity

'The only medical benefit of obesity is seen in osteoporosis, where bone density increases in response to increased mechanical stress'.(Hanlon ea, 2006, p. 111)

Obesity has always stalked humanity.(Haslam & Rigby, 2010)¹⁸⁷⁹ Obesity is, however, increasing at an alarming rate throughout the developed and developing world,(Crawford, 2002; Jain, 2004) including in children (Kipping ea, 2008), despite some hopes of a reversing trend.(Lobstein, 2008) Obesity is overrepresented in people with mental disorders in some but not all studies and, in a study of London civil servants, this association becomes stronger with age.(Kivimäki ea, 2009) Obese children and adolescents are at increased risk as adults for coronary heart disease¹⁸⁸⁰.(Baker ea, 2007; Bibbins-Domingo ea, 2007; Ludwig, 2007) Estimated US health costs for obesity are enormous: direct costs amounting to 7% of health care budget in 1995 (\$50 bn) and rising to \$98 bn (plus \$241 bn indirect costs) in 1997.(Wirshing & Meyer, 2003, p. 36) Estimated US health costs for obesity (2 out of 3 adults) and being overweight (1 in 5 children) in 2009 was \$147 bn.(Anonymous, 2009) WHO estimated (Groves, 2006) that obesity in Europe accounted

¹⁸⁷⁷ Other associated self-soothing behaviours include body rocking, head banging, and thumb sucking.

¹⁸⁷⁸ Some pregnant women eat ice and become anaemic. Both the anaemia and the ice consumption may respond to iron.

¹⁸⁷⁹ Obesity among patients in psychiatric institutions has been noted for many years, e.g. Charles Dickens noted recorded this phenomenon among patients resident for a matter of weeks during the 1850s.(Arnold, 2008, p. 213)

¹⁸⁸⁰ Other complications of childhood obesity: precocious puberty, low self esteem/social isolation/educational problems/low exercise tolerance, eating disorders, anxiety/depression, asthma, sleep apnoea, constipation, glomerulosclerosis, back pain/flat feet, fracture of forearm, Blount's disease (tibia vara – lower leg angles inwards), slipped capital femoral epiphysis, GORD, steatohepatitis, cholelithiasis, hypertension/coagulation problems/endothelial and inflammatory problems/dyslipidemia/type II diabetes.

for 6% of direct health costs and over 12% in indirect costs (foreshortened lives, decreased production, and reduced earnings). Haslam and James (2005) estimated that 30,000 people died annually in the UK (one-tenth of the US figure) from obesity.

Quételet's¹⁸⁸¹ body-mass index (BMI) = weight in Kg/height in metres² (Kg/M²)
 Grades 0, 1, 2, and 3 obesity corresponds to BMI values 20-25, 25-30, 30-40 ('clinically relevant'), and 40+ ('crippling') respectively
 The body's energy expenditure is made up of BMR (73%), thermogenesis (15%) and physical activity (12%)
 BMI inappropriate measure in childhood/early adolescence (needs to be corrected for age followed by reference to weight for height for age tables) and athletes (increased muscle mass yields high BMI no due to increased adiposity)

The epidemiology and prognosis of the eating disorders are summarised below in table form. Parents are poor at recognising obesity in themselves¹⁸⁸² (Morgan ea, 2008) and in their children.(Jeffery ea, 2005) Obese people often blame their 'glands' or 'genes'. Obese people have increased concentrations of insulin and cortisol in their serum and decreased plasma growth hormone levels, but these are probably due to being obese since they normalise when weight is lost. Wahrenberg ea (2005) found that a waist circumference of less than 100 cm excludes insulin resistance in both sexes. Montgomery and Ekblom (2002) reported an increased risk for diabetes and obesity among the offspring of women who smoked during pregnancy. Hypothyroidism, hypogonadism, hypopituitarism, and Cushing's syndrome are associated with obesity among other things. Maternal obesity is one risk factor for stillbirth.(Smith & Fretts, 2007) Clifford (2003) reviewed the literature on the connection between having been breast-fed (or not) and later obesity (or its absence) and found the evidence to be inconclusive. Obese children and adolescents appear to have relatively short sleep time, a core aspect being reduced REM sleep.(Liu ea, 2008) Also, children with poor hand control and coordination and who are clumsy may be more likely to be obese as adults.(Osika & Montgomery, 2008)

Multiple peptides contribute to increase or decrease food intake at the level of the hypothalamus. The characterization of an obesity gene (ob) on chromosome 6 in mice (and its human homologue) was reported in 1994. It was hypothesised that the ob gene on chromosome 7 produced an ob protein (this turned out to be leptin¹⁸⁸³) that acted on brain ob receptors leading to satiety and a reduction in food intake. It was later suggested that overexpression of the ob gene (and an increase in its mRNA) in adipose tissue might account for obesity in humans.

In fact, in excess of one hundred genes have been implicated in the determination of body weight. These act mainly through the brainstem and hypothalamus and influence food intake and tendency to exertion. For example, the melanocortin 4 receptor (MC4R) conveys food intake-suppressing and energy expenditure-increasing signals from the hypothalamus. SNPs in the fat mass and obesity-associated gene (FTO) influence adiposity, energy intake, and preference for foods of high caloric density (Leibel, 2008); FTO is highly expressed in brain and appears to influence brain volume.(Hoa ea, 2010) An extension of the Framingham Heart Study (Debette ea, 2010) suggests that as BMI/visceral fat rises brain volume decreases in healthy middle-aged people. Lindgren ea (2009) performed a meta-analysis of 16 genome-wide association studies and identified two loci strongly associated with measures of central adiposity that mapped near TFAP2B and MSRA, whilst a third locus (near LYPLAL1) was associated with waist-hip ratio in women only.

Leptin ('ob protein'; Gk: *leptos*, thin) levels are chronically elevated in obese humans. Apart from the few people with inherited leptin deficiency, therapeutic leptin use failed to work. According to Watts (2007) cells produce leptin to prevent too much weight loss during lean times rather than to prevent obesity!

Leptin

¹⁸⁸¹ Lambert Adolphe Jacques Quételet (1796-1874), Belgian astronomer, mathematician, statistician, and sociologist.

¹⁸⁸² E.g. self-reported BMI in Ireland in 2007 was lower than measured BMI for overweight and obese men and women.(Morgan ea, 2008)

¹⁸⁸³ **Leptin**, found in murine and human plasma, is a 16-kd protein. When injected into the peritoneum it causes a reduction in feeding and an increase in energy output. Lack of the ob gene causes obesity whereas leptin decreases body fat. (see box)

An interleukin 6 cytokine and a product of fat cells
 Reduces food intake, decreases insulin levels, and lowers blood glucose concentration in the ob/ob (obese) mouse but not in the db/db (mutant diabetic) mouse
 Leptin might exert its central effects via neuropeptide Y (NPY), a very powerful orexigenic¹⁸⁸⁴ peptide. Leptin inhibits NPY and agouti gene related peptide (Agrp) expression
 Central administration of NPY induces feeding and rest¹⁸⁸⁵
 A certain threshold of weight or body fat may be required for normal pulsatility of gonadotrophin-releasing hormone, but the underlying mechanism is unknown
 Leptin may help regulate reproductive function and signal the hypothalamus when fat mass is reduced. Leptin levels are reduced in underweight anorexia nervosa patients but these normalise with restoration of weight (Halmi, 2003, p. 1003)
 Alpha-melanocyte stimulating hormone¹⁸⁸⁶ reduces appetite and leptin stimulates α -MSH production
 Mouse and human melanocortin receptor gene mutations lead to hyperphagia and obesity; α -MSH is an agonist at this receptor
 A fall in food intake \rightarrow decreased leptin \rightarrow increased NPY/Agrp + reduced POMC activity \rightarrow inhibition of GABA interneurons \rightarrow increased appetite (Connan, 2002)
 A deficiency of leptin acts as a defence against starvation (this seems to be its primary role)

YY₃₋₃₆ (also called PYY₃₋₃₆), a peptide hormone, is produced by the intestine after a meal. It inhibits neuropeptide Y (a powerful appetite stimulant) in the arcuate nucleus of the hypothalamus¹⁸⁸⁷. Injections of PYY₃₋₃₆ in humans leads to a reduced consumption of calories over the following 24 hours (Batterham *et al.*, 2003) and a single intraperitoneal injection of the same substance can reduce food intake for up to a week in rats. Korner and Leibel (2003) warn about extrapolating from single injects: the development of antibodies or tachyphylaxis through receptor downregulation may limit the efficacy of prolonged PYY administration.

Bilateral ablation of the lateral hypothalamus¹⁸⁸⁸ causes anorexia and loss of weight, whilst destruction of the paraventricular nucleus leads to hyperphagia and obesity. Galanin is an orexigenic peptide that probably acts at the level of the paraventricular nucleus. The latter nucleus also contains anorexigenic peptides such as TRH and CRH.

Cocaine- and amphetamine-regulated transcript (CART) may be part of the anorexigenic system of the arcuate nucleus. CART neurones are stimulated by leptin.

Peripheral produced CCK suppresses eating by acting on the vagus nerve and activating hind brain circuits. (Konsman & Dantzer, 2002)

Orexins/hypocretins¹⁸⁸⁹, discovered in 1998, are neuropeptides produced in the lateral hypothalamus ('feeding centre'). The latter sends projections throughout the CNS. Orexins stimulate feeding and may have a role in narcolepsy.

In animals, cannabinoid-1 receptor (CB1) blockade produces a lean phenotype that protects against obesity related to diet and its associated dyslipidaemia. There was evidence in humans that the selective CB1 blocker rimonabant¹⁸⁹⁰, combined with a low calorie diet, promotes decrease of bodyweight and waist circumference and improvement in cardiovascular factors. (Van Gaal *et al.*, 2005)

¹⁸⁸⁴ Increases appetite, i.e. opposite to anorexigenic.

¹⁸⁸⁵ It needs to be given repeatedly to cause significant gain in weight.

¹⁸⁸⁶ α -MSH – derived from POMC.

¹⁸⁸⁷ Destruction of the arcuate nucleus leads to hyperphagia and obesity: if the arcuate nucleus is destroyed there is no response to leptin.

¹⁸⁸⁸ A major site of expression of the orexigenic melanin concentrating hormone.

¹⁸⁸⁹ Gk. *orexis*, appetite.

¹⁸⁹⁰ **Rimonabant (Acomplia) had its European marketing authorisation suspended by the European Medicines Agency in 2008**

because of associated depression. It is a selective CB1 cannabinoid receptor blocker that is said to reduce weight and weight circumference, improve glycaemic control (HbA 1c), increase HDL-c, and reduce triglycerides (Anonymous [2007] was critical of the degree of such changes). It was indicated as an adjunct to diet and exercise for obesity or overweight adult (> 18 years) patients with associated risk factors, e.g. type II diabetes or dyslipidaemia. (Scheen *et al.*, 2006) Caution was required in cases of moderate liver impairment or epilepsy, and it was not recommended in the presence of severe hepatic or renal impairment. It should be avoided in uncontrolled serious psychiatric disorder and it was not recommended for people on antidepressants. In 2007 FDA has warned of an increased risk of depression and suicide with rimonabant and, despite depressed mood being an exclusion criterion in trials, Christensen *et al.* (2007) found in their meta-analysis that 20 mg/day rimonabant increases the risk of depression and anxiety (The endogenous cannabinoid anandamide has an antidepressant-like effect in rodents, an effect blocked by rimonabant: see Mitchell & Morris, 2007). Rimonabant contains lactose. CYP 3A4 inhibitors like ketoconazole increase plasma rimonabant levels, whereas inducers of CYP 3A4 (St John's Wort, carbamazepine, etc.) reduce plasma rimonabant levels. It was not recommended during pregnancy and is contraindicated during breastfeeding.

Peroxisome-proliferator-activated receptor (PPAR, especially PPAR δ) activates metabolism and appears to decide if body cells store or burn fat. Mice whose gene for PPAR δ remains in the 'on' position put on less weight than other mice.(see Wang ea, 2003; Watts, 2007)

The psychological routes to obesity include responses to depression¹⁸⁹¹, anxiety, boredom or other unwelcome affects. Social or cultural factors may moderate or mediate the association between obesity and mood disorder.(Simon ea, 2006) According to the Framingham Heart Study, a person is 57%, 40% and 37% more likely to become obese if his/her friend, adult sibling or spouse becomes obese respectively¹⁸⁹².(Christakis & Fowler, 2007) Nocturnal eating, nibbling between meals, and eating the wrong food¹⁸⁹³ and other bad habits play a role, as does alcohol. Unresolved dynamic-neurotic factors and learning theory are generally considered to be operative. Severely obese people may have low self-esteem. Volkow and O'Brien (2007) point out that DSM-IV does not recognise obesity as a psychiatric disorder and offer a list of behaviours for this 'food addiction'.

Suggested psychiatric criteria for obesity (Volkow & O'Brien, 2007)

Need to eat more to be satisfied (tolerance)
Dieting-associated distress/dysphoria
Eats more than intended
Always wants food and can't curtail amount consumed
Avoid activities because of fear of rejection due to obesity
Overeats despite knowing of ill effects and psychological sequelae

Clouston, in 1881, wrote that fattening a patient would improve the mental state. In the 1980s it was noted that haloperidol seemed to put on less weight than other neuroleptics, a finding attributed to more selective DA blockade. Around the same time, it was suggested that perhaps 5-HT receptor blockade in the hypothalamic satiety centre¹⁸⁹⁴ greatly increased appetite for food. The TCAs, MAOIs and lithium tend to cause weight gain. Direct intra-hypothalamic injection of chlorpromazine in animals leads to an increase in food intake.

Morbid obesity provides an increased reservoir for psychotropic drugs with persistence of the effects of such drugs.(Janicak ea, 1997)

Apart from the well known physical complications of obesity¹⁸⁹⁵ there is evidence that obesity is associated with in the risk for almost all cancers,(Calle ea, 2003, 2007; Renehan ea, 2008) including colon, rectal, and pancreatic cancer in males and endometrial¹⁸⁹⁶, non-Hodgkin's lymphomas, and ovarian¹⁸⁹⁷ in females¹⁸⁹⁸. Animals that have their food intake restricted have less cancer than do animals allowed to eat as much as they wish. Adami and Tichopoulos (2003) felt that the risk of cancer from obesity is small relative to the effects of smoking, a view not shared by Haslam and James¹⁸⁹⁹.(2005) Possible ways in which obesity

Very common – nausea, upper respiratory tract infection

Common – gastroenteritis, depression, anxiety/irritability/nervousness, sleep disorders, memory loss, hypoaesthesia, sciatica, hot flushes, diarrhoea, vomiting, itching, sweating, tendonitis, muscle cramps/spasms, asthenia/fatigue, influenza, falls/bruises/joint sprains

Uncommon – panic, anger, 'dysphoria', 'emotional problems', lethargy, hiccups, night sweats

Rare – hallucinations

¹⁸⁹¹ The relationship between obesity and depression may be reciprocal with depression leading to obesity and obesity causing depression.(Luppino ea, 2010)

¹⁸⁹² These effects were not seen among immediate neighbours.

¹⁸⁹³ E.g. 'fast-foods': Pereira ea.(2005)

¹⁸⁹⁴ A fall in glucose activates the lateral hypothalamus (LH) and activity within the LH gives rise to hunger. Glucose activates the ventromedial hypothalamus (VMH) and activation of the VMH causes a feeling of satiety and inhibition of further feeding. I.e. lateral hypothalamus = **hunger centre** and ventromedial hypothalamus = **satiety centre**.

¹⁸⁹⁵ Cardiovascular (Rich-Edwards ea, 2005), phlebitis, hypertension, respiratory, gall bladder disease, pancreatitis, diabetes, (non-alcoholic) fatty liver (disease), dyslipidaemia, cataracts, joint problems, skin disorders, gynaecological problems, gout, etc.

¹⁸⁹⁶ Endometrial hyperplasia occurs in the obese because there is increased aromatization of androgen to oestrogen in fat.

¹⁸⁹⁷ A large US study of women aged 50-71 found that obesity was associated with an almost 80% higher risk of ovarian cancer – the increased risk only applied to women who had never used menopausal hormone therapy and women with a negative family history for this malignancy.(Leitzmann ea, 2009)

¹⁸⁹⁸ It is estimated that 5% of all cancers in UK postmenopausal cancers are attributable to being overweight/obese.(Reeves ea, 2007)

¹⁸⁹⁹ These authors suggest that obesity overtook smoking as the leading preventable cause of illness and premature mortality.

might increase cancer risk include altered concentrations of insulin, insulin-like growth factors, and sex steroids leading to a change in the balance between cellular proliferation and apoptosis; altered metabolism of adipokines; localised inflammation; oxidative stress; changed immune response; hypertension¹⁹⁰⁰; lipid peroxidation; non-alcoholic fatty liver; and, because of abdominal obesity, gastro-oesophageal reflux.(Larsson & Wolk, 2008) Obesity shortens the telomere.(Valdes ea, 2005) Abdominal obesity, because of visceral¹⁹⁰¹ fat accumulation, may be a problem in elderly depressives.(Vogelzangs ea, 2008)

Pseudotumour cerebri

Raised intracranial pressure, papilloedema, visual loss, VI cranial nerve palsy

Headache, if present, is typically pulsating

Classically affects young obese women

Can be - *primary* (idiopathic intracranial hypertension)

- *secondary* (e.g. neoplasm, obstructed ventricles, cerebral vein thrombosis, cardiac failure, COPD, eclampsia, sleep apnoea, vitamin A and derivatives, tetracycline, lithium, corticosteroids withdrawal, renal disease, hypoparathyroidism, plumbism, Lyme disease, SLE, hypertensive encephalopathy)

Management of primary cases: weight loss, repeated lumbar puncture, diuretics, topiramate, emergency steroids or surgery (e.g. fenestration of II nerve sheath) to preserve vision

Pregnancy complications associated with obesity¹⁹⁰² (Stotland, 2009)

Reduced fertility

Congenital malformations¹⁹⁰³

First trimester spontaneous abortion and miscarriage

Large babies

Gestational diabetes mellitus

Hypertensive disorders (chronic hypertension or pre-eclampsia)

Prolonged labour

Unplanned caesarean delivery

Patients may have excessively optimistic expectations of each novel therapy.

Current criteria for using anti-obesity drugs are: BMI of at least 30 or BMI over 27 when co-existing conditions are present. Anti-obesity drugs do not cause particularly significant weight loss¹⁹⁰⁴ and have their own adverse event profile. The chief approach is a normal reducing diet: eat plenty of fibre and exercise regularly.(Lean ea, 2007; van Sluijs ea, 2007) A low calorie diet¹⁹⁰⁵ is prescribed. As long as the calorie content of the diet is reduced it doesn't seem to matter whether the emphasis is on protein, carbohydrate or fat when composing such a diet.(Sacks ea, 2009) Crash diets should be avoided. Obese people tend to eat more than they report during a diet and to overestimate physical activity. Self-monitoring, response prevention strategies to counter identified behavioural and cognitive cues, reinforcement, family or marital work, and psychotherapy are all useful in individual cases. Short term goal and self reward for various degrees of weight loss are critical. Follow up sessions may be needed during crises.

Severe diarrhoea, deficiency states, and renal problems may complicate surgery¹⁹⁰⁶, such as jejunio-ileal bypass, gastropasty, and cholecystjejunostomy. Liposuction (fat removal by suction) may reduce weight (often temporarily), girth, and leptin levels in plasma, but it may not improve metabolic problems associated with obesity and therefore may not reduce the risk for coronary disease.(Klein ea, 2004)

¹⁹⁰⁰ It is important to use a large cuff when measuring blood pressure in a person with a large arm.

¹⁹⁰¹ Centrally located fat (particularly intra-abdominal) is more likely to be associated with severe abnormalities of serum lipids.

¹⁹⁰² 1 in 5 women were obese at their first antenatal visit at the Coombe Maternity Hospital, Dublin.(Barry ea, 2009)

¹⁹⁰³ Stothard ea (2009), in a meta-analysis, found that obese mothers had an absolute risk of having a baby with a neural tube defect or a serious cardiac anomaly was 0.47 and 0.61/1,000 births respectively greater than was the case for mothers whose BMI was in the recommended range.

¹⁹⁰⁴ Orlistat, sibutramine, and rimonabant reduce weight by less than 5 kg on average.(Rucker ea, 2007)

¹⁹⁰⁵ 800-1,000 K cal daily – lower levels may reduce BMR.

¹⁹⁰⁶ Bariatric surgery is the technical term for anti-obesity procedures. There is a small mortality risk in the short term and abdoninoplasty may be required by many patients.(Arterburn, 2008)

Drugs such as T3, dinitrophenol and sympathomimetics can be toxic and are useless anyway. Central stimulants (phentolamine, diethylpropion, and amphetamine) act on adrenergic receptors causing central stimulation and may precipitate psychiatric problems.

Fluoxetine, an SSRI, is useful for binge eating. In acute treatment, fluoxetine and fluvoxamine may cause weight loss (at least in the short term), whereas citalopram, sertraline and paroxetine seem to be weight neutral.¹⁹⁰⁷ Nevertheless, the question arises that SSRIs when followed up for long enough may cause weight gain.(Sherman, 1998) Fenfluramine acts by releasing 5-HT. Fenfluramine could increase satiety rather than causing anorexia.¹⁹⁰⁸

Phentermine (Ionamin), an amphetamine derivative¹⁹⁰⁹, should not be given for longer than 6 months and is usually given for 4-6 weeks. Phentermine therapy should be adequately supervised and is not a first-line therapy. Side effects include headache, anxiety, insomnia, hypertension, bradycardia, and palpitations. It can cause pulmonary artery hypertension. Contraindications include pulmonary artery hypertension, severe systemic arterial hypertension (monitor BP in hypertensives and patients at risk of same), present or past cerebro- or cardio-vascular disease, a propensity for alcohol or substance abuse (not as big a problem as with other amphetamines), or children under 12 years of age. It should be avoided in the presence of current or past psychiatric disorder (including anorexia nervosa and depression). According to Eckel (2008) efficacy and safety data for phentermine are limited and there is a potential but low possibility of abuse.

Orlistat (Xenical), 120 mgs (capsules) tds with meals, used in conjunction with a low calorie diet¹⁹¹⁰, promotes weight loss by selectively inhibiting gastrointestinal and pancreatic lipase activity, so reducing dietary fat absorption by 30%. According to Anonymous (2007) orlistat (tetrahydrolipstatin) is the obesity drug with most evidence for efficacy and safety¹⁹¹¹. Xenical, which is not absorbed, is indicated if the BMI is 30 or more. It is said to decrease LDL cholesterol more than does diet alone. It reduces the LDL: HDL cholesterol ratio, to decrease fasting plasma glucose and insulin concentrations to improve glycaemic control, and it may offer some protection against the development of type II diabetes mellitus. Some concern has been expressed over an association between orlistat and hypertension.(Persson ea, 2000) It can cause faecal incontinence and urgency, oily spotting, and flatulence.(Noël & Pugh, 2002) There is a potential for malabsorption of fat-soluble vitamins.(Hanlon ea, 2006, p. 115)

Sibutramine, (Reductil) is a MAOI which increases noradrenaline peripherally at beta-3 receptors¹⁹¹² and causes weight loss by heat production and increased consumption of oxygen. European regulators suspended marketing authorisation for sibutramine and the FDA placed restrictions on its licence because of concerns about raised risks of heart attacks and CVAs.(Sayburn, 2010; Williams, 2010)

Liraglutide is a glucagon-like peptide-1 (GLP-1) analogue that can be given subcutaneously and may hold promise in the treatment of obesity.(Astrup ea, 2009)

Naltrexone plus bupropion combination treatment (Greenway ea, 2010) may have a role in treating overweight and obese adults. The commonest adverse effect is nausea, others including headache, dizziness, constipation, vomiting, and dry mouth being less common. Most obese patients do not need medical help to lose weight and most will drop out from treatment.

Yanovski and Yanovski (2002) remind us that the main approaches to the treatment of obesity are behavioural (improved diet and increased physical activity) with weight-loss medications reserved for patients at substantial risk because of their obesity and where non-drug treatments have failed. In motivated patients, the aim is to achieve gradual and modest weight loss by caloric restriction, physical activity, and behavioural treatments.(Noël & Pugh, 2002) Promotion of cycling is practical step advocated by Lavery.(2008)

¹⁹⁰⁷ Of course, SSRIs should be given with food to reduce GIT side effects!

¹⁹⁰⁸ It could be associated with depression if suddenly withdrawn. It was contraindicated in those patients with a psychiatric history. Other associated problems included nausea, diarrhoea, lethargy, dyspnoea (pulmonary hypertension), and increased dreaming. Diethylpropion (adrenergic stimulant that releases brain noradrenaline) was removed from the Irish market in 1995 because it was being abused and can also cause pulmonary hypertension. Anorectic drugs like phentermine, diethylpropion, fenfluramine, and D-fenfluramine can cause a serotonin syndrome if given in conjunction with a MAOI. Servier (Ireland) voluntarily removed fenfluramine and dexfenfluramine from the market in 1997 because of reports of heart valve lesions. Similar withdrawal occurred in Europe.

¹⁹⁰⁹ Like diethylpropion, this is an adrenergic stimulant that releases brain noradrenaline and reduces food intake.

¹⁹¹⁰ Some authors wonder if the accompanying low-fat diet (which reduces side effects) is actual the active therapy.(Hanlon ea, 2006, p. 115)

¹⁹¹¹ Orlistat was approved by the FDA in the US for use over the counter in 2007.

¹⁹¹² It is also a serotonin reuptake inhibitor. It was contraindicated in the presence of psychiatric disorder, coronary artery disease, congestive heart failure, or a blood pressure greater than 145/90. It was licensed for use in the treatment of obesity for a period of one year. It was effective in the treatment of patients with binge-eating disorder in a number of studies.(Appolinario ea, 2003; Wilfley ea, 2008) If taken with diet and support it reduces weight by 5-7%.(Anonymous, 2001) However, weight is quickly regained when sibutramine is stopped. It can cause dry mouth, constipation, insomnia, tachycardia and hypertension and it potentially interacts with drugs affecting cytochrome P450 3A4 and those increasing serotonin levels. One reviewer (Anonymous, 2001) described it as 'difficult and impractical to use' and of 'limited potential benefit'. Reports from around the world of sibutramine-related fatalities prompted Italy to suspend sales and other countries to initiate reviews of the drug.(Noël & Pugh, 2002) Sibutramine (Clark & Harrison-Woolrych, 2004) and other 5-HT reuptake inhibitors, such as fluoxetine,(Joss ea, 2003) have been reported to be associated with memory impairment.

According to Noël and Pugh (2002), surgery for obesity¹⁹¹³ should be confined to patients who are at least 18 years of age who have a BMI of at least 40 or have a BMI of 35-40 with serious complications of obesity. Intensive, specialised interventions should have failed or there should be an inability to maintain weight loss with non-surgical approaches. There should be no contraindication to surgery or anaesthesia, and the patient must be willing to undergo long term follow-up. According to Mason (2003), opinion differs on the use of surgery for obesity and different procedures are employed in different countries. Wernicke-Korsakoff syndrome may follow bariatric surgery.(e.g. Foster *et al.*, 2005) According to The Longitudinal Assessment of Bariatric Surgery (LABS) Consortium (2009) adverse 30-day outcomes of surgery are related to a history of DVT, pulmonary embolus, obstructive sleep apnoea, impaired functional status, and extreme values of BMI.

Since **obesity** has become more common in genetically stable populations it must be of primarily **environmental origin** according to Ebbeling *et al.* (2002)

Suggestions for tackling the problem

Breastfeeding (Groves, 2006)¹⁹¹⁴

Domestic - healthy meals (less salt, sugar, and fat) at fixed times, more activity, less TV¹⁹¹⁵

School - physical education, healthier food, no fattening food/beverages from vending machines

Town planning - encourage exercise¹⁹¹⁶ (Kimm *et al.*, 2005); bicycles instead of cars (Groves, 2006)

Non-drug management of antipsychotic-induced weight gain¹⁹¹⁷, e.g. individual/group approaches, CBT, and nutritional counselling (Ávarez-Jiménez *et al.*, 2008)

Better insurance cover for proven treatments for obesity

Marketing/media¹⁹¹⁸ - discourage bad foods, encourage good foods, clear labelling, and discourage advertisements aimed at youth

Politicians - no contributions from food industry

A major problem in tackling obesity is that many obese people may not see obesity as being a problem for them.(Johnson *et al.*, 2008) Population changes in physical exercise and diet are the main culprits according to Kipping *et al.*(2008a,b) Education aimed at discouraging children from drinking carbonated drinks has led to weight loss in the short term only¹⁹¹⁹.(James *et al.*, 2004, 2007) Such programmes may need to be sustained to have a persistent effect.

Epidemiology of eating disorders

<i>Year</i>	<i>Data</i>	<i>Comments</i>
Obesity		
1987	8% men, 12% women	British prevalence
1993	2nd cause of death after cigarettes	USA (McGinnis & Foege, 1993)
1994	9-10 year olds; 10 year follow up	Danish; parental neglect promotes obesity
2002	15 million people in US have BMI of 35 kg/m ² or more	This means 1 in 20 people
	16.7% boys, 15.4% girls	US prevalence
2004	32.7% of men obese	Japan Society for Study of Obesity

¹⁹¹³ E.g. adjustable gastric banding, Roux-en-Y gastric bypass, and sleeve gastrectomy. See Leff and Heath (2009) for a review.

¹⁹¹⁴ Groves (2006) was quoting WHO which brought European states together in November 2006 to initiate European Charter on Counteracting Obesity.

¹⁹¹⁵ According to the Kaiser Family Foundation in early 2010, children aged 8-18 years spend an average of 7.5 hours watching TV, playing video games, or listening to music on computers.

¹⁹¹⁶ Exercise improved motor skills but did not reduce BMI in young children in one trial.(Reilly *et al.*, 2006) Irish adolescents may exaggerate the level of exercise taken.(Shiely & MacDonncha, 2009)

¹⁹¹⁷ Potentially all antipsychotics can induce weight gain. Weight gain develops rapidly.(Tarricone *et al.*, 2010) Visceral obesity, a risk factor for metabolic syndrome, is the usual pattern. Weight gain should be monitored and interventions should be early. Some clinicians use anti-obesity drugs and behavioural approaches. Entrance into a 'wellness programme' may help. Many clinicians switch to a different antipsychotic, e.g. aripiprazole or ziprasidone.

¹⁹¹⁸ E.g. the *Change4Life* programme in Britain in 2009.(Mayor, 2009)

¹⁹¹⁹ Kipping *et al.* (2008) suggest that the main things we can change in relation to children who are obese are gestational diabetes in the mother, amount of time in front of TV, level of exercise taking, parental inactivity, and amount of fat/carbohydrate/sweetened drinks imbibed.

600

2006	1 in 5 Europeans obese 31.1% of men and 33.2% of women are obese in USA	WHO Non-Hispanic Blacks and Mexicans in US have very high rates
2007	2.7 comorbid medical diagnoses; 40.7% metabolic syndrome (F>M); 51% obese; 51% cholesterol > 5; prolactin raised in 2/3 females	Long-stay patients; GP input needed (O'Brien et al, 2007)
2008	Overweight children do not always become overweight adults No increase in childhood obesity between 2003/4 and 2005/6 Small fall in obesity in better off children Decrease in prevalence of overweight girls 22 million children in world are overweight Eating quickly and to fullness associated with obesity In Europe general and abdominal adiposity are associated with increased risk of death Overweight/obesity has same risk for death as does smoking General population survey	Japanese, cross-sectional, retrospective of females* USA France Sweden 75% live in low/middle income countries (WHO) Japanese study Supports use of waist circumference or waist-to-hip ratio as well as BMI in assessing risk of death 46,000 Swedish late adolescent conscripts
2009	US obesity prevalence rose by 37% during 1998-2006 More than 70,000 new cancers annually in Europe related to excess body weight Mid-life adiposity reduces chances of good health in old age Common mental disorders increase obesity risk Obesity will outweigh effects of decline in smoking in US	Schizophrenia but not affective psychosis associated with obesity (Finnish study of people aged 30 years or more; results remain after controlling for medication, diet, smoking and education) 'Weight of the Nation' conference, Washington DC Especially endometrium, postmenopausal breast, and colorectal
2010	Objective activity reduces obesity in 12-14 year olds	Study of US female nurses Study of London civil servants Obesity reduces life expectancy
Anorexia nervosa		
1989	7% of cases are male	
1991	13% of 16 year old schoolgirls score above cut-off on the EAT**; 4% took laxatives	Dublin
1995	Median prevalence of 1.3/1000 families AN not increasing in prevalence	Analysis of 29 cross-sectional surveys
1996	Clinic cases had excess higher social classes	Social classes evenly distributed in community
1997	Significant weight/shape concerns in girls: 11.5%, 11-12 year old; 14.9%, 12-14 year old; 18.9%, 15-16 year old	Significant ideational/behavioural disturbance in older group only
1998	Probably not associated with high social class but may be linked to education	Richard Morton (17th century) relieved a case by banning study!
2001	Recovery still possible after many years, but so is relapse	21-year prospective follow-up
2005	No change in incidence 1994-2000	Primary care setting (incidence 4.7/100,000 pop.)
2010	SMR ⁺ = 6.9 BP associated with excess of eating disorders (ED) in Italy Every other US child has BMI that is at least at 85th centile on age-specific national growth charts for ideal weight gain	Natural and unnatural causes of death more common in 20 years or more after first admission of females (retrospective Swedish register study) 148 patients (BP-I, BP-II, +/- cyclothymia): 31% had lifetime ED; AN = 15.5%; BED = 14.2%; BN = 5.4%; multiple EDs = 4.1% National Health and Nutrition Examination Survey
Bulimia nervosa		
1989	F:M ratio of 3:1	
1990	1% prevalence in adolescent/young adult women	USA
1992	1-2% of young adult women have it	Britain
2005	Incidence 6.6/100,000 pop.	Primary care setting
2006	Decline in point prevalence 1982-2002 in females at one US university	Not due to changed service use; may be explained by changing socio-cultural factors

*However, Japanese children may be less fat than Westerners; there may be social pressures encouraging weight loss; and young Japanese girls smoke more today than heretofore.

**Eating Attitudes Test. ^ SMR: standardised mortality ratio.

Prognosis in the eating disorders

<i>Year</i>	<i>Data</i>	<i>Comments</i>
Obesity		
2000	At least 1 in 3 Americans have weights at least 20% over desirable weight	50% US females & 25% US males dieting today, usually with little prolonged benefit (most put it back on)
2003	Obese elderly women at increased risk of dementia	18-year follow-up
2005	Obesity limited to childhood has little impact on adult outcomes; persistent obesity in women associated with poorer employment and relationship outcomes; persistence in men has no adverse outcomes	British birth cohort, part of 1970; 29/30 year follow-up
2005	Parental obesity, early BMI or adiposity rebound, > 8 hrs in front of TV at 3 years, catch-up growth, standard deviation score for weight at 8 months, weight gain first year, birth weight, and short sleep duration at 3 years predict childhood obesity	Prospective UK study
2006	Obese people at increased risk of dementia Obesity in middle age associated with increased risk of death	Follow-up from age 40-45 in 1960s/70s to mid-1990s in California US follow-up of people 50-71 years old
2009	BMI predicts mortality	Collaborative analysis of 57 prospective studies – higher BMI-related Deaths related to vascular disease; smoking important at lower BMIs
Anorexia nervosa		
1991	Poor outcome if later onset, neurotic or personality disturbance, dysfunctional family, longer illness	UK 20 year follow-up
1995	Mortality rate in AN higher than in female psychiatric patients or general population	Meta-analysis
1997	Early-onset: half recover by 2 years	Healthy family function and precipitating life events = good short-term outcome (lose predictive power at 2 years because of improvement in other cases)
1998	10% still have AN after 10 years; rest have low weight and cognitively AN, e.g. perfectionist; depression, alcohol abuse & anxiety common	Females attending special clinic during early 19980s v controls
1999	Specialty inpatient units have better outcomes	More expertise and experience than general inpatient settings
2002	½ recover, 1/3 improve, 1/5 chronic	Review of 2nd half 20th century; better outcome with younger onset & longer follow-up, worse with vomiting, bulimia, purgation, chronicity, obsessional/compulsive personality
2006	Mortality rate improved from 4.4% to 1.3% in hospitalised cases of AN	Swedish register study of 2 adolescent cohorts born 1958-67 and 1968-77 – due to specialist units?
2006	Mortality rate of 1.2%	Swedish study; born 1968-77; 9-14 year follow-up; 8.7% had persistent psychiatric problems requiring hospital care; 2.4% required public financial assistance
2007	33% full recovery at 2 years; 27% Still with AN; out-patient treatment as good as in-patient treatment	Multicentre randomised controlled trial
2009	Teenage-onset AN 18 years post-onset	No deaths. 12% persistent eating problem (half of these had AN). 39% had at least 1 psychiatric disorder (often associated with no job). Poor outcome: premorbid obsessive-compulsive personality disorder, age at onset of AN, and autistic traits
Bulimia nervosa		
1991	Borderline personality disorder	Poor therapeutic outcome
1994	52% fully recovered, 9% had full syndrome, 39% had some symptoms	10 year follow up of 88% of sample
1994	31% relapse rate, especially in first 6 months	2 year follow up, female attenders, eating disorder centre, Toronto
1995	Decreased prevalence in both sexes and improved clinical profile	US college students, 1982-92

2002	4 months after CBT, 44% relapsed	Poor outlook if very preoccupied with/ritualise eating, less motivated, or shorter abstinence during treatment period
2004	Course & outcome of BN (purging type) generally better than for AN	12-year follow-up, females
2004	Early change in frequency of purging was best predictor of response at end of treatment and at 8-month review	CBT and interpersonal psychotherapy
2006	EDNOS 60%, BN 25.5%, AN 14.5%	Percentages of different eating disorders in a community sample
2009	45% full recovery, 27% considerable recovery, 23% chronic protracted course 22.5% cross-over to another eating disorder 0.32% crude mortality rate; other psychiatric diagnoses common; highest recovery rates at 4-9 years follow-up	EDNOS = eating disorder not otherwise specified 79 studies that varied in what they covered; lack of standardised outcome criteria
2011	Crude mortality rates as % for AN, BN and EDNOS* = 4, 3.9, and 5.2 respectively	Treated at academic specialised centre

*EDNOS = eating disorder not otherwise specified.

Anorexia nervosa (AN)¹⁹²⁰

Epidemiology

The incidence is c. 1/100,000 of the population, although figures vary. The point prevalence for Britain was estimated by Crisp to be about 10,000 severe cases.¹⁹²¹ According to Morris and Twaddle (2007) the prevalence of AN is about 0.3% of young women, the average age of onset is 15 years, it is the commonest cause of weight loss in young women, and 80-90% of cases are female.

Clinical features

¹⁹²⁰ Sir William Withey Gull (1816-1890), the famous English physician, is credited with describing both myxoedema and AN, the latter in 1868 (as *aepsia hysterica*) -74 (as *anorexia nervosa*). 'AN' is a misnomer since loss of appetite is not one of its features. Gull actually acknowledged the French neuropsychiatrist Ernest Charles Lasègue (1809-1883) as having written about the condition ('hysterical anorexia') before him, and Richard Morton (1637-1698, the Englishman who stated that tubercles are always found in TB) published his account of 'nervous consumption' in 1694. The German name is *Magersucht*, meaning an addiction to being thin. Other names include 'chlorosis' and 'green sickness' (these terms also referred to anaemia; 'tropical chlorosis' referred to hookworm infestation in Egypt). 'Anorexia mirabilis' of Medieval Europe wherein a person with deep religious devotion practiced severe food restriction was seen as being non-pathological. Between 1914 and 1949 AN was confused with Simmonds' disease (Morris Simmonds, 1855-1925, described hypophyseal cachexia, i.e. hypopituitarism – Harold Leeming Sheehan, 1900-86, recorded cases of acute postpartum pituitary necrosis: Kovacs, 2003) and patients with AN were given pituitary extract! Heavy vinegar consumption was once a noted problem in AN. Did St Catherine of Siena (1347-1380) have anorexia nervosa? The last of 25 children, Catherine cut off her hair when her parents insisted that she marry. She is recorded as starving herself, bingeing, using a reed to induce vomiting, and employing herbs to purge herself.(Bell, 1985) Catherine, contrary to some written opinion, was literate.

¹⁹²¹ Claims for an increase in the incidence of AN may reflect an increase in the number of young women in the population and an increase in re-admission rates,(see Currin ea, 2005) rather than due to any real increase in risk, although some authors strongly believe that there has been a real increase.(Halmi, 2003, p. 1004) DSM-IV required a body weight of < 85% of that expected for age and height whereas DSM-III-R required at least 25% weight loss, a change that could itself cause a spurious increase in cases of AN.

AN consists of failure to eat, some type of body image disturbance, body weight of less than 85%¹⁹²² of that expected or BMI of 17.5 or less, and amenorrhoea¹⁹²³ of 3 or more months' duration (criteria vary). About 5% of cases are male. A BMI of 17.5 or less may indicate a case of anorexia nervosa. Denial of problems¹⁹²⁴ and depression are common. Low self-esteem, perfectionism and undue compliance are said to be common premorbid characteristics. Other possibilities include tomboyishness, excessive emphasis on big family meals¹⁹²⁵, and a premorbid 'ideal' child. Sufferers with AN are often socially withdrawn and may dream about food whilst starving themselves!

According to Cohen (2003, pp. 324-330) 95% of AN starts with normal dieting, the dieting then becoming out of control and autonomous. Up to three-quarters of cases report engaging in excessive exercise before starting to diet.¹⁹²⁶ The problem here is that the individual reaction to dieting may be more important in the genesis of AN than dieting as such. (Fairburn, 1999) The number of people who have only a few or have relatively mild symptoms of AN greatly outnumber those who achieve syndrome status.

A diabetic with AN may deliberately underdose herself with insulin in order to reduce the metabolism of her food. Thyroid hormone may rarely be abused to reduce weight.

In restrictive AN, there is a severe restriction of calorie intake. In bulimic AN¹⁹²⁷, there is a severe restriction of food intake with episodes of binge eating (often nocturnal and in secret) ending with self-induced vomiting or the use of purgatives or diuretics. Early morning waking may occur in AN as a result of restlessness. Some cases go on eating binges, vomit¹⁹²⁸, or abuse purgatives. Problems include hypokalaemia, dehydration and, rarely, convulsions. Downy hair (lanugo), constipation, bradycardia¹⁹²⁹, orthostatic hypotension, peripheral cyanosis (acrocyanosis), bright orange skin (carotenoderma due to carotenaemia¹⁹³⁰), brittle hair and nails, anaemia¹⁹³¹, hypercholesterolaemia, a low blood pressure, hypothermia¹⁹³², hypokalaemic nephropathy, dependent oedema¹⁹³³, seizures¹⁹³⁴, leucopaenia with relative lymphocytosis, acute pancreatitis, gastric rupture, rectal prolapse¹⁹³⁵, muscle atrophy, neuropathies, a small heart with reduced heart muscle mass, QTc prolongation, ST-T wave abnormalities, cardiac arrhythmias and sudden death, and a fall in basal metabolic rate may all occur. The anorexic heart is unable to compensate for exercise. Elevated hepatic enzymes due to fatty degeneration of the liver may be found during starvation and refeeding. Cerebral ventricular enlargement, reduced gray and white matter, and cognitive dysfunction are described in AN.

A 'euthyroid sick syndrome'¹⁹³⁶ has been described in association with eating disorders. T3 and T4 are reduced but TSH is normal or only moderately reduced (one would expect an increase)¹⁹³⁷. No intervention is required¹⁹³⁸ because the findings normalise with recovery of the primary disorder. The stress of starvation is known to increase CSF endorphin levels, a possible explanation for the hypothesised addictiveness of weight loss.

Body image (perceived body size divided by actual body size: Wade *et al.*, 2003) is distorted: they think they are fatter than they really are. In fact, women with AN, bulimia nervosa or a combination of the two usually

¹⁹²² ICD-10 states that body weight is maintained at least 15% less than expected (lost or never gained).

¹⁹²³ Precedes obvious weight loss in 20% of cases; some authors feel that it is not an essential feature of the disorder. Patients on the contraceptive pill may still have vaginal bleeds.

¹⁹²⁴ Patients may acknowledge the need for admission after some time in hospital. (Guarda *et al.*, 2007)

¹⁹²⁵ Patients may prepare big meals for the family; patients may underfeed their own offspring.

¹⁹²⁶ Rats that are given only one meal per day and allowed to run on an activity wheel tend to reduce food intake and may run to the point of death. This has been 'explained' as a foraging response to food restriction and as a response to DA or endorphin release during starvation/exercise. Healthy male volunteers deprived of food become preoccupied with food, do not feel satiated after feeding, and will cook for others and enjoy watching them eat!

¹⁹²⁷ AN, binge-eating/purging type in DSM-IV.

¹⁹²⁸ People with peptic ulcer may induce vomiting to relieve pain.

¹⁹²⁹ Probably results from increased vagal tone. It is not benign (as in athletes) and is associated with reduced stroke volume.

¹⁹³⁰ E.g. on palms and soles.

¹⁹³¹ The classic normocytic hypochromic anaemia of starvation may be replaced by iron deficiency (microcytosis) in vegetarians.

¹⁹³² Hypothermia may mask infection.

¹⁹³³ Oedema is multifactorial in AN.

¹⁹³⁴ Due to electrolyte and fluid changes.

¹⁹³⁵ Usually found in long-standing cases with emaciation, emesis, and abuse of laxatives.

¹⁹³⁶ Or 'sick euthyroid syndrome'. In fact, any pattern of results can occur. This is a non-thyroidal disorder secondary to severe systemic upset (e.g. pneumonia, myocardial infarction). Peripheral conversion of T4 to T3 is decreased.

¹⁹³⁷ Some authors give a different description: low total T4, normal free T4, and low T3.

¹⁹³⁸ In fact, prescribed thyroid hormone could exacerbate metabolic and cardiac status in AN. Seek an independent cause of hypothyroidism if TSH is raised.

have body image distortion. AN has been described in the blind. Fear of fatness may not be universal in AN, e.g. in China.(Lee ea, 1993)

Bone loss in AN is significant, is related to the duration of illness, and improves to a variable degree with weight gain. However, a reduction in bone mass occurs even with brief illness and recovery may not be complete. Pathological fractures, including vertebral collapse, may occur. Stress fractures from excessive exercise (running and jumping) are another complication. Bone density does not correlate with basal oestrogen.

Eating Attitudes Test (EAT) was developed by Garner & Garfinkel in the late 1970s. A shortened, 26-item version is used to evaluate behaviours and attitudes found in anorexia nervosa (AN). A cut-off point is used to distinguish AN from normal controls. EAT has its limitations because classic eating disorders are uncommon – this reduces its positive predictive value (the proportion of true cases divided by the number scoring positive on the test) Using the EAT during the early 1990s, it was found Halpin & Fitzgerald (1992) 2.8% of Dublin adolescent males scored above the cut-off point, whereas between 6.8% of London schoolgirls scored positively and 13% of Dublin schoolgirls scored highly.

CT typically shows cortical atrophy following significant weight loss, reverting to normal with adequate nutrition, although some authors report persistent neurological (e.g. cerebellar) and neuroradiological (e.g. grey matter volume deficiencies) in AN. Functional imaging show increased metabolism in the caudate nucleus before weight restoration. A 1% reduction in global grey matter volume has been found on MRI and region specific grey matter loss in the anterior cingulate is directly related to clinical severity.(Mühlau ea, 2007) Impaired behavioural response shifting in AN¹⁹³⁹ may be associated with under activation of in the ventral anterior cingulate-striato-thalamic loop that subserves motivated behaviour, with AN patients showing mainly activation (on fMRI) of fronto-parietal networks that indicates effortful and supervisory cognitive control when performing a task.(Zastrow ea, 2009) Ventral striatal (reward system) activity on fMRI is higher in AN than in controls when processing underweight stimuli.(Fladung ea, 2010) There is mild lengthening of the QT interval in AN¹⁹⁴⁰, even in the absence of electrolyte imbalance, that may be due to autonomic imbalance secondary to starvation. Of unknown clinical significance, left ventricular mass is reduced. Clinical heart failure is a recognised complication of refeeding. (Reversible) mitral valve prolapse¹⁹⁴¹ is probably is probably of similar prevalence to the general population. Sudden death has been reported which may be due to centrally or peripherally mediated autonomic imbalance, QT lengthening¹⁹⁴², or some other cause.(Cook & Chambers, 1995)

The family

Sheppard ea (1984) reviewed nine cases of male AN and wondered if the incidence of male AN might be on the increase. Male victims had a high incidence of affected relatives. They quote the literature as suggesting a figure of 25% for psychiatric illness among patients' relatives and stressed the amount of parental discord and role problems experienced by parents. OCD may be over represented among the mothers of patients with AN.(Halmi, 2003, p. 1007) The family discord could be covert, and the maternal affiliation may be very close with an absent or ineffectual father. Jacobs ea (2009) divided 'AN trios' (patient and two biological parents) into three classes: 33% consisted of mildly symptomatic patients and healthy mothers; 43% comprised probands who had strong drives for thinness, were unhappy with their bodies, and were neurotic, anxious (trait), and avoided harm and whose mothers had mild trait anxiety and perfectionism; and 24% where both mother and patient had eating disorders and had anxious, perfectionistic traits. Fathers did not differ markedly between the three groups. Minuchin ea (1978) described the family characteristics of AN cases as including enmeshment (overinvolvement with each other, unable to break away), rigidity (difficult to change behaviour patterns, even with increasing age), lack of conflict resolution (usually denied or avoided), overprotection, and involvement of the patient in family conflict regulation. Family dysfunction may be greater in the purging subgroup.(North ea, 1995) However, other workers (Blair ea, 1995) found no evidence for enmeshment, rigidity or weak boundaries between generations in AN families. Indeed, the results suggested that AN caused the family disturbance.

¹⁹³⁹ AN patients demonstrate difficulties with tasks that involve changing rules and give stereotyped or perseverative responses, i.e. they are inflexible.

¹⁹⁴⁰ The QT interval is prolonged in starvation and with electrolyte imbalance, a point to remember when prescribing medication.

¹⁹⁴¹ Listen for systolic click.

¹⁹⁴² Reported in people on a liquid protein diet. Prolonged QT found in AN even when serum electrolyte levels are normal.

As Morris and Twaddle (2007) point out, AN can be 'found without apparent precipitants in otherwise well functioning families'.

Theories of causation in anorexia nervosa

'Through the modern cult of youth, the body was becoming an object of worship through its initiation into a disappearing act'. (Porter, 2003, p. 243)

'Anorexia has no single cause'. (Morris & Twaddle, 2007)

Socio-cultural: increasing recognition or incidence of AN; common in dance/ballet¹⁹⁴³ students (affecting as many as 25%), models (Treasure ea, 2008), and in well-to-do teenagers in developed countries; pressure on young people by advertisers/society to be thin¹⁹⁴⁴. (Becker ea, 2002; The McKnight Investigators, 2003) Gastrointestinal symptoms and picking at food during childhood correlates with anorectic behaviour in adolescence. (Marchi & Cohen, 1990) Pre-adolescent peer dietary characteristics influence eating behaviours and anxious children may be more susceptible to such influences. (Farrow ea, 2009) Excessive exercise (including competitive athletics) is common in the histories of AN patients; food restricted rats may run themselves to death on a wheel. (Konsman & Dantzer, 2002) Whilst disorders such as AN and type A behaviour have been described as Western culture-bound syndromes, AN and bulimia nervosa have been reported in non-whites.

Family pathology: ill child maintains family integrity by becoming a scapegoat for its problems; childhood mealtime disorganisation and maternal strong control and disharmony; (Cooper ea, 2004) but Blair ea (1995) - who compared normal families, families with a cystic fibrosis child and families with a daughter with AN - found little to distinguish such families; Stein ea (2006) found that 10-year-old children's eating disturbance was associated with length of exposure to maternal eating disorder and mother-child mealtime conflict.

Genetic: tentative evidence: phenotype changeable. Possible link of restricted AN to chromosome 1p34. Chromosome 13 might be linked to drive for thinness, perhaps via the serotonin receptor gene (HTR2A). The BDNF gene may be important (Collier & Treasure, 2004), e.g. Ribases ea (2005), in a large European study¹⁹⁴⁵, found that the Met allele of a mis-sense variation in the BDNF gene was associated with AN. Serum BDNF levels may be low in AN and BN, but normal in recovered AN (Nakazato ea, 2009) and binge-eating disorder. (Monteleone ea, 2005)

Individual dynamics: child tries to escape from over-possessive (and perhaps older than average) parents through illness; child sexual abuse (CSA) may be important to later development of AN, bulimia nervosa, and obesity; a small number are premorbidly promiscuous or drug abusing; it has been said that there is no reduction in sexual interest in AN - whilst the present author's cases have been quite varied in this regard it is probably true that the modern anorectic is more sexually active than was the case in the past; high levels of harm avoidance and lower self-directedness and cooperativeness might be trait characteristics in people prone to eating disorders (Klump ea, 2004) Psychoanalytic theories suggests a fear of oral impregnation; problems separating from mother (introject of interfering mother is 'starved' and own needs are projected into others who are cared for); and projective identification in relations

Developmental psychobiology: associated with Arthur Crisp; phobic avoidance of adolescent weight gain - is fat the main fear rather than food? Puberty arrested by slimming; mainly carbohydrates avoided; fear of fatness may be absent in some oriental cases of AN (Lee, 1994)

Hypothalamic disease: tumours may mimic AN (rare); most biochemical and physiological changes return normalise with weight gain - may include raised somatotrophin, increase in cortisol and loss of its normal diurnal variation, low T3, and decreased gonadotropins; the body seems unaffected by neuropeptide Y in AN; some authors point out that 20% of cases stop menstruating before losing weight and that the rate of cortisol is increased in AN but reduced in starvation, suggesting a possible primary endocrine disorder

Other organic: dysmorphic delusions in temporal lobe epilepsy (rare); pro-inflammatory cytokines, whilst having important effects on food intake and weight in conditions like cancer and AIDS, probably have little

¹⁹⁴³ Being in a dance class, having higher concern about body shape, and lower family support is associated with having an eating disorder in Taiwan. (Tseng ea, 2007)

¹⁹⁴⁴ However, pressure on wealthy people to achieve a slim figure was 'well-established' by the 1920s. (Brunton, 2004, p. 368) Nevertheless, the advent of Western TV to Fiji may have been responsible for an increase in eating disorder among adolescent females. (Becker ea, 2002)

¹⁹⁴⁵ N = 1,500 patients.

role in AN; right frontal lesions may closely mimic AN (Uher et al, 2002); various perinatal problems (Favaro et al, 2006, 2010) such as 'dysmaturity'

Abnormal serotonin transmission – blunted prolactin response to d-fenfluramine, persistent altered serotonergic function and anxiety after recovery from AN (Bailer et al, 2005)

Affective disorder: primary or secondary? Mangweth et al, (2003) in a study of relatively small sample size, found that the familial aggregation of eating disorders (AN, BN, and binge-eating disorder) with mood disorders was significant and of the same magnitude as the aggregation of mood disorders alone.

Anorexia – true loss of appetite only occurs in severe, late stages

Differential diagnosis

This includes Simmond's disease, TB, malignancy, alcohol and drug abuse, affective disorders, paranoid psychoses, political hunger strikes, food fads, malabsorption states, and other causes of primary and secondary amenorrhoea.

Malignancy, chronic organ failure, GIT disorders, endocrine disorders, chromosomal abnormalities, and deprivation/abuse should be ruled out in prepubertal cases. Women who are taking contraceptive pills or hormone replacement therapy (HRT) may have vaginal bleeds, but this does not rule out a diagnosis of AN.

Cognition

People with eating disorders appear to have problems with global processing of information. (Lopez et al, 2008) In *selective abstraction* an isolated detail is used as to make an important conclusion. An example of *overgeneralization* includes the belief that the slightest use of carbohydrates would cause obesity.

Magnification is the overestimation of the significance of undesirable events. *All-or-nothing reasoning* includes the idea that the slightest weight gain will snowball toward obesity. An example of *excessive self-reference* would be 'I feel embarrassed when other people watch me eat'. In *magical thinking* a sweet is considered to be automatically and instantly converted to fat.

*Set-shifting*¹⁹⁴⁶ problems occur in eating disorders. (Roberts et al, 2007)

Management

Some cases do well with minimal intervention whilst others may require huge investments of time and may cause the therapist to despair. (Russell, 2004) It is hardly surprising that out-patient failures do poorly when admitted. (Gowers et al, 2007) Management comes down to putting on (post-voiding and gownned) weight¹⁹⁴⁷ and psychotherapy, individual and family. Expressed emotion in the family, if excessive, should be the subject of intervention. Day programmes for both AN and bulimia nervosa have become more popular than previously. The reasons why patients are admitted more or less readily in different jurisdictions may be more to do with financial and litigation considerations than any scientific-medical thinking.

Psychotherapy for AN

Not recommended: Randomised trial of **CBT and interpersonal therapy** (McIntosh et al, 2005): neither active treatment was better than non-specific clinical management

Recommended: Longterm **Motivational enhancement therapy/interviewing**¹⁹⁴⁸, a non-psychodynamic approach dealing with manifest thoughts and actions, is used to avoid unhelpful patient responses (e.g. anger or deception)

Recommended: Family therapy to educate the family, avoid excess permissiveness (secondary gain), and to provide support (Eisler et al, 2000)

Monitor potassium¹⁹⁴⁹, magnesium, calcium and phosphate during early treatment. Rapid re-feeding and weight gain may lead to serious consequences (see box).

Re-feeding syndrome

¹⁹⁴⁶ Set-shifting, an important executive function, is the ability to move back and forth between many tasks, operations, or mental sets. It may show as inflexible thinking (concrete, rigid, stimulus-bound) or responding (perseverative or stereotyped).

¹⁹⁴⁷ Beware of patients who place weights in their pockets or who drink large amounts of water. Also, if purging is suddenly stopped rebound oedema may increase a patient's weight.

¹⁹⁴⁸ Derived from work with substance misuse – reframe resistance to change as ambivalence about change.

¹⁹⁴⁹ Hypokalaemia is common in people who vomit. Potassium supplements may be required.

Depleted body reserves of substances such as potassium and phosphates
 Stimulation of metabolism by re-feeding increases demands for such intracellular substances
 Body must draw on plasma for these chemicals
 Can cause gastric bloating, dyspnoea, weakness, oedema, hypophosphataemia, seizures, delirium, coma, haemolytic anaemia, and rarely congestive cardiac failure
 Thiamine deficiency may lead to delirium, especially in the second week of re-feeding

To achieve the essential weight a behavioural regimen¹⁹⁵⁰ is used, privileges are granted only on reaching a certain body weight. However, operant approaches have been criticised as being coercive and are now less popular. Personal belongings are not withheld. Patients may secrete food on their person or elsewhere, or carry weights to weigh down the scales. Good nursing supervision is essential¹⁹⁵¹. Drugs (trimipramine, chlorpromazine¹⁹⁵², cyproheptadine [Periactin¹⁹⁵³], and insulin) were commonly used in the past but were generally ineffective. An exception is the use of antidepressants (e.g. fluoxetine, reboxetine, venlafaxine) for comorbid depression.¹⁹⁵⁴ SSRIs do not help the low-weight state, possibly because of a lack of serotonin to prevent the uptake of. (Brewerton, 2002) Fluoxetine may assist with weight maintenance, but citalopram has led to weight loss. (APA, 2002, pp. 733-4) Olanzapine has been used with some success to improve weight gain during refeeding. (see Connan, 2002, p. 1141) It may also have some effect on distorted beliefs, anxiety, and agitation. (Hodes ea, 2008, p. 846; Bissada ea, 2008) Bupropion (Zyban) is contraindicated by the manufacturers in AN. As a general rule, drug treatments are best delayed until following weight restoration or at least until hepatic function and electrolyte balance are normalised. A disturbing development is the presence of internet ('pro-ana') sites that promote anorexic eating practices and divert people from seeking professional help.

Prognosis

Periods may not return for months after weight restoration. According to Patton (1989) about 1 in 30 AN patients will die, and half will recover fully after 6 years. Robert Palmer (2003) of Leicester stated that, whilst AN causes much morbidity, most cases recover eventually. The predictors for death were lowest reported weight and repeated hospital admissions. Half of those who died had killed themselves through overdose. Suicide seems to be more common among bingeing/purging patients than among restricting types. Franko ea (2004) found that severity of depressive symptoms and drug use predicted suicide attempts in AN. Predictors of poor outcome were lowest weight, length of illness, older age at onset, and disturbed family relationships. Chronic, low weight cases may show CT evidence of irreversible ventricular enlargement and partially reversible sulcal enlargement¹⁹⁵⁵. Patients may be arrested for stealing food, clothes, laxatives¹⁹⁵⁶, or other items.

Unlike most research, certain population-based studies (Wentz ea, 2001; Korndorfer ea, 2003) have reported no excess mortality in AN – perhaps explained by inclusion of milder cases, population characteristics, or reduced deaths from obesity-related cardiovascular diseases.

Finnish female twin study (Keski-Rahkonen ea, 2007)
 Lifetime prevalence of DSM-IV AN was 2.2% (higher than usual)
 Half the cases were not detected by health care services
 Incidence in females 15-19 years = 270/100,000 person years
 5-year recovery rate = 66.8%
 Outcome no different whether detected or not!

¹⁹⁵⁰ This is now less strict than was the case in the past. Less strict approaches may be just as effective. Vitamin and mineral supplements are often prescribed. If oral feeding fails the nasogastric feeding may be necessary; feeding via gastrostomy or jejunostomy have been used rarely; and total parenteral nutrition tends to be avoided because of attendant complications.

¹⁹⁵¹ The nurse helps the patient to see that eating need not be equated with loss of control over her body weight, to maintain clear targets, and to prevent vomiting/purging.

¹⁹⁵² Chlorpromazine is sometimes given to reduce mealtime nausea in purging anorexics.

¹⁹⁵³ An antihistamine used to treat allergic symptoms; has been used to stimulate appetite in the medically ill; can cause sedation and dry mouth/nose/airways.

¹⁹⁵⁴ It should be noted that depression often improves as weight is restored. Weight loss through dieting lowers tryptophan availability.

¹⁹⁵⁵ I.e. reversing when weight is put on.

¹⁹⁵⁶ The sweetener sorbitol can cause an osmotic laxative effect and weight loss. It is present in many foods, including chewing gum. It, like mannitol and xylitol, is a polyalcohol sugar. (Bauditz ea, 2008)

By 5 years the AN cases were just like their co-twins in every way (fully recovered)

Babies of AN women tend to have a low birth weight.(Micali ea, 2007)

Male AN: some issues

The reasons why AN is less common in males can only be guessed at. Possibilities might relate to a later age at puberty, testosterone, and a society that advocates fitness rather than thinness.(Buckley ea, 1991)
Instead of amenorrhoea, male cases have loss of libido and impotence

Prepubertal AN

This is uncommon¹⁹⁵⁷. In a large series of cases the males make up a third, which is markedly different from the male to female ratio found in older age groups. They may have failure to gain weight rather than loss of weight, and hormonal changes are not as obvious. Some cases may fail to grow in stature. Girls do not develop breasts and have primary amenorrhoea. Boys have juvenile genitalia. If recovery occurs, puberty will often be completed normally but the onset of menses will be delayed. Depression is common. Admission may be required for joint medical and psychiatric assessment. Growth may be stunted and breast development may be severely affected. The menarche may be delayed. Early feeding difficulties may be elicited, and there may be a history of feeding problems (such as fads) in the family. Adverse life events appear to precipitate AN more commonly in prepubertal cases. They may have a history of early behavioural difficulties with poor peer relationships. There may, in some cases, be a positive family history of AN (found in 7-10% of first-degree relatives in AN of older onset). There is an increased history of family psychiatric disorder. There is also a high level of family disturbance with an excess of overinvolvement and a disturbance in parent-child relationships, and evidence of problems in intrafamilial communication. These youthful cases are treated as inpatients. The ward milieu should provide a safe environment with age-appropriate firm handling. Drugs are only used for associated depression, and amitriptyline has been recommended, although SSRIs appear safer. Family therapy is important to improve problem-solving skills. The parents may be helped to form a strong, effective alliance, and so to take control of their child's food intake. The prognosis is complex, and more follow-up studies are needed. Certain factors, such as depressive features and one-parent families, are associated with a poor outlook.

AN in the elderly

AN can occur in older people, affecting women more often than men. Amenorrhoea, of course, cannot be used diagnostically. Some cases seem to be precipitated by stress, such as bereavement. About two-thirds improve with treatment.(Nicholson & Balance, 1998) It is important not to misdiagnose another disorder, psychotic depression, as AN in this age group.

Bulimia nervosa (BN)¹⁹⁵⁸

Epidemiology

Some authors suggest that BN is a product of the late 20th century, pointing to its apparent absence in older cohorts. Drewnowski ea,(1988) in a prospective study, found an incidence of 2.1% per 6 months among female freshman students, or 4.2 new cases per 100 women per year. Emergent cases were offset by partial remission. Therefore the prevalence rates remained stable between their autumn and spring surveys. Hsu ea (1987) reported that BN affected 2-19% of young women in England and in the US.

Aetiology

Kassett ea (1989) reported that the close relatives of BN patients are found to have an excess of major affective disorders, eating disorders, and alcoholism when compared with control subjects. They surmised that major mood disorders and BN might be caused by a common diathesis. Others see anxiety and depression as secondary phenomena, and while BN patients may have the same total scores as primary depressives on depression rating scales the profiles may be very different (i.e. the items scored differ between the two groups).(Cooper & Fairburn, 1986)

¹⁹⁵⁷ There is evidence that puberty influences expression of genes for disordered eating.(Klump ea, 2007)

¹⁹⁵⁸ Russell (1979) described BN (bulimia = 'ox hunger') as a variant of AN ('A sister spawned from anorexia nervosa', to quote Gerard Russell at a talk given to the Royal Academy of Medicine in Ireland, Dublin, 09.03.1999). His diagnostic criteria are no loss of insight, bouts of subjectively excessive overeating, dieting, vomiting, purging, abuse of diuretics or anorectics, and awareness of and upset by slight increases in weight and/or shape. Famous cases are Princess Diana and Jane Fonda (see her *My Life So Far*).

Stein and Fairburn (1989) reported that as children their cases were ignored or smacked, had problems with breast-feeding, were too heavy or too light in childhood, and their parents may have been over-concerned about the child's size. Marchi and Cohen (1990) found mealtime problem behaviours and early pica to be associated with BN during adolescence. Waller (1991) found that bulimics reported more CSA in their histories than did anorexics and suggested that CSA was not a cause of eating disorder per se but perhaps might determine its final form. Pope and Hudson (1992) found no support for a causative role for CSA in BN. Other reports of the connection between CSA and BN are summarised in the table.

Kendler ea (1991), using DSM-III-R criteria, looked at female twins from a population-based register. Risk factors for BN were birth after 1960, low paternal care, widely fluctuating weight, dieting, frequent exercise, slim body image, low self esteem, external locus of control, and high neuroticism. Concordance for narrowly defined BN for MZ twins was 22.9% and for DZ twins it was 8.7%. Sullivan ea (1998) suggested that bingeing and vomiting in their population-based sample of female twins (n=1897) were due to the influence (mainly) of multiple genes and (less so) individual-specific environmental influences. BN with self-induced vomiting and obesity may be linked to chromosome 10p.(Bulik ea, 2003)
BN patients may have a blunted ghrelin¹⁹⁵⁹ response to food intake, normals showing a drastic decrease in circulating ghrelin under such circumstances.(Monteleone ea, 2003)

Eating disorders and child sexual abuse (CSA, in temporal order)

<i>Findings</i>	<i>Comments</i>
CSA associated with more bingeing and, to lesser extent, with vomiting	Females, Britain
Borderline personality disorder may partly explain the alleged connection	
CSA not a factor in BN	Women in US, Brazil, Australia
CSA only one type of abuse experienced	Women in California
CSA not essential; general childhood abuse common	Austrian female university students
CSA vulnerability factor for psychiatric disorder in general but not EDs in particular	Normal controls and depressives
44% of BN cases reported CSA but these had many other difficulties*	
A real, non-specific aetiological factor	Russell, G, Dublin, March 9, 1999
There is no specific sexual abuse syndrome	Adult female twins
Recall of parental mental health problems and early unwanted sexual experience assoc. with lifetime eating problems, laxative use and vomiting in pregnancy and marked concern over shape/weight in pregnancy	

Eating disorder = ED; bulimia nervosa = BN

**More depression, earlier onset of BN, worse overall functioning, alcohol and substance dependence, conduct disorder, etc.*

Patients with BN may not engage frontostriatal circuits (subserving self-control) appropriately (Marsh ea, 2009). CSF 5-HIAA levels are low in BN.(e.g. Jimerson ea, 1997)

Diagnosis & clinical features

A diagnosis of AN takes precedence over a diagnosis of BN. The majority of AN sufferers are restrictive, but the minority (bulimic AN) overlap with BN.

The *Bulimic Investigation Test Edinburgh* (BITE) is a brief questionnaire used for the detection and description of binge eating. The scale has measures of both symptoms and severity.(Henderson & Freeman, 1987)

Individual components of the syndrome are common. Patients seek help either if the condition is severe (they spend quite a lot of money on food) or if there is associated severe anxiety or depression. Nearly all cases are female, but there is a certain amount of evidence that more men with eating disorders may have BN than AN and that there may be an excess of homosexuality or bisexuality among these males.(Carlat ea, 1997) One-quarter are married. They are somewhat older than AN cases. About 50% of AN cases have bulimic episodes.

BN patients have bouts of secretive overeating which they feel are excessive and beyond their control. Disgust is common. They may weigh themselves several times a day. The feminine curves of the lower

¹⁹⁵⁹ **Ghrelin** is 28-amino-acetylated peptide. It is produced in the gastric fundus by oxyntic cells.

torso occupy much of their attention. They may socially isolate themselves if they feel that they are gaining weight. They view themselves as expert dieticians, may pride themselves on their cooking prowess, and may work in the catering trade. A few practice regurgitation and rumination. They may vomit up their food later, spit it out there and then, or drink large amounts of fluids to assist vomiting. Absorption of food is enough to keep them around normal weight. Jogging and keep-fit classes are common pastimes. Stealing food from shops is not uncommon in BN.

Obsessive-compulsive symptoms are common during bulimia and during recovery. It is possible that these are traits rather than state symptoms.

Oligomenorrhoea, amenorrhoea (perhaps in one-third of cases: Hodes *et al.*, 2008, p. 847) and irregular menses may occur, even in the absence of low weight.

BN has been divided into purging (self-induced vomiting or laxative abuse present) and non-purging (self-induced vomiting or laxative abuse absent) types.

PET studies suggest that left anterolateral prefrontal cortex hypometabolism may vary with the level of depressive symptoms in BN.

Comorbidity

Comorbidity (e.g. depression, personality disorder, or substance abuse) is present more often than not. (Yates *et al.*, 1989) Van Hanswijck de Jonge *et al.* (2003) found that binge eating in eating disorders is more strongly associated with personality disorder than is the absence of binge eating in such conditions. Thompson-Brenner and Westen (2005) found that most patients with bulimic symptoms matched one of three personality subtypes (high-functioning/perfectionistic, emotionally dysregulated/undercontrolled and emotionally constricted/overcontrolled) and that those who were more dysregulated or constricted take longer to treat and do less well. Kendler *et al.* (1991), referred to above, found significant comorbidity with AN, alcohol abuse, panic disorder, GAD, phobia, and major depression. Overdosing is not uncommon. (Lacey, 1993) Franko *et al.* (2004) found that laxative use and a history of substance use predicted suicide attempts in their prospective study. Perhaps a third of BN cases have a history of AN, and a minority have both syndromes simultaneously.

Complications

There can be erosion of dental enamel, buccal tears, enlarged parotids (*chipmunk facies*)¹⁹⁶⁰, enlarged submandibular glands, downy hair growth (e.g. upper lip and forearms), tetanic spasm, and scarring/calluses over the first metacarpo-phalangeal joint due to the gnawing effect of the upper incisor teeth during self-induced emesis (Russell's sign). Stopping diuretics may lead to rebound oedema thus perpetuating their use. Excess ipecac may cause cardiac problems: cardiac failure due to cardiomyopathy in these cases is very often fatal; symptoms such as chest pain, dyspnoea, generalised muscle weakness, hypotension, tachycardia, raised serum aldolase concentration, and ECG changes should suggest the likelihood of ipecac poisoning. Hypokalaemia is sometimes avoided by potassium supplementation. Many cases of BN have elevated serum bicarbonate levels, but a few have reduced levels (metabolic acidosis, especially if abusing laxatives). Fractures may occur due to low oestrogen levels and consequent osteopenia.

There may be impulsiveness, alcohol and drug abuse, promiscuity, stealing for food, irritability, anxiety, depression, fractures, hypokalaemia, convulsions, cardiac arrhythmias, finger clubbing¹⁹⁶¹, fatty stools, hoarseness, damage to dentition, acute gastric dilatation, medication loss from purging¹⁹⁶², and obesity from eating excessively.

BN patients often have anovulation and menstrual problems despite a normal weight. This might be due to gross fluctuations in carbohydrate intake, disturbances of fluid and electrolyte balance caused by self-induced vomiting and laxative abuse, or by vomiting leading to excessive dopamine activity centrally. BN may improve during pregnancy only to return during the puerperium¹⁹⁶³. There may be an increased risk among those with active AN or BN of Caesarean section and postpartum depression. (Franko *et al.*, 2001) A history of miscarriages is relatively common among women with BN. (Micali *et al.*, 2007) The risk of suicide

¹⁹⁶⁰ With increased serum amylase levels if bingeing and vomiting. Salivary isoenzyme of amylase will be raised with parotid enlargement.

¹⁹⁶¹ Purgative abuse is an uncommon cause of clubbing.

¹⁹⁶² Giving medication at bedtime may help.

¹⁹⁶³ See Ward (2008) for discussion of eating disorders and pregnancy: treat before pregnancy, provide nutritional education, refer early if disorder is active, observe for postnatal depression or worsening of disorder, support breastfeeding, and monitor baby.

is increased in BN. In fact, the mortality rate has been said to be the highest of any (presumably 'functional') psychiatric disorder.

Management

Cognitive-behavioural therapy (CBT)¹⁹⁶⁴ is offered as an outpatient over a number of months (average 20 sessions over 6 months). The beneficial effects of CBT seem to outlast active treatment, an attribute that may be true for drugs. Personality disorder alone may not reduce the effectiveness of CBT, but comorbidity with depression and low weight may do so. Emphasis is placed on regular eating habits. Dietary diary keeping is encouraged. Education about the eating disorder is furnished, as well as the normal body weight changes to be expected over time. Other problem-solving strategies are explored. An attempt is made to change fixed, maladaptive ways of looking at things. Interpersonal psychotherapy has produced good results, at least as good as CBT in some studies. Serum amylase estimations may be used to monitor vomiting behaviour.

Antidepressants of a number of classes¹⁹⁶⁵ have been reported as alleviating the symptoms of BN. SSRIs,¹⁹⁶⁶ particularly fluoxetine, may facilitate weight loss¹⁹⁶⁷. Since desipramine has been shown to be effective, it has been suggested that antidepressants may actually work by reducing hunger. 5-HT₃ antagonists, such as ondansetron, may have anti-bulimic effects.(Faris ea, 2000) D-fenfluramine, a 5-HT agonist, whilst it was useful in overweight patients was ineffective in BN. Topiramate, the dose of which should be increased gradually, reduces binge eating and purging in BN and can cause paraesthesiae, weight loss, and interfere with cognition. Bupropion (Zyban) is contraindicated in bulimia nervosa because of an associated high incidence of seizures. Also, trazodone has been associated with delirium in this patient group.

The combination of CBT and antidepressants may be more effective than either alone, but the literature is conflicting.

Prognosis

According to Keski-Rahkonen ea (2009) BN is often missed by clinicians, the condition is relatively chronic, and recovery is gradual, and, even when bingeing and purging is abandoned, psychological symptoms are common. Poor prognosis has been reported in association with high BDI scores on admission¹⁹⁶⁸ and (even subthreshold) vomiting. In general, a poor prognosis is associated with psychiatric comorbidity, mixed AN-BN, severe symptoms, and a lack of social supports. Good prognosis has associated with younger age at onset, higher socioeconomic status, and a family history of alcohol abuse. A number of authors (e.g. Kaye ea, 2000) have reported either relapse or exacerbation of BN following acute depletion of L-tryptophan.

Other eating disorder

The DSM-IV approach in terms of how much a case must binge or vomit strongly underestimates the frequency of such behaviours in the population at large. Clinicians encounter people who lack one or more features of AN or BN, i.e. partial syndromes. They also see cases that are not severe enough to warrant a diagnosis of AN or BN, i.e. subthreshold disorders. Anxious people who vomit those people who stop eating for attention-seeking reasons (personality disorder, political hunger strike) are not suffering from a formal eating disorder.

People who recurrently binge but have no other features of BN may be said to have 'binge-eating disorder',¹⁹⁶⁹ a syndrome that is reminiscent of what is commonly called compulsive overeating. (Cf. box)

Binge eating disorder

Two percent of women have this 'stable'¹⁹⁷⁰ (Pope ea, 2006) disorder and the M:F ratio is 2:3 making it the eating disorder with the highest rate for males. Like AN and BN, binge-eating disorder may be uncommon

¹⁹⁶⁴ **Phases of CBT in bulimia nervosa:** (1) Careful history and self-monitoring: food intake, binge eating, purging. (2) Slow shaping of at least 3 meals/day to shorten the long intervals between eating episodes typical of BN and to lessen dietary restraint. (3) Tackle cognitive distortions regarding caloric intake and body shape and weight. (4) Relapse prevention, e.g. coping with high-risk situations.

¹⁹⁶⁵ Because MAOIs have been associated with fatalities in BN as a result of non-adherence to dietary restrictions they should be avoided in this population.

¹⁹⁶⁶ Zimeldine (Zelmid), a 5-HT re-uptake inhibitor, was shown to be helpful but it was withdrawn because of an association with the Guillain-Barré syndrome. The newer SSRIs have stepped into the place vacated by zimeldine.

¹⁹⁶⁷ Paroxetine may cause weight gain.

¹⁹⁶⁸ But other workers found depression to be a non-significant prognosticator.

¹⁹⁶⁹ This was first described by Stunkard.(1959)

in black women.(Striegel-Moore ea, 2003) Childhood obesity and familial eating problems are risk factors for binge-eating disorder.(Striegel-Moore ea, 2005) There is consumption of large quantities of food in a short period of time, a sense of loss of control, followed by guilt and distress but no compensatory behaviours such as vomiting or laxative abuse. This pattern should occur at least two days per week for six months. Most, but not all, cases are obese. Binges may be driven by emotion more than hunger since the salivary response to food exposure is diminished.(Karhunen ea, 1997) CBT and interpersonal psychotherapy appear to be helpful (Shafran ea, 2008, p. 633; Wilson ea, 2010) and fluoxetine performed more poorly than CBT in one study.(Grilo ea, 2005) Guided self-help on CBT appear to be effective.(Wilson ea, 2010) Sertraline has been shown to be helpful and to be well tolerated. D-fenfluramine reduces the rate of bingeing at first but loses efficacy thereafter. Sibutramine¹⁹⁷¹ (Q.V.) has been effective and well tolerated in a study from Brazil.(Appolinario ea, 2003)

Purging disorder

Proposed subtype of eating disorder not otherwise specified.(Keel ea, 2005) It resembles BN but lacks full blown binge-eating episodes.

Night-eating syndrome

Prior to the description of binge-eating disorder, Stunkard ea (1955) described a 'night-eating syndrome', also known as nocturnal eating or drinking syndrome or 'sleep-related eating disorder'. The syndrome may affect 1.1-1.5% of the general population and many more people in weight reduction programs or awaiting bariatric surgery. Episodes occur before or at any time during the sleep period. Patients may be groggy during an episode and feel ashamed of what they have done. They may reduce their diurnal food intake in order to compensate for nocturnal eating or feeding behaviour may be normal by day. Some authors draw a distinction between night-eating syndrome (full consciousness, eating excessively before retiring or during awakenings) and sleep-related eating disorder (arising from non-REM sleep) on the basis of the level of awareness but they probably represent a continuum. Various drugs can precipitate the syndrome (anticholinergics, lithium, triazolam, zolpidem) as can drug withdrawal (including tobacco and alcohol) and dieting, stress, and narcolepsy. The classic case is an obese woman who eats or drinks excessively during the night ('evening hyperphagia' or taking in at least one-quarter of daily calories after supper). The condition may lead to obesity.(Stunkard ea, 2008) Chronic insomnia occurs (awakenings with ingestions at least 3 times/week). SPECT shows a significant increase in 5-HT transporters in the midbrain. SSRIs are the treatment of choice.(O'Reardon ea, 2006; Stunkard & O'Reardon, 2009)

Psychogenic vomiting

It has been suggested that there is a disorder called 'psychogenic vomiting' (Anonymous, 1992) in which there is chronic and episodic vomiting following meals and not accompanied by nausea. It is said to be less common than BN (self-induced following episodes of uncontrolled overeating), to be more common in females, and usually presenting in early or middle adult life. Treatment suggestions include psychotherapy and behaviour therapy.

Abuse of women, children and elders

Brian O'Shea

Many different people are at increased risk of suffering from abuse, e.g. the institutionalised, minority populations and those with intellectual disability. The latter are living longer than before and, because of the loss of loved ones, may be exploited, neglected or abused in some other way. (Turk & Brown, 1993) Factitious disorder by proxy, a disorder with a high lethality (Sheridan, 2003), is discussed elsewhere.

Violence against women

Most violence against women¹⁹⁷² is global, widespread, ongoing, under-reported, and is associated with poor physical and mental health. (Kumar ea, 2005; Clark & Wyshak, 2005; Ferris, 2007; Ellsberg ea, 2008) Perpetrators vary from spouses to bosses. (Watts & Zimmerman, 2002) Like many trauma survivors in general, survivors of domestic violence with PTSD have dysregulated HPA axes. (Griffin ea, 2005) According to Scott (1974), wife battering is often part of a wider 'battering family' and is associated with immaturity, jealousy, substance use and dependence, dependency, fear of loneliness, ignorance about more mature relationship patterns, personality disorder (particularly dependent and aggressive types), psychiatric illness in general, and, possibly rarely, sadomasochism. Gender inequality, be this in the social or muscular sense, seems an obvious factor. (Jewkes, 2002) According to Buist ea (2007, p. 436) some women remain in abusive relationships because they were abused as children and had inadequate parenting resulting in a poor self-image. However, women who leave an abusive relationship are at increased risk of lethal violence and the perpetrator often controls the available finances. (Beck, 2008, p. 1125) A woman may also stay in such a relationship in order to protect her children or because she has been manipulated into feeling responsible for or deserving of abuse. (Beck, 2008, p. 1130) Also, illegal aliens may fear deportation. Kyriacou ea (1999) lists the characteristics of the battering male partner as abusing alcohol or drugs, unemployed or intermittently working, less than high-school educated, and a former or estranged husband/boyfriend of the victim. Drug abuse in the victim may also be a factor. (Grisso ea, 1999) In one sample of American women, (Martin ea, 2001) 6.9% were abused before pregnancy, 6.1% during pregnancy, and 3.2% during the first few months postpartum. Violence during pregnancy¹⁹⁷³ seems to be more common when the pregnancy is unwanted or mistimed, (Gazmararian ea, 1995) and victims are not likely to inform medical staff (O'Donnell ea, 2000) or to be asked about it. (Bradley ea, 2002; Richardson ea, 2002) The antenatal clinic provides an opportunity to make enquiries about domestic violence. (McDonnell ea, 2006) Hegarty ea (2008) suggest that where intimate partner violence is suspected that all family members should be asked about any abuse in the family, that the safety of all family members should be checked on, that a safety plan may be necessary, that the response should be non-judgmental, on-going support should be offered, and that women and children should be referred to advocacy and therapeutic programmes, but that couple counselling is not to be offered outside specialist agencies. Do not raise the question of intimate partner violence with a perpetrator without the victim's permission.

¹⁹⁷² Such violence takes many forms, varying from forced prostitution and trafficking through domestic sexual abuse to wartime rape and female infanticide or selective abortion of girls. (Plafker, 2002; Fikree & Pasha, 2004; Sheth, 2006; Jha ea, 2006) About 1.2 million children are traded as commodities every year. The BMA points out that domestic abuse can be physical, sexual, psychological, and financial. (www.bma.org.uk) Sexual exploitation of children by UN peacekeepers and non-governmental (NGO) workers came to light in 2008; the UN is relatively powerless in such situations and member states must take responsibility. (Anonymous, 2008c) Rates of violence among same-sex couples are probably on a par with those in heterosexual households. (Beck, 2008, p. 1125)

¹⁹⁷³ The pregnant woman is likely to be beaten on the abdomen, the non-pregnant woman is more often struck in the face. (Stewart & Robinson, 1995) Spousal violence in Africa was shown to be associated with increased likelihood of single and repeated fetal loss, largely due to violence. (Alio ea, 2009)

Children should be educated about abuse in order to prevent the development of ingrained negative attitudes toward women and the 'normalisation' of violence and intimate partner violence should be viewed as unacceptable and morally abhorrent by the community. (Anonymous, 2009a)

Honour killings usually refers to the murder of a female relative by a man who does so because he believes the woman has shamed the family, e.g. by infidelity. In Pakistan in 2007 women were the victims of 636 honour killings, 731 rapes, and 736 kidnappings. (Anonymous, 2008; see Dobson, 2009) In one study of homicide in the Middle East honour killing was common and mostly committed by a brother. (Kulwicki, 2002) It would be a mistake to believe that such acts were confined to Muslims. The core problem appears to be the inferior or even slave status given to women. (Lafta, 2008)

Physical violence directed against male partners by women is not uncommon but tends to be less violent than *vice versa*. It is generally in self defence.

Child sexual abuse (CSA)¹⁹⁷⁴

Child sexual abuse (CSA) is not new (O'Shea, 2001a,b,c, 2009) but has received much greater coverage by the media than heretofore, largely as a result of 'revelations' of abuse by persons in positions of authority¹⁹⁷⁵. It is an international problem. (Reza ea, 2009) Historically, the first modern work on child sexual abuse (CSA) was that of Tardieu¹⁹⁷⁶ in 1857, although his writings were largely ignored. In 1883, Brouardel¹⁹⁷⁷ dismissed CSA as the result of genital hallucinations or a tactic to gain attention. Freud was convinced of the role of CSA in neurosis early in his career only to change his mind later when he stated that such reminiscences were imaginary. By that time he had alienated a number of his supporters because of his emphasis on the role of sex in the origins of neurosis.

Child maltreatment, including, CSA is a violation of children's human rights (Reading ea, 2009), be it at the level of the individual, institution, or wider in society. CSA is a sexual act imposed on a child, irrespective of its emotional, maturational, and cognitive development. Children cannot legally give informed consent for sex. Under Irish law, child abuse includes physical neglect¹⁹⁷⁸, CSA¹⁹⁷⁹, and adverse

¹⁹⁷⁴ This is discussed here because of its topicality and importance in practice with adult patients. Apart from CSA there may be neglect (extremely common: the child is not protected or cared for) or emotional abuse (persistent and severe rejection or maltreatment that jeopardises emotional/behavioural health, e.g. rejection, harassment, criticism, ridicule, humiliation, and threats; the child is usually neglected and emotionally abused). **Emotional abuse** may involve encouragement to develop inappropriate behaviour (ranging from drug abuse to sexual acts), preventing wider societal experience, non-inclusion in family activities, not providing emotional warmth, humiliation, intimidation, and exposure to violence, and generally poor parenting (unreliable, inconsistent, unpredictably changing rules, etc). The **National Counselling Service** (helpline 1800-234-111; www.hse-ncs.ie) provides free confidential professional counselling and psychotherapy for adults who were abused or neglected in childhood; the counsellor/therapist has a reporting duty if he/she 'has a reasonable concern that harm may be done to yourself, another, or where a child may be at current risk of abuse or neglect'. Delays of 'a number of months' before therapy are possible.

In 2009, the *Irish Medical Council* (medicalcouncil.ie) stated that child abuse/neglect must be reported to the appropriate authorities and/or statutory agency without delay and parents/guardians should be so informed unless doing so places the child in danger. If an adult discloses a history of childhood abuse the doctor must assess current risk to others and if someone is likely to be at risk the clinician should report the revelation, preferably with the patient's consent.

Of 3 million reports of alleged incidents of child maltreatment to US protective agencies in 2005 one in three were substantiated. 60%, 20%, 10%, and 5% of substantiated cases involve neglect, physical abuse, sexual, and emotional abuse, the remainder being unspecified; about 1,500 American children die each year from maltreatment. (US Department of Health and Human Services, Administration on Children, Youth and Families, 2007)

A systematic review of 23 prospective studies based on 16 cohorts (Weich ea, 2009) found that abusive parenting predicted depression, anxiety and PTSD and that maternal early emotional unavailability predicted attempted suicide in adolescents.

¹⁹⁷⁵ See the *Ryan and Murphy Reports* in Ireland of 2009 which looked at institutional and Dublin Archdiocese child abuse respectively. This author was well aware of such events at the rumour level when a schoolboy, but it was not something one confided to adults at the time. (O'Shea, 2009) Neither did one complain much of the corporal punishment handed out in school, although the latter would readily meet modern criteria for brutality. These Irish scandals are not unique and such abuse of power and cover up by clerical in general have an international dimension. (Anonymous, 2009b) Pope Benedict XVI sent a written apology to Irish victims of clerical sex abuse in March 2010. He called for a strengthening of child protection policies by the priesthood.

¹⁹⁷⁶ Auguste Ambroise Tardieu (1818-1879) was the most famous forensic medical man of the mid-19th century. He was Dean of Medicine at the University of Paris. His book, *Etude Medico Legale*, reached its 6th edition in 1978. He is better known for his writings on battered child syndrome (Tardieu's syndrome).

¹⁹⁷⁷ Paul Camille Hippolyte Brouardel (1837-1906) was a French pathologist and professor of forensics at the University of Paris.

¹⁹⁷⁸ See Dubowitz and Bennett (2007) and Gilbert ea (2009a,b).

¹⁹⁷⁹ Posing for pornographic movies/photographs should be included.

effects on any aspect of the child's development.¹⁹⁸⁰ Incest is variously defined by statute as a specific sexual act¹⁹⁸¹ performed between persons who are prohibited to marry. It should not be forgotten that sexual abuse can occur at any age, including in old age, and childhood abuse of any variety may predispose to abuse as an adult.(Coid ea, 2001).

Under the *Punishment of Incest Act 1908* a male perpetrator of incest can receive a life sentence whereas a female perpetrator can only be gaoled for up to 7 years.
Under the *Irish Criminal Law (Sexual Offences) Act 2006* the age for consent for sex for males and females is set at 17 years. Anyone defiling a person under 15 years of age will receive a life sentence; those defiling someone aged 15-17 years will receive up to 5 years in prison, double that period if the perpetrator is a person in authority over the victim. Consent is not a defence where the victim is less than 15 years old, but an honest belief that the victim was over 17 years may be allowed as a defence in the case of older children.

Estimations of the incidence of CSA vary considerably (Johnson, 2004) with time, place, definition (e.g. emphasis on incest) and methodology.

England

Estimates from police records - incidence of 6.6/million population in late 1970s

Over 100,000 cases a year in US in early 1980s

USA

One-fifth of female and one-tenth of male college students reported having some type of sexual experience (incl. exhibitionism) with much older person during childhood

Two million children run away from home annually, perhaps up to half of them because of abuse, primarily sexual

Up to 70% of prostitutes report childhood incest and/or rape

Incidence of violence in general (incl. physical/sexual abuse of minors, assault, suicide and homicide) is said to be common among Native Americans (Indians) (Nelson ea, 1992)

Australia

History of CSA in 5.9% of women and 2.5% of men

Ireland

About 1.2/1000 Irish children/year are CSA victims

50% of reported cases are confirmed¹⁹⁸²

McGee ea (2002) identified 16% of men and 20% of women in Ireland as having been victims of CSA

New Zealand

In a study of 16-27-year-olds, child protection agency history for maltreatment (abuse and neglect) is significantly associated with a range of subsequent mood, anxiety, and substance use disorders (Scott ea, 2010)

Views vary on the frequency of inter-sibling incest vary between those who believe it to be the commonest form of incest to those holding that its frequency has been exaggerated. Clinical experience may be with the most damaging or damaged cases of incest. Father-daughter incest, the most frequently reported form, often starts when the girl begins to develop adult sexual characteristics. Mother-offspring incest and other forms of female-perpetrated CSA are not as rare as was once believed and the perpetrator is not necessarily psychotic; in fact, society may have conspired against accepting the existence of incestuous mothers.

¹⁹⁸⁰ Of infant homicides, 6 of 10 are killed by the mother. The *Medea complex* refers to killing of a baby to spite a partner/spouse. Killing of a baby within a day of birth may involve mothers from problematic homes who hide their pregnant state from others. Some mothers may abandon the baby. Abduction of a child may reflect custody disputes, sex slave traffic, kidnapping (e.g. for ransom), or so-called baby-stealing, the latter usually being a female crime and may involve a psychotic woman with delusions (perhaps messianic) about the infant, an intellectually disabled woman who seeks comfort from the baby, or someone who uses the baby to influence her partner (e.g. she may feel insecure after a miscarriage and tell her partner that the baby is theirs).

¹⁹⁸¹ Usually involving some form of intercourse.

¹⁹⁸² Garda Commissioner in 1920s reported that CSA of girls under age of 14 was reported in only 25% of cases, only 15% of cases being prosecuted.(Ferriter, 2004, p. 324)

Female abusers may represent in excess of 10% of perpetrators¹⁹⁸³. Homosexual incest (e.g. father-son) is usually seen in very disturbed families with violent, alcoholic or psychopathic fathers, a dependent mother, and disrupted of roles and identities; it is rarely reported - the daughters are often also abused by the father in such cases. Abused sons may become violent towards themselves and others. It has been reported that males comprise between one-sixth and one-half of the total numbers of adults reporting CSA and that male children are more likely to be abused outside the family and to come from neglectful homes and those that were mother-headed. Casey and Craven (1999) wondered if boys were really abused less often than girls, and pondered about the possibility that abused females might simply be more likely to disclose the abuse. According to one estimate, the relationship of the perpetrator to the child victim is father in half of cases, step-father in 17%, father and mother in 2%, mother's boyfriend in 7%, uncle in 7%, grandfather in 6%, and brother in 11%. The age distribution of CSA victims in a 1989 Irish study, wherein almost a quarter of perpetrators were under 16 years of age, was 32% of victims aged 1-5 years, 44% aged 10 years, 21% aged 11-15 years, and 3% aged 16 years. A broader view of CSA from abroad revealed that most perpetrators are men known to the child, are often in authority positions¹⁹⁸⁴, and 'contrary to popular opinion, relatively few come from the child's immediate family'.

Abuser characteristics: CSA occurs in all socioeconomic groups. Many if not most adult child abusers may start abusing children when they themselves are still adolescents. Alcoholism is reported very frequently among those convicted of incest. Mental illness is unusual, IQ is usually normal, but personality disorder is common. In one random community sample, a childhood history of a disrupted home, substance abuse, suicidal behaviour, inadequate parenting, and physical abuse were associated with women who had experienced CSA. The long-absent man returning to an unfamiliar and aging wife and a teenage daughter, the bereaved husband, the overcrowded home, the socially or geographically isolated family, the rejected spouse, and psychopathy, increase the chances of father-daughter incest. Incest families compared to non-incest families demonstrate a rigid internal belief system, a dysfunctional parental coalition, parental neglect and emotional unavailability, and an inability to nurture autonomy in its members. Brother-sister incest is often the result of poor adult supervision, although, in the authors' experience, the parent(s) may also be involved, as may, rarely, children living in the neighbourhood. It should be noted in passing that about 10% of paedophiliacs¹⁹⁸⁵ are bisexual in orientation. Most are heterosexual and many have a personal history of CSA.

The spouse may promote the relationship or deny its existence. She may report it after a row and then stand by her partner. In fact, she is rarely the reporting party. In the authors' experience, this fact has attracted varying judicial interpretations, varying from compassion to condemnation.

The act: Sexually abusive behaviours include genital exposure, fondling, masturbation, fellatio, and cunnilingus, digital penetration of the anus or vagina, or penile penetration of the vagina. The father may simply lie with her with no intention of incest at first. Later there is masturbation and inter-femoral intercourse. The average length of such a relationship in one Northern Ireland study was eight years. Psychoanalysts stress a potential need of the child to subconsciously view the abuser as good, allowing a turning to the perpetrator for relief of distress; also, the abuser may find it essential to be seen as good by the child victim rather than as a predatory seducer.

Diagnosis: CSA can present in a wide variety of ways. CSA usually presents in one or more of 5 ways: an account by the child; disturbed or altered behaviour; physical signs or symptoms; by association with other forms of maltreatment; and through allegations by parents, relatives or other adults.

Pointers to possible CSA

Over compliant or pseudomature behaviour

¹⁹⁸³ A study of US males (Holmes, 2007) aged 18-49 years in which two-thirds of the sample participated showed that men from one-parent families were more than twice as likely to report having been sexually abused as those from two-parent families. The former were more likely to be abused by a female and a non-relative (female baby-sitters were alleged perpetrators in several cases) whilst those from two-parent families were more likely to be abused by a male and a relative.

¹⁹⁸⁴ Teachers, activity leaders, family friends, etc. The UK *Kerr/Haslam Inquiry*, published in 2005, concerns sexual abuse of patients by two male psychiatrists in North Yorkshire. According to Kennedy, (2006) 3-6% of doctors internationally have engaged in intimate sexual contacts with patients (without assault) and psychiatrists, GPs and gynaecologists may be at relatively high risk.

¹⁹⁸⁵ A small number of children are abused by 'sex rings', i.e. groups of paedophiles.

Acting out, aggressive or regressive behaviour, running away
 Hints about sexual acting out
 Persistent and inappropriate sexual play with peers or toys, seductiveness
 Detailed and age-inappropriate understanding of sexual behaviour
 Lack of trust
 Poor or deteriorating school performance
 Excessive fear of males
 Sleep disturbances
 Depression and suicidal ideas¹⁹⁸⁶
 Pregnancy
 Discharge (vaginal, urethral)
 Bleeding (vaginal, rectal)
 Sexually transmitted disease
 Psychosomatic and behavioural problems (abdominal pain, drug overdose, anorexia, encopresis, and enuresis)

A complicated course of bipolar disorder (drug misuse, early onset, attempted suicide) may be linked to various forms of abuse in childhood.(Garno ea, 2005) Certainly, the combination of PTSD (with reports of physical or sexual assault) and bipolar spectrum disorder significantly interferes with social functioning.(Neria ea, 2008) Psychosis in adult females should prompt enquiry about abuse of any type in childhood.(Fisher ea, 2009)

About 70% of children who have been sexually abused have no abnormal physical signs. The report of the enquiry into CSA in Cleveland in 1987 stated that *abnormal physical signs are rarely unequivocally diagnostic, with the exception of the presence of semen or blood of a different group to that of the child.* Reflex anal dilatation¹⁹⁸⁷ occurs in 14% of children, in most of whom abuse is not suspected.

On interviewing the child, the same principles as in the general psychiatric examination of a child should be used, and the child's spontaneous account should be acquired; repeated probing sessions are unhelpful and potentially harmful. The child psychiatrist should approach the interview with an open mind and, if a family interview has been conducted, an interview with the child should be conducted on his/her own. The psychiatrist should steer a course between the extremes of overly leading questioning and, on the other hand, being insufficiently enabling for the reluctant child. Toys and other materials may assist recall. Use of anatomically correct dolls requires special training, and video tape recording reduces the need for repeated interviews, although some children may find the latter inhibiting. Written records should be kept and must be compiled at the time of the interview.

Sequelae and adjustment: Abused females are at increased risk in adulthood for personality disorders (and earlier conduct disorder), anxiety (including panic: Goodwin ea, 2005) and depression¹⁹⁸⁸ (Kendler ea, 2004), self-harm¹⁹⁸⁹, suicidal ideation, alcohol and/or substance abuse and dependence¹⁹⁹⁰, (Nelson ea, 2006) increased sensitivity to stressful life events, (Kendler ea, 2004) and frigidity or sexual aversion.

Women who have experienced CSA are at risk for posttraumatic stress disorder which may be associated with diminished anterior cingulate blood flow on positron emission tomography during traumatic script-driven imagery and whilst recalling memories of the abuse. Summit (1983) described a 'child sexual abuse accommodation syndrome' wherein the victim keeps the abuse secret for fear of terrible consequences that might follow its revelation; secrecy carries the risk of being helpless to avoid further abuse; maladaptive behaviour with negative effects on personality development; disclosure, when it eventually occurs, is

¹⁹⁸⁶ Suicide attempts, without apparent explanation, especially among teenage girls, should raise suspicion of CSA. The connection between later depression and CSA seems to a general and non-specific one and allowance must be made for the activity of other variables.(Maniglio, 2010)

¹⁹⁸⁷ With child in lateral position, dilatation of anus when buttocks are gently parted.

¹⁹⁸⁸ This depression may be associated with smaller hippocampal volumes (Vythilingam ea, 2002), although PTSD may account for a greater reduction in size than does the CSA.(Bremner ea, 2003) Gershon ea (2008) found that gender differences in the prevalence of such internalising disorders as depression did **not** seem to be attributable to differences in victimisation during childhood.

¹⁹⁸⁹ A history of sexual abuse, together with a dysfunctional family of origin and imprisonment of self or other, has been correlated with repeated self-harm.(Keeley ea, 2003) In a meta-analysis (Klonsky & Moyer, 2008) found no direct relationship between CSA and non-suicidal self-injurious behaviour; instead, there is a modest relationship due to correlation with the same psychiatric risk factors.

¹⁹⁹⁰ Including a positive family history of alcohol misuse.

delayed and therefore more difficult to believe; and the person may then retract the allegation to prevent breakup of the family unit.

Worldwide 21-country¹⁹⁹¹ study: childhood adversity and persistent suicidal behaviour (Bruffaerts ea, 2010)

Interviews to record childhood adversities predating age 18 years

Suicidal behaviour = thinking, plans and attempts

Increased risk of suicidal ideation and attempt associated with childhood adversities

Sexual and physical abuse were the strongest risk factors for onset and persistence of suicidal behaviour, especially during adolescence

There is evidence that female CSA victims may have a sensitised anterior pituitary and counter-relative adaptation of the adrenal cortex that is independent of major depression. On subsequent exposure to stress, these women hypersecrete CRF/CRH that in turn leads to down-regulation of adenohypophyseal CRH receptors and symptoms of depression and anxiety. The TAT haplotype¹⁹⁹² of the CRH receptor 1 (CRHR1) gene may offer protection against adult depression in females following maltreatment in childhood. (Polanczyk ea, 2009)

The incidence of unconsciously motivated ('conversion') non-epileptic seizures has been shown to correlate with CSA, and in particular with the degree of sexual penetration and closeness of relatedness to the perpetrator. Reported also was an excess of CSA in the personal histories of patients with generalised tonic-clonic episodes. A New Zealand study of women who had experienced CSA reported an excess of immature defence styles (displacement, passive-aggression, somatisation, and projection, but, interestingly, not dissociation), increasingly so with the severity of abuse.

One theory holds that women internalise their own abuse with resultant problems such as eating disorders, whereas men may externalise by abusing others. One study of referrals to an eating disorders clinic found that 30% had a history of CSA and 52% were rated as personality disordered, and CSA figured more prominently in women with disorders of personality than in those without such disorders. However, others find no support for CSA as a risk factor for bulimia nervosa. CSA may be a vulnerability factor for psychiatric dysfunction in general but not for eating disorder in particular. However, a history of CSA may worsen and complicate the course of eating disorders.

Cause-effect relationships between CSA and later psychiatric problems in victims are very difficult to establish with certainty.¹⁹⁹³ CSA may have a stronger affect on adult depressive symptoms in adults with certain alleles, i.e. Met allele of BDNF gene and S carriers of the 5-HTTLR polymorphism. (Aguilera ea, 2009)

In a study looking at two groups of adult women, a non-clinical sample and an outpatient sample, the possibility of a good adjustment appeared strongly associated with the nature of the abuse experience. Non-forceful, non-intrusive, and rare or infrequent sexual contact, were the least likely to cause lasting harm. With more severe forms of sexual abuse, however, few women were able to avoid persistent ill effects. Those who experienced forceful, repeated, or prolonged abuse or severe physical violation, and especially those abused by much older men, especially at the hands of fathers or stepfathers, were very likely to report persistent sexual problems in adult life. Depression may also be somewhat more likely in women, who experience CSA, especially if it involved attempted or actual penetration. CSA may be associated with long-term hyper-reactivity of the hypothalamic-pituitary-adrenal axis and autonomic nervous system, similar to that found in depressive states, especially in females; and stress in adulthood could then be more likely to provoke depression.

Spataro ea (2004) conducted a prospective study of boys and girls to determine the subsequent levels of treatment by public mental health services for mental disorder. Victims of both sexes had higher rates of treatment than did general population controls (12.4% v 3.6%) and rates were higher for childhood mental

¹⁹⁹¹ These did not include Ireland or the UK.

¹⁹⁹² TAT haplotype is formed by rs7209436, rs110402, and rs242924.

¹⁹⁹³ CSA is reported as being over-represented in a number of disorders, e.g. irritable bowel syndrome.

disorders, anxiety disorders and major affective disorders, but not for schizophrenia. Male victims received treatment more often than females (22.8% v 10.2%).¹⁹⁹⁴

Abuse by fathers or stepfathers may have a more negative impact than abuse by other perpetrators. Only a small percentage of women subjected to severe abuse reported that these experiences had no lasting effects. Actual genital contact, especially if prolonged and penetrative, and the use of force seem more traumatic for the victim. When the families do not support the victim or if the victims were taken out of the home, the outlook may in fact be worse. Adult women sexually abused as children show increased rates of depression, self-destructive behavior, anxiety, low self-esteem, feelings of loneliness, drug abuse, and a tendency to re-victimisation. In one study, women who had been abused as children, when compared with controls, were more depressed, anxious, and fearful; fear and distrust of men, and difficulty with sexual functioning were the most common reported long-term difficulties.

Children with disability are at increased risk of all types of abuse; language delay is common in child victims of CSA; and developmental delay may be a consequence of CSA.

According to American follow-up research on abused children, data on whether they are removed from or returned to their parental is not often recorded. They may spend years in 'temporary' accommodation awaiting a judicial decision, and if they are offered up for adoption there are few families willing to accept them.

A history of physical and sexual abuse in childhood is common in the histories of criminals. Similar findings have been reported for adults with conversion disorder.(Roelofs ea, 2002)

Transgenerational abuse (TA): The rule of one-thirds has been applied to whether child sexual abuse (CSA) victims grow up to abuse their children: one-third does, one-third doesn't, and one-third might do it if stressed. Salter ea (2003) followed up 224 former male victims of sexual abuse over 7-19 years and found that 26 (11.6%) became abusers themselves, typically abusing children from outside their own families. Childhood risk factors for later perpetrator status included material neglect, lack of supervision, sexual abuse by a female, witnessing serious violence at home, and cruelty to animals. Protective factors were not discernible, despite the fact that the majority did not become 'victim-abusers'. Such resilience probably stems from a combination of genes, environmental factors and willpower.(Bouvier, 2003)

Legal: Hefty prison sentences await the perpetrator, but only a minority of cases are detected and less reach conviction; and some cases may only be detected during the investigation of unrelated offences.

Children's and Young Persons Act, 1969

England and Wales

Social services must inform police of suspected CSA

Mistaken professionals, reporting in good faith and with due care, have been offered protection against legal redress for longer in Britain than in Ireland

Court of Appeal ruled (August 2003) that children can sue healthcare trusts and local authorities that wrongly conclude that they have been the victims of abuse (Dyer, 2003)

Protection for Persons Reporting Child Abuse Act, 1998

Ireland

Came into operation in January 1999

Persons (acting reasonably and in good faith) reporting to designated officers of health boards (medical staff, social workers, psychologists, substance abuse counsellors, physiotherapists, and radiographers) or Gardaí are protected from civil liability

Malicious reporting: fine of £15,000 and/or 3 years imprisonment

Employers cannot penalise the reporter

Various provisions for appeal by/against employers

¹⁹⁹⁴ Of course, some of the controls may have been abused and perhaps only the most seriously abused may have been brought to the attention of the authorities.

Irish Department of Health and Children may be preparing a White Paper aimed at enforcing mandatory reporting of child abuse

Professionals in Ireland should notify the local health authority (Community Care) and/or Gardaí of suspected physical or sexual abuse or wilful neglect of minors without waiting for confirmatory evidence. (Department of Health & Children, 1999)

Mandatory reporting (after Gilbert et al., 2009b)

For: improves awareness and better information on the problem can be accumulated; promotes early reporting; child protection agencies receive more reports; stresses official seriousness; furthers debate on ethical and legal issues

Against: swamping of services; inhibits reporting by parents in case they lose control of child's future; vulnerable people are over-reported; avoids development of community supports for children; greater emphasis on investigation than on intervention; professionals may pass on the problem rather than share it; subjectivity regarding threshold for reporting

Culturally sanctioned female genital mutilation, (Morris, 2006) widespread in Africa, is increasingly likely to be encountered in the West, and research is needed into its psychological effects and legal implications.

'False memory syndrome' (FMS)/ factitious CSA dilemma

No absolute test of trustfulness in a private crime, shrouded in secrecy

Untruthful allegations may be more likely with custody and visitation disputes and when constructing a legal defence

In terms of child abuse generally, untruthful allegations of child abuse occur in about 5% of evaluated cases

Can destroy professional careers

Complaints of CSA may be true, partly true or false (Dyer, 2005)

False accusations have been knowingly made by child's mother (Rand, 1996)

Professionals should keep an open mind

Confrontational methods of extracting 'memories' of CSA are fraught with pitfalls and can harm the innocent

Hypnosis aids recall of both true *and* confabulated memories

Factitious rape, stalking, and amorous attraction are not unknown

Management: This includes individual and family psychotherapy, anti-androgen compounds such as cyproterone in selected cases, the management of other problems such as alcoholism, and safeguarding of younger siblings. Psychotherapeutic strategies to help abusers include taking responsibility for the abusive behaviour, identifying patterns of ab, learning preventive measures, victim empathy training, and learning how personal abuse may be shaping abusive behaviour.

The abused child must be helped to relinquish previously necessary but now redundant emotional coping strategies such as dissociation and self-blame, including guilt over any sexual satisfaction derived from the abuse. Denial is facilitated by the secrecy surrounding abuse. Therapists must recognise and contain the victim's anger (or muteness), handle their own feelings, and be cognisant of the reflections of past relationships in the transference, including role reversal of abuser-abused relationships¹⁹⁹⁵. A process akin to grieving must be negotiated before the abused can begin to live with abusive memories in some sort of tolerable way.

¹⁹⁹⁵ Child subconsciously assumes role of perpetrator and assigns child's role to therapist.

Based on a review of twelve studies, Ramchandani and Jones (2003) concluded that the best evidence of efficacy for improving psychological symptoms in sexually abused children was for CBT¹⁹⁹⁶, especially for young children.

Group therapy of sexually abused adolescent children more benefit girls more than boys, the latter often being vulnerable, needy and sexually aggressive and perhaps in denial.

Caution must be taken against professional over-reaction where knee-jerk actions are taken to confirm suspicions and without considering options for the child. Also, be wary of under-reaction: not believing the child and taking no action to protect the child. The protection and best interests of the child must remain paramount. Case conferences are necessary, as liaison can be critical. To remove the child or perpetrator from the family home, how best to screen prospective employees in sensitive occupations and how to supervise carers are perennial questions and these must be answered in context. Electronic tagging of paedophiles is practiced in some countries: the police know if the paedophile strays beyond certain geographical limits. Extreme measures such as castration are practiced in some jurisdictions, e.g. California.

Some preventive issues: Children should know about appropriate and in-appropriate touching. The employment of the sexual attractiveness of minors, for example in fashion magazines, should be critically re-examined. Governmental support for families is important. There is evidence that male babysitters and stepfathers may be more abusive than female babysitters and biological fathers.

Comments: Early research concentrated on incest, only later enlarging its purview to include CSA outside the nuclear family. Abuse by teachers and religious and of those placed in care, the subject of intense media coverage, has hardly been researched at all in the scientific literature.

The childhood profile of those who eventually developed the strongest suicidal behaviour in a 21-year follow-up New Zealand study was characterised by the accumulation of many adverse social, family, personality, and mental health factors, only one of which was CSA. Those who were abused often denied it had happened. Childhood sexual and physical abuse is associated with later alcoholism, but such abuse is also associated with a family history of alcoholism, especially in the father. Suicidal ideation in a community sample of women with major depression was associated with a history of childhood physical abuse.(McHolm ea, 2003)

The great majority of fathers do not abuse children and the quality of parenting by **both parents** is a factor in determining risk of CSA by biologically unrelated perpetrators. Preliminary work with non-abusing parents of CSA victims is suggestive of a positive effect on psychopathology in both themselves and their children.(Forbes ea, 2003)

Elder abuse

Elder abuse/maltreatment or 'granny battering', abuse of an older person within a relationship normally based on trust, has only received attention since the mid-1970s and doctors¹⁹⁹⁷ are not as familiar with the concept as they are with, say, child abuse. A majority of cases are not reported. Definitions are unclear, there are no pathognomonic indicators, patients may conceal abuse, cases may not hold up in court when 'beyond reasonable doubt' is required of evidence, and professionals may accept or deny it. %. According to Hirsch & Vollhardt (2008, p. 734), depending on methodology¹⁹⁹⁸, the community prevalence of elder abuse has ranged from 1.2% to 10.8%. However, Cooper ea (2009) conducted a cross-sectional survey of English¹⁹⁹⁹ family carers of demented relatives living at home and found that 52% of carers reported some abusive behaviour and 34% reported more significant levels of abuse, whereas only 1.4% (3 carers) reported occasional physical abuse. The authors point out that those who practiced the most abusive behaviour may not have reported it.

¹⁹⁹⁶ Abused children with PTSD may benefit from a **trauma-focused CBT** comprising psychoeducation (teach child and caregiver ways of avoiding abuse), anxiety management (relaxation to reduce fear in response to abuse-related memories), exposure (talk, drawing, writing to gain mastery), and cognitive therapy (replace cognitive distortions and self-blame).(Cohen ea, 2000)

¹⁹⁹⁷ Medical students may misclassify non-abusive measures, such as exit camouflage to prevent egress, as abusive.(Thompson-McCormick ea, 2009)

¹⁹⁹⁸ *Action on Elder Abuse* (2007: www.elderabuse.org.uk) reported 62,000 cases of physical abuse, 86,500 cases of financial abuse, 105,000 cases of neglect, and 42,000 cases of sexual abuse in the UK. The *Mental Capacity Act 2005* in England makes it an offence to wilfully neglect or ill treat someone who lacks capacity.(Williams, 2008) The *Adult Support and Protection Act 2007* in Scotland more specifically protects vulnerable adults.

¹⁹⁹⁹ London and Essex.

Perpetrators include spouse, adult children and other persons/organisations who occupy caring roles. Perpetrators may suffer from alcoholism or psychiatric disorders. Care giving may lead to an excessive burden and depression in the carer. (Cooper *et al.*, 2010) Carers, who may be financially dependent on a sick relative, often give up important parts of their lives in order to care and this may lead to emotional difficulties, social isolation, and physical exhaustion. An early abusive relationship between carer and patient may antedate current mutual abuse. Abuse may be triggered by, e.g. stress in the carer or incontinence or dysphasia in the victim. Multiple forms of maltreatment constitute the commonest scenario and a sense of helplessness compounded by passivity on everyone's part often complicates matters. Victims are often unable to defend themselves. They may have a physical or psychiatric disorder, including cognitive disorders. The abused elder may become disturbed which may lead to further abuse. Abuse may arise from acts of commission (physical, psychological/emotional, financial) or of omission (neglect and abandonment).

Institutional abuse, as in hospitals and nursing homes, takes many forms and includes loss of personal power in an excessively authoritarian environment, poor staff levels and wages, burnout, underappreciated work, poor training and supervision, over-large facilities, and stresses in the personal lives of care workers. Aggressive behaviour in the patient may predate retaliation by staff. Abuse may be inherent in cultural values, as when it is assumed that being old is synonymous with lack of competency (infantilization) and a drain on societal resources.

Some pointers to elder abuse

General – repeated admissions, restricting visitors, forcing elder to live where he/she does not want to live, e.g. a care home

Physical – bruising in strange places like wrists or soles, cuts, injuries of various age, bilateral injuries, restraint injuries, occult fractures, over-medication, broken spectacles or hearing aid, etc

Psychological – inconsistent history, unusual behaviour/mood

Sexual (O'Brien & Smock, 2003; Kennelly *et al.*, 2007) – injury to breasts/genitalia, rectal/vaginal bleeding/bruising, STD, etc

Financial – stealing, bank account violations, not filling prescriptions or other poor care despite having money to meet such needs, etc

Neglect – delayed help-seeking, infantilization, irregular/excess/inadequate medication, decubiti, malnutrition, severe weight loss, dehydration, poor hygiene, dirty home, unsafe stairs, etc

Iatrogenic – ageism, not paying heed to dignity issues, etc

The Irish Health Services Executive (HSE) elder abuse service²⁰⁰⁰ originally received about 1,500 referrals²⁰⁰¹ over 12 months, 10% of which were notified to the police²⁰⁰². 83% of referred people lived at home and the vast majority (965) of cases involved intrafamilial abuse. Further details are given in the box.

Health Service Executive (HSE) elder abuse service 12-month referrals (Mulholland, 2008)

Type of abuse – 29% psychological; 21% neglect; 20% financial; 17% physical

Referrers – 34% community healthcare staff; 23% other HSE staff; 11% family

HSE elder abuse service 12-month referrals for 2009 (Mulholland, 2010)

1,870 referrals of which 435 were for self-neglect only – of remaining 1,435: 34% psychological; 22% financial; 20% neglect; 14% physical

Alleged perpetrators: 46% son/daughter; 20% other relative; 18% partner/husband/spouse

Elder abuse (including excessive coercion and sedation in institutions), which is more often chronic than once-off, should not be tolerated and society must canvass for protection of its elderly. Blame is not constructive and is best avoided, unless referral to the legal authorities is considered necessary. The media should highlight the problem in a constructive way. Victims should receive treatment for any psychological or physical damage incurred and protection at a level commensurate with past abuse and the likelihood of

²⁰⁰⁰ The HSE launched a campaign called 'Open Your Eyes' in 2008 order to raise awareness of elder abuse.

²⁰⁰¹ Acknowledged as not reflecting elder abuse in total.

²⁰⁰² Referral to Gardaí (Irish police) depends of elder's wishes and type of alleged abuse.

its persistence. Photographs of injuries should of forensic standard. Multidisciplinary team involvement is necessary to ensure that all needs are recognised and, as far as possible, met. Everyone involved should be interviewed alone and collectively. Communication, problem-solving, and conflict resolution skills should be thought. Acknowledging the difficulties inherent in caring may lead to open admission of shortcomings. Day care, respite admission, nurse visitation, and home help are among the interventions to be considered. The GP must be informed of the findings of any assessment. Good documentation of decision-making pathways is important if the clinician is wrong about abuse having occurred.(Williams, 2008)

Psychosexual medicine²⁰⁰³

Brian O'Shea

'Sexuality is a social construction, and medicalisation is the new social construction'. (Tiefer, 2002)

Unfortunately, training in psychosexual medicine amongst psychiatrists is often poor and few of them feel comfortable the psychosexual aspects of clinical work. (Rele & Wylie, 2008) DSM-IV and ICD-10 artificially divide up sexual disorders in a way that does not reflect clinical practice. For example, it is not uncommon to see a male patient who has both premature ejaculation and erectile dysfunction or a woman with combined hypoactive sexual desire (low sex drive) and vaginismus. Concerns have been rightly raised that we may pathologize sexual problems. Low or absent desire may reflect problems in a relationship and some difficulties may be relatively mild and transient.

Gonadal and secondary sexual differentiation

Genetic sex is determined at conception. During the first weeks of pregnancy the gonads are undifferentiated. A Y chromosome causes testicular development through the agency of H-Y antigen. Absence of Y chromosome or H-Y antigen leads to ovarian development. The presence or absence of foetal androgen (from any source) determines genital development. Foetal androgen in a genetic female, such as occurs in adrenal hyperplasia, leads to male genitalia, even if ovaries are present: the baby has male or ambiguous genitalia. Even in a foetus with Y chromosome and testes, absence of foetal androgen, as occurs when an enzyme is deficient, or the presence of abnormal androgen receptors, such as happens in testicular feminisation, lead to female genitalia.

Congenital adrenal hyperplasia: *In this inherited condition²⁰⁰⁴, a girl (genetically females with ovaries, etc) produces excess androgens whilst still in utero and is born with masculinised external genitalia. If the latter are surgically corrected in infancy the girl will have a female gender identity and role; if not corrected, she will view herself as being male and act as such. This condition flies in the face of theories that androgenisation in utero influences the formation of gender identity. Psychological adaptation studies variously report no excess (Morgan et al, 2005) or an excess (Slijper et al, 1998) of psychiatric morbidity. In real life, most probably cope well, others finding life difficult. Barriers to help-seeking need to be overcome. (Cull, 2005)*

Imperato-McGinley syndrome: *This condition was described in 1979. Testosterone is converted to dihydrotestosterone by testosterone 5- α -reductase. Testosterone is thought to masculinise the brain and internal genitalia, and dihydrotestosterone to masculinise the external genitalia. The chief source of androgens in females is the adrenal. When there is a deficiency of testosterone 5- α -reductase the production of dihydrotestosterone does not happen, with a resultant female appearance to the external genitalia at birth. Virilisation occurs at puberty. These people have a heterosexual male gender identity and psychosexual orientation.*

Normal range of sexual responses

The normal sexual response of the mature male consists of a baseline followed by excitation to a plateau phase that culminates in orgasm²⁰⁰⁵. Orgasm is succeeded by a refractory (to further sexual excitation) period during which there is sexual quiescence. The female response is similar with the exception of the absence of a refractory period. The longer resolution phase in the female may occasionally cause problems if the partner simply goes to sleep after sex. It should be noted that the normal outer one-third of the vagina narrows and the inner two-thirds dilate when the woman becomes sexually excited.

Ejaculation is mediated via the sympathetic nervous system and the thoracolumbar spinal cord²⁰⁰⁶. Orgasm in both sexes involve involuntary contractions in both internal and external sphincters with, in addition, 4-5 contractions of prostate, seminal vesicles, vas

²⁰⁰³ Paraphiliacs usually have more than one deviation. The history is usually lengthy, presentation being for the one for which the person was arrested. The relapse rate is very high. Claims of being 'cured' may arise for legal purposes. Sexual crimes accounted for 1% of indictable offences in the Republic of Ireland in 1998.

²⁰⁰⁴ **Pseudogenes** are mutated gene duplications incapable of translation into functional proteins. They may misalign with a neighbouring normal gene during meiosis and a crossover may mutate the normal gene. An example is the mutation of the gene for 21-hydroxylase, leading to congenital adrenal hyperplasia.

²⁰⁰⁵ Orgasm may occur in some females with complex partial seizures whereas their male counterparts may only experience discomfort in the penis!

²⁰⁰⁶ Truitt and Coolen (2002) found a possible ejaculation generator in rat lumbar spine.

deferens, and urethra in males, and, in females, 3-15 contractions in lower vagina as well as sustained uterine contraction starting in fundus and spreading to cervix.

Orgasmic intensity may decline with age for various reasons, e.g. reduced strength of muscle contraction.

Sexual orgasm has been reported in humans of either sex when the septal area of the brain is stimulated directly. Stimulation of the posterior portion of the postcentral gyrus can give rise to genital sensations. Epileptic foci arising from the paracentral lobule can give rise to genital sensations as part of the aura. (Ike & Segraves 2003, p. 339) Most patients with spinal cord injury fail to ejaculate, or if they do, it is either without orgasmic sensation or only with an awareness of some altered feeling. The majority of male paraplegics with spinal cord injury put resumption of sexual function first in their list of priorities. (Anderson, 2004) Patients with spinal cord injury often say that they develop an area of arousal lying superior to the level of the lesion leading to sexual satisfaction ('phantom orgasm') from tactile experiences such as a caress.

When a man is sexually stimulated the penile tissues produce nitric oxide²⁰⁰⁷ that then stimulates the release of guanylate cyclase, the latter triggering the conversion of guanosine triphosphate to cAMP; cAMP relaxes smooth muscle²⁰⁰⁸ leading to vasocongestion and penile erection. Phosphodiesterase 5 deactivates cAMP. Since the clitoris has no tunica albuginea the clitoris becomes swollen but not rigid.

Visual stimulation leading to an erection is accompanied by activation of claustrum, paralimbic regions, hypothalamus and striatum, whereas direct penile stimulation is associated with activation of the insula. (Georgiadis & Holstege, 2005)

Testosterone does improve sexual interest in hypogonadal men but it does nothing for sexual desire in males who already have enough testosterone. Very low testosterone levels in females (adrenalectomy, oophorectomy, menopause) may impair sexual desire and the administration of testosterone may improve matters, but most women with low sexual desire do not have excessively low testosterone levels and giving them testosterone may make matters worse (facial hair, acne, etc.). (contrast Bhasin et al, 2007 with Heiman, 2008) A female testosterone patch (Intrinsa) is available for women with low sexual desire associated with distress who have had an early menopause due to hysterectomy and bilateral oophorectomy and are receiving concomitant oestrogen therapy. Oestrogen does not significantly affect a woman's sexual drive (Moynihan, 2005) and the evidence for progesterone is mixed. (Meston & Frohlich, 2002) Dopaminergic drugs like levodopa tend to increase sexual desire in males, and there is limited evidence for such an effect in females. Longterm use of opioids reduces libido in both sexes, possibly by decreasing testosterone and luteinising hormone (LH) levels. Sexual arousal in females is facilitated by the sympathetic nervous system. Sexually functional women and those females with low sexual desire show increased physiological sexual arousal after exercising (or if given ephedrine) if they were then shown an erotic film, exercise alone not being enough. Conversely, drugs such as clonidine (sympatholytic) impair sexual arousal. (Meston & Frohlich, 2002)

The mean reported onset of menstruation in a sample of Irish schoolgirls in 1990 was 12.5 years. (Fitzgerald et al, 1990) The mean reported onset of menstruation in Irish girls was 13.52 and 12.53 in 1986 and 2006 respectively. (O'Connell et al, 2009)

Women can remain clitorally responsive throughout life and can be multi-orgasmic at an advanced age and, unlike males, they have little change in the post-orgasmic refractory period, but they may face a scarcity of sexual partners, have vaginal dryness, etc. Sex is not confined to the young. (Kleinplatz et al, 2009)²⁰⁰⁹

There is little evidence for an andropause (the equivalent of the female climacteric in males). Gould et al (2000) suggested that androgen sensitivity develops in older men and might benefit from testosterone.

Masturbation is an almost universal practice that may be excessive under conditions of anxiety. Guilt over this practice is either cultural or depressive. Mutual masturbation, cunnilingus (blowing air into the pregnant vagina is a rare cause of death – embolic?), and fellatio are not abnormal *per se* and may form part of normal foreplay. Masturbation fantasies may play an important part in perpetuating deviant sexual behaviour. In such cases it is necessary to advise either neutral thoughts or ordinary heterosexual intercourse fantasies during the act.

Preventable causes of death in the US in 1990 included 1% of total deaths from high-risk sexual behaviour. One should not prematurely conclude that all sexual inadequacy in chronic mentally ill people is due to prescribed drugs. Such illnesses have a profound effect on psychosexual development and function, as have institutional life, intellectual disability, illegal drugs, lack of opportunity, and so on. Most effeminate boys grow up to be heterosexual, some will be homosexual, and transsexualism is the least likely outcome. Tomboyish behaviour in girls is less likely to cause parental concern than effeminacy in their sons.

We are living in a rapidly changing world. Cybersex (teledildonics) involves computer programmes of increasing sophistication designed to deliver 'virtual' sex to the user! The net is crowded with advice on how to improve one's sex life. One such promise is to deliver a larger penis! In fact, there are two procedures for doing so: division of the suspensory ligament that holds the penis to the pubic arch and injected of fat removed from elsewhere. The first procedure leads to a slightly longer penis that falls forward and with hair on the shaft (pubic skin pulled forward), and the second gives an uneven, lumpy penis! (Bolton, 2005)

Sexual disorders in psychiatric practice are classically divided into the deviations and the dysfunctions. Before proceeding to deal with these conditions we will deal with the premenstrual syndrome (PMS).

²⁰⁰⁷ Nitric oxide (NO) seems to control tone in the vaginal smooth muscle and high NO levels are associated with better vaginal lubrication.

²⁰⁰⁸ Anoxia is thought to stimulate conversion of corporal smooth muscle cells into fibrocytes.

²⁰⁰⁹ **Sex in the elderly:** Doctors should enquire about the sexual lives of older people and older people generally want to be asked. Such enquiries normalise and affirm what has for too long been taboo. (Kleinplatz, 2008) Whilst older men think about sex, older women are more likely to be satisfied with intimacy. (Basson, 2000) Even if older people do not have sex it does not mean that they do not view it as important. (Gott, 2005) Lindau et al (2007) found that older US adults are often sexually active (M>F), they were less sexually active if they believed they had poor health, and those (common) with sexual dysfunction (M: erectile problems; F: low desire, dry vagina, inability to climax) infrequently spoke to a doctor about it. Relationship factors and mental health may be better predictors of sexual activity than physiology in older women compared to their male counterparts. (Bancroft, 2007) A Swedish study of 70 year olds found that the amount and quality of sexual experience has improved over a 30 year period. (Beckman et al, 2008)

The premenstrual syndrome (PMS)

The reason women complain about physical, psychological and behavioural changes during the week before menstruation are complex and aetiology is most likely multifactorial. Some symptoms do not cease with menstruation (hence the term 'paramenstrual') and some women experience mild symptoms during the follicular phase. In a study of over 40 women in Oxford during the 1980s, the symptoms of PMS disappeared in two-thirds of patients after hysterectomy (? primary psychological cause) and persisted, albeit less intensely, in the others (? primary physical cause). (After hysterectomy, certain core complaints, such as irritability and breast tenderness, may persist in cycles, suggesting a possible role for the hypothalamus or ovaries.) In an earlier study, two-fifths of PMS developed for the first time following pregnancy. A later twin study found evidence in favour of a genetic factor in the aetiology. However, a still later twin study could not distinguish between environment and genes; neither could it determine what was inherited, e.g. PMS itself or neuroticism. Other possible causes include dysregulation of the serotonin system²⁰¹⁰, hormones (low progesterone, high oestrogens, and raised prolactin), MAO, BDNF Met, a deficiency of pyridoxine²⁰¹¹, cyclical transient hyperparathyroidism²⁰¹², and activation of the renin-angiotensin - aldosterone system.

Epperson ea (2002) conducted an MRS study on PMS and healthy females. They found a relative reduction in cortical GABA levels during the follicular phase in the PMS group. Cortical GABA levels declined across the menstrual cycle in healthy women, whereas women with PMS experienced an increase in cortical GABA levels from the follicular phase to the mid- and late-luteal phases. Whilst some women are found to have thyroid dysfunction the consensus is that PMS/PDD is 'not a masked form of hypothyroidism'. (Steiner & Yonkers, 1998, p. 3)

Many physical (migraine, allergy, asthma, seizures, herpes genitalis) and psychiatric (depression, mania, psychosis, anxiety/panic, bulimia, drug abuse) disorders are exacerbated premenstrually. These conditions should not be confused with PMS. Ekebert ea (1986) found no relation of statistical significance between the day of self-poisoning and the menstrual cycle phase in a study of women with regular menstruation admitted for self-poisoning. However, the idea that women kill themselves or commit illegal acts²⁰¹³ more commonly in the premenstruum persists.

The term '*premenstrual dysphoric disorder*' (PDD – DSM-IV) may cover a much less common group than PMS does: 3-8% v up to 75% of women according to Steiner and Yonkers (1998) and as low as 1.3 according to Gehlert ea. (2009) However, Yonkers ea (2008) suggested that most cases of PMS meet PDD criteria. Gehlert ea (2010) state that while PDD shares somatic symptoms with PMS, its psychiatric symptoms preponderate and they suggest that PMDD might be seen as a psychiatric condition. PDD cases are very depressed, anxious, with labile affect, and have reduced interest in activities. Strictly defined, PDD occurs during the week before a period but never after one. However, at least 75% of women report minor or isolated premenstrual changes. (Van Leusden, 1995) There may be a deficiency of GABA.

Three to five percent of women (figures vary) report that at least one physical or psychological symptom reaches severe or temporarily disabling proportions during the week before a period. Some women's symptoms peak after the start of menstruation.

Clinical features of PMS

Physical - painful or tender breasts, feeling of being swollen, pain in head/ back, stomach cramps, rashes

Psychological - tension, depression, irritability, fatigue, insomnia, labile emotions, forgetfulness, feeling lonely

Behavioural - inefficiency, dropping things, accident-proneness, avoidance of social gatherings

DSM-IV premenstrual dysphoric disorder

²⁰¹⁰ E.g. tryptophan (5-HT precursor) depletion or use of methergoline (5-HT receptor antagonist) may exacerbate the symptoms. (e.g. Roca ea, 2002)

²⁰¹¹ Acts as a co-enzyme, pyridoxal phosphate, in DA and 5-HT synthesis.

²⁰¹² Reduced peri-ovulatory calcium levels and increased levels of parathormone levels (due to increased oestrogen before ovulation?) in PMS and premenstrual dysphoric disorder patients reported by Thys-Jacobs ea. (1995) Supplemental calcium (600 mg b.i.d.) might normalise fluctuations in calcium/parathormone, thereby regulating effects of calcium on neurotransmitters.

²⁰¹³ Malmquist (2006, p. 77) is not impressed by the level of evidence.

In the majority of menstrual cycles during the last 12 months: at least 5 of the 11 symptoms shown below are present for most of the last week of the luteal phase and they remit within a few days of onset of menstruation and are not present in the 7 days after the period (at least 1 symptom must be from 1-4)

1. Low mood/dysphoria
2. Anxiety/tension
3. Labile mood
4. Irritability
5. Reduced interest in usual activities
6. Poor concentration
7. Lack of energy
8. Significant changes in appetite, including craving food/overeating
9. Too much or too little sleep
10. Overwhelmed by everything
11. Other physical complaints, e.g. bloating or tender breasts

Symptoms must severely disrupt coping/relationships, not be an exacerbation of another condition, and diagnosis is prospectively confirmed by rating symptoms every day for at least 2 consecutive cycles

Management: A diary should be kept for a few months before and during treatment. Psychological problems should be sought and addressed.

Some proposed treatments for PMS

Placebo²⁰¹⁴

Supportive psychotherapy, marital counselling, other forms of psychotherapy

Treatment of any thyroid anomaly

Regular small meals to prevent hypoglycaemic tension

Multivitamins or vitamin B6²⁰¹⁵

Polyunsaturated fatty acids as in evening primrose oil²⁰¹⁶

Calcium carbonate

Exercise and relaxation

Pure progesterone

Combined oral 'pill'²⁰¹⁷

Oestradiol implants with combined cyclical progestagen²⁰¹⁸, oestradiol patches

Bromocriptine²⁰¹⁹

Danazol

Diuretics without potassium supplements

NSAIDs

Gonadotrophin releasing hormone analogues

Naltrexone

Light therapy may reduce depressive ratings. SSRIs, e.g. fluoxetine 20 mgs/day (continuously or from day 15 of cycle to several days after start of each period), are often effective for PMS.(Dimmock ea, 2000) Sertraline gives better results with longer treatment although relapse rates are still high and especially so if baseline symptoms are severe.(Freeman ea, 2009) It should be noted that after a decision by the European drug regulator that premenstrual dysphoric disorder was not 'a well-established disease entity', this indication was dropped from Prozac's (fluoxetine) data sheet in early 2004.(Moynihan, 2004) PDD may be a sounder argument for drug therapy than PMS. CBT may produce an effect that is slower in onset but lasts

²⁰¹⁴ Some say 50% response, range 20-80%., others putting it at 40-90%.

²⁰¹⁵ B6 may cause neuropathy with ataxia, numb hands and perioral numbness, if used in high dosage: > 2 G/day, or > 200 mgs/day in the long run – this may persist.(Tomkins, 1994)

²⁰¹⁶ Gamma-linolenic acid – used because some PMS cases have reduced blood levels of essential fatty acids; randomised controlled trials have not produced evidence of efficacy.(Steiners & Yonkers, 1998, p. 15)

²⁰¹⁷ This has made some cases worse and evidence for efficacy is lacking.

²⁰¹⁸ E.g. dydrogesterone.

²⁰¹⁹ Take at night because of side effects.

longer than SSRIs.(Hunter ea, 2002) Alprazolam given in the late luteal phase²⁰²⁰ may help some cases. 'A simple approach', according to Massil and O'Brien (1986), would be to use an oral contraceptive for younger women who do not want to become pregnant, and a progestagen (e.g. dydrogesterone) for women unsuitable for the 'pill'. Both regimens may be combined with vitamin B6. Dydrogesterone (Duphaston) 10 mgs, b.i.d., from day 12 - day 26 of the menstrual cycle may be of benefit for those patients with multiple symptoms. Exercise helps. Alcohol and caffeine are best avoided before a period.

Rape trauma syndrome

This has two phases.(Burgess & Holmstrom, 1974) The short term (hours to days) is characterised by emotional shock, disbelief, despair at a life-threatening experience, and somatic symptoms, eating and sleeping problems, and emotional reactions such as mood swings, anxiety and depression. During the long term (months to years) the victim tries to reconstruct her life and relationships.

*Lesbian and gay people (homosexuality)*²⁰²¹

'The concept of unconscious homosexuality has been so exaggerated...that...there would be...only two types of men, those who are homosexual and those who think they are not'. (Jean Delay, quoted by Moussaoui, 2002, p. 99)

In the recent past, when homosexuality²⁰²² (HS; O'Shea, 2001; Kaplan, 2004) was considered a 'disease', various forms of 'therapy' were employed, including electrical aversion therapy (high voltage, low amperage), lysergic acid, chemical castration (with hormones), narcoanalysis, gender reassignment surgery (in South African military hospitals), and psychotherapy. Homosexuality may be less common than bisexuality.

Data from the USA in 1993 based on a national survey of men showed that only 2% of sexually active men had sex with other men during the preceding ten years, and only 1% were exclusively HS, figures significantly lower than in the classic, unrepresentative, and probably inflated, Kinsey²⁰²³ (Kinsey ea, 1948, 1953) reports. Later Western studies of homosexual practices (Johnson ea, 2001; Jorm ea, 2002) found prevalence rates for males and females of 1-2.8% and 1.4-2.6% of males and females respectively. Too many studies have been confounded by recruitment in gay bars, and such results are unlikely to be typical of the wider population. Definitions of homosexuality vary between studies. In 1979 in the US 10% of adolescents were said to have experience of HS, whereas in 1994 in the UK 6% of 16 to 24 year olds had such an experience. HS activity is often transient in adolescence.

The nerve supply to the anal margin is the same as for the genitalia. Males who are raped by anal intercourse may be particularly upset if they experience erection and even ejaculation, not realising that this is a physiological response to pressure on the prostate.(Osterman ea, 2003) One-third of HS males do not practice anal sex; one-third of British couples practice it occasionally and about 10% have it as the preferred or regular method; therefore more British heterosexuals practice anal sex than do gay men! Also, one in ten heterosexual couples in the US practice anal sex at least occasionally.

Since 1973, the APA has dropped HS as a disorder. Female transvestism is apparently very rare, and unlike male cases, these women are almost always HS.²⁰²⁴ The primary transsexual (always believed he is

²⁰²⁰ **Premenstrual dysphoric disorder (PDD):** DSM-IV-TR excludes mere exacerbation of symptoms of other disorders, e.g. depression or panic disorder, or indeed of personality style/disorder magnification. However, a woman may have the latter plus PDD. In women having menstrual periods, the *late luteal phase* occurs between ovulation and menstruation onset. The *follicular phase* starts with menstruation. In women without periods (including those who had the uterus removed) the timing of phases may need measurement of reproductive hormones.

²⁰²¹ Gay Doctors Ireland: gaydoctorsireland.ie

²⁰²² The term lesbian (syn. sapphism) comes from the island of Lesbos on which the poetess Sappho once resided. Another name for homosexuality in Krafft-Ebing's day was 'congenital inversion'!

²⁰²³ Alfred Kinsey (1894-1954), American biologist.

²⁰²⁴ **Homosexuality (HS) as a disorder:** Karl Heinrich Ulrichs (1825-1895) argued against German sodomy laws in a treatise of 1864 and suggested that HS represented a third sex. Ulrichs was fired as a legal adviser to a Hanoverian district court when it became known that he was homosexual. Karl-Maria Kertbeny (1824 [Vienna] -1895 [Budapest]), a journalist and another advocate of the dissolution of sodomy laws, coined the term 'homosexual' during the 1860s. Richard von Krafft-Ebing (1840 [Mannheim] – 1902) adopted Kertbeny's terminology but believed that HS was a degenerative disorder of the nervous system. In 1914 the German homosexual psychiatrist, Magnus Hirschfeld (1868-1935) added his voice to the third sex idea. The Nazis burned books taken from his *Institut für Sexualwissenschaft* in 1933. Sigmund Freud (1856-1939) saw HS as a normal phase in development but that its adult persistence was due to arrested development, i.e. fixation at an earlier psychosexual stage. Later, Sandor Rado (1890-1972), a Hungarian, viewed HS as a phobic avoidance of heterosexuality caused by problems with early parenting. Largely as a result of gay protests and studies such as those of Kinsey, the APA removed HS as a disorder from the seventh printing of DSM-II in 1973 but

female), unlike his secondary counterpart (later onset of belief in opposite sex status, e.g. during adolescence) does not have HS fantasies. The combination of HS and personality disorder makes for difficulties in interpersonal relationships, just as it does in the case of heterosexuality. Homosexual erotomania, the delusional belief that someone (who may even not know one) loves one, has been described in a patient with AIDS.

HS occurs from time to time in animals but exclusive HS is confined to humans. Most children who develop an HS orientation²⁰²⁵ have heterosexual parents. A small minority of HS only become aware of their orientation late in life, sometimes in the setting of a failing marriage or the responsibilities of parenthood, but most people know their orientation very early on. The determinants of sexual orientation and the timing of its development are poorly understood, and they are not necessarily the same in each sex. Most effeminate boys grow up to be heterosexual in orientation, and tomboyish behaviour in girls is less likely to cause parental concern. Psychoanalytic explanations for lesbianism have included a rejecting, emotionally distant mother and a powerful, frightening father. A minority of psychotherapists may still occasionally view homosexuality in a client as a pathology requiring treatment. (Bartlett *et al.*, 2001; King *et al.*, 2004) Some HS or bisexual people experience negative reactions to the discovery of their sexual orientation because of attitudes acquired from others, so-called 'internalised homophobia'. Awareness of homosexuality can surface at widely different ages for different people. A large controlled community study of retrospective accounts by HSs of their parenting found no major differences from those of heterosexuals. The finding that the adoptive brothers of HS twins were more prone to HS than their biological siblings favours an environmental role. Cultures accepting of HS may allow expression of HS and heterosexuality in the same individual. Cultures discriminating against gays and bisexuals may account, at least in part, for reports of high levels of mental disorder (especially in males: Fergusson *et al.*, 2005) in these people. (Warner *et al.*, 2004) Many women, and to a lesser degree men, seem able to change or modify their sexual preferences at different times during their lives.

In a study of identical and non-identical twins and the adoptive sisters of HS probands recruited through advertising in American lesbian-oriented publications, and after complicated corrections and assumptions were made, Bailey *et al.* (1993) concluded that the heritability of their sample was significant at over 25%. Hamer *et al.* (1993) linked male HS to the X-chromosome, but there are several methodological problems associated with this research. Baron (1993) stated that if HS was genetically determined it 'would have become extinct long ago because of reduced reproduction'. There are interpretative problems with twin research, and adoption studies are rare.

Two small groups of neurones in the human hypothalamus show sexual dimorphism (inter-sex differences), being nearly twice as large in men as in women. There is some evidence that these nuclei may also be smaller in male HS, which has been explained on the basis of circulating perinatal androgens. However, explanations which favour hormones as the chief source of gender identity²⁰²⁶ (person's concept of him/herself as male or female, as distinct from sexual orientation) must contend with the proven effects of rearing in people with difficult-to-assign sex²⁰²⁷ at birth. There is in fact no demonstrable hormonal difference unique to HS. Also, any reported difference in structure or function has to account for the feedback effect of HS itself! Similar problems bedevil research into anorexia nervosa.

HS is no longer illegal in Ireland. In England, the age of consent for heterosexuals is 16 years. It is also 16 years (reduced from 21 years in 1994 and 18 years in 1998) for male HS, despite House of Lords opposition²⁰²⁸. Custody and visiting rights are more likely to be granted to HS women than men. However, few cases come to court or are reported. There is a need for follow-up studies on children reared by HS couples. Children are just as likely to be sexually assaulted by a heterosexual parent as by a HS one. (King & Pattison, 1991) The British Parliament voted to allow unmarried couples, whatever their sexual orientation, to adopt children jointly. (Golombok, 2002) A number of jurisdictions now permit same-sex

replaced it with 'sexual orientation disturbance', i.e. ego-dystonic HS. The latter was replaced by 'ego-dystonic HS' in 1980 in DSM-III but was omitted from DSM-III-R in 1987. DSM-IV-TR contains 'sexual disorder not otherwise specified' (including persistent and marked distress concerning sexual orientation), 'identity problem' (can include uncertainty about sexual orientation/behaviour), and 'phase of life problem' (problems associated with phase of development or life circumstances not explicable by mental disorder).

²⁰²⁵ Sexual orientation is probably best viewed dimensionally, from exclusive homosexuality to exclusive heterosexuality. Most adolescents who engage in homosexual behaviour will become heterosexual adults.

²⁰²⁶ Gender identity develops early and is usually established by 3 years of age.

²⁰²⁷ E.g. women with congenital virilising adrenal hyperplasia.

²⁰²⁸ No special age for females!

marriages (and attempts to curb them – 1996 US *Defence of Marriage Act* defines marriage as a heterosexual matter: 26 US States ban same-sex marriages and a number of other US States offer civil unions) and some others offer marriage in everything but name²⁰²⁹.

Jurisdictions allowing same-sex marriage (SSM; gay marriage)

2001 – Netherland first country to allow SSM

2005 – Spain²⁰³⁰ (and Canary Islands) recognises equality between SSM and opposite-sex marriage
Belgium, Canada, Norway and South Africa

USA – Massachusetts and California

Most paedophiles are heterosexual: according to Meston & Frohlich (2003) 2% of the general population are homosexual as against 40% of paedophiles. Those who are stalked by people of the same sex as themselves get less consideration from law enforcement agencies that victims of opposite gender stalking. HS males have an increased risk for perianal carcinoma. Oral sex is relatively safe from the HIV point of view²⁰³¹, but carries the risk of contracting gonorrhoea and non-specific urethritis. Lesbians are at relatively low risk for HIV. Faeco-oral spread may involve Giardia and hepatitis A. Increased risk for hepatitis B indicates multiple partners rather than individual sexual practices.

King ea (2003) conducted a cross-sectional survey in England and Wales and found that gays of both sexes demonstrate an excess of psychological distress, saw a mental health professional more often, deliberately harmed themselves more frequently, and were more likely to use recreational drugs than were heterosexuals; lesbians were more likely to have experienced verbal and physical intimidation and to consume more alcohol than heterosexual women. Smith ea (2004) point out that, despite decriminalisation of HS in Britain in 1967, attempts to treat it continued, leaving many in distress.

If the problem is one of adapting to HS (or bisexuality) the therapist helps in clarifying thoughts, options and consequences. If the orientation is bisexual or mainly heterosexual and the client wants to 'be' heterosexual, the avoidance of HS cues (incl. thinking about it while masturbating), the seeking of closer liaison with the opposite gender (e.g. clubs), and thought distraction techniques could be advised. Lesbians may enquire about relationship problems such as jealousy, insecurity, or sexual dysfunction with other women, or indeed with a man in their lives. Despite Freud's thinking on the origin of paranoid thinking there is no evidence for a specific link between HS and pathological jealousy.

Obesity and sexual health

Obesity is associated with greater likelihood of erectile dysfunction. A French study (Bajos ea, 2010) found that obese women are less likely to have had a recent sex partner compared to women of normal weight but that obese people have similar sex practices and enjoy sex as much as other people do; obese women, more than obese men, are more likely to have an obese sex partner; and unplanned pregnancy and abortion are more likely among obese females because of reduced use of contraception. Goldbeck-Wood (2010) suggests that contraception data, focusing on the 'pill' and condoms, be treated cautiously and that long acting reversible contraceptives are suitable for obese women.

²⁰²⁹ Same-sex partnerships that are not recognised by law are associated with various difficulties: next-of-kinship, pensions, tenancy, inheritance tax, and illness in, institutionalisation of, or death of a partner.

²⁰³⁰ Spain allows gays to adopt and receive artificial insemination on same terms as heterosexuals.

²⁰³¹ According to the Irish Department of Health, 35% of deaths from AIDS up to July 1991 were among 'homosexuals/bisexuals' (H/Bs). This same group constituted 38% of known AIDS cases; there were 79 cases of AIDS among H/Bs, with 33 deaths, up to September of the same year, another 2 cases being recorded by late November. Seven of the latter were known IV drug users, with 6 deaths. However, a different source puts the figure for AIDS among HSs at 185 by that date; and another source still gives a minimum figure of 94 cases of H/B AIDS cases by the end of 1991! By the end of 1992, a year in which 38 Irish people died of AIDS, the rate of increase in HIV-infected cases was greatest in the heterosexual population. One fifth of HIV infected persons in 1994 were HSs, compared with 50% IV drug users and 13% heterosexuals. Twenty three percent of HIV cases notified in 1998 were HS. The breakdown of actual new cases of HIV in the following year was: total 209, drug misuse 69, heterosexual 59, HS 40, children 23, and prisoners 13.

In the US, up to the end of 1993 62% of males with AIDS got it from sex with other men, 2% of females received it from other women, and men infected 35% of women.

Parkinson's disease

Up to 60% of cases have arousal or orgasmic dysfunction. L-DOPA may increase sexual drive²⁰³² and improve erections. Increased sexual drive is common in patients treated with dopaminergic agents. Reduced levels of prolactin may play a role in such cases. A very few percent of patients on L-DOPA, especially males with early-onset paralysis agitans, become hypersexual and may masturbate excessively, indulge in sexual liaisons, and develop a wide variety of paraphilic tendencies. Management includes reduction in the dose of the offending drug and, if necessary, low a potency antipsychotic drug or anti-testosterone therapy.(Levy & Cummings, 2000)

Paraphilias²⁰³³

Sexual identity - personal feeling of maleness or femaleness

Gender identity - feeling that one is a man or a woman

Gender role - behaviours and attitudes considered appropriate for males and females in a given culture

Gender constancy - refers to the belief that one's sex is immutable - occurs at 5 to 6 years of age

Paraphilia - absence of a socially normative sexual object (the conservative object being the mature heterosexual partner) and aim (sexual intercourse, courtship, rearing a family, etc)

Exclusive paraphilia - deviant behaviour is essential for sexual satisfaction

Non-exclusive paraphilia - person is able to experience conventional as well as paraphiliac desires, although the latter are often preferred option

Intermittent paraphilia – the person only occasionally pursues paraphiliac needs (e.g. when under stress) or may have experienced paraphiliac needs during adolescent that later became dormant (e.g. during a satisfying sexual relationship) only to become overt again when under stress (e.g. break-up in a personal relationship)

Deviation - has many applications:

(a) unusual

(b) a symptom of an illness, physical or psychiatric

(c) behaviour is not acceptable to the society or subculture, e.g. immoral, illegal, etc

What behaviour is acceptable has varied with time and place throughout human history.(de Silva, 1999)

Not all sexual offences are driven by sexual desire. In such cases there is nothing to be gained from attempts at drive reduction.

Only the imagination limits what has been found to be sexually arousing, varying as it has from sneezing to the wind. Paraphilic behaviour is more common in males, although the number of females thought to be affected may be underestimated.(Agnew, 2001) No single personality profile would characterise any one paraphilia. Multiple paraphilias in the same person (polymorphous perversity) is a common finding. Paraphiliacs have achieved officially sanctioned positions looking after children, e.g. leader of a youth group. Not all paraphiliacs act out their fantasies or commit offenses. Few paraphiliacs look for help before an offence and the history is usually one measured in years before the person is arrested.

*Paedophilia*²⁰³⁴ (*vide supra*) is much commoner in males²⁰³⁵ and about 1% of homosexuals are paedophiles. Perhaps 60% of paedophiles are heterosexual, although figures given for different sexual orientations by different sources may add up more than 100%! Most give a history of CSA. Paedophilic behaviour may commence in the late years of life as a consequence of the disinhibiting effects of dementia. Psychopathy and brain damage (e.g. temporal lobe dysfunction) are common in the uncommon cases of paedophilic homicide. Most children seem to become involved with paedophiles because of fear, but a few may be promiscuous and delinquent. Contact may be made with minors via the internet. SSRIs and naltrexone are among the drugs reported to be helpful in some cases of paedophilia.

²⁰³² Sometimes this amounts to paraphilia.

²⁰³³ These were formerly known as sexual deviations/variations. 'Paraphilia' (*para*, beyond the usual; *philia*, love) was coined by Wilhelm Stekel (1868-1940) in 1923. Stekel, an Austrian physician and psychologist and one-time disciple of Freud, died from suicide in London. Paraphilias in DSM-IV, disorders of sexual preference in ICD-10.

²⁰³⁴ *Child molestation* is broader than paedophilia: some paedophiles never act on fantasies and a person who never fantasises about minors might still have abused them.(Brotto & Klein, 2007, p. 540) Technically, paedophilia means sexual attraction to prepubescent children whereas *hebephilia* refers to sexual attraction to postpubescent children.

²⁰³⁵ But it is not exclusive to males.(Brotto & Klein, 2007, p. 541) It has been reported in association with Klinefelter syndrome.

Fetishism comes from the Portuguese for charm (*piquantism*, Fr. to arouse another's curiosity, infers the use of a fetish to facilitate sexual intercourse). Any living or inanimate object (e.g. soft or shiny materials, nappies, gloves) becomes necessary for successful sexual arousal. According to classic psychoanalytic theory, fetishism involves persistence of castration anxiety, anxiety being warded off by an uncommon belief that women possess a penis (therefore they won't want to cut off the man's penis)! There have been reports of an association with temporal lobe epilepsy. It has been rarely reported in women. (Brotto & Klein, 2007, p. 539) However, de Clérambault described 4 women who were arrested for stealing silk: they could only masturbate with stolen silk. (Draaisma²⁰³⁶, 2009, p. 264)

Necrophilia - sexual relations with the dead – may kill to obtain a corpse - schizophrenia, intellectual disability, and psychopathy common

Gerontophilia - sexual preference for elderly people - assault and rape may occur - young males are the usual perpetrators

Autogynaephilia – sexual arousal from notion of being equipped by physical attributes of both sexes; may look for hormones in order to achieve this state (e.g. a man wants breasts to go with his penis)

Apotemnophilia – sexually aroused by crippled people or amputees - much more common in males - may seek amputation or attempt it themselves²⁰³⁷ - *idée fixe* rather than a delusion – First (2005) draws parallels between amputation-seeking and gender identity disorder

Acrotomophobia – desire for sex with an amputee

Pygmalionism – use of sexual fetishes in human form

Partialism - focusing on one part of the body, such as the feet, to the exclusion of all else- aetiological theories usually based on learning theory (baby follows mother's feet leading to imprinting) or analytical philosophising.

Vogueing – dressing up as a celebrity to achieve arousal; *trashcanners* steal objects from dustbins of famous people for the same reason

While the use of actual fetish objects is more common among males, fetishistic fantasies are possibly equally distributed between the sexes. Treatment is either aimed at extinguishing the fetish (aversion therapy) or helping all parties concerned to adapt to harmless fetishes.

*Sadomasochism*²⁰³⁸: (a) *Sadism*²⁰³⁹. The sadist loves to make (consenting or non-consenting) others suffer. Sadists express their fantasies overtly. Consequences for the victim range from humiliation through beating to rape or death. Treatment is disappointing. (b) *Masochism*²⁰⁴⁰: The masochist wants to be humiliated²⁰⁴¹, this experience being necessary for orgasm. Behaviour therapy may have some effect. Reasons underlying the need to 'atone' require exploration. It is not uncommon to find both traits in the one person, with one predominating.

*Pornography*²⁰⁴² is strictly defined as obscene written descriptions used to induce sexual excitation although it can and does involve the other senses in practice. Sometimes a distinction is made between 'soft' (e.g. showing breasts) and 'hard' (e.g. showing genitalia) 'porn'. This may make as much sense as the same distinction between drugs of abuse. The relationship between pornography and sexual offences is controversial. Use of 900-number telephone sex lines in the USA, and similar facilities elsewhere, may lead to great financial indebtedness. This is only a paraphilia if there is a compulsive quality to it and if it is preferred to actual sex with a partner. Personality disorder and/or paraphilias may be overrepresented.

*Voyeurism*²⁰⁴³: The voyeur observes others involved in sexual activity, rarely harming anyone. Most are immature males who are afraid of real female contact. It may date from the viewing of parental sexual

²⁰³⁶ Draaisma (2009, p. 268) suggests that de Clérambault himself may have harboured similar fetishes!

²⁰³⁷ Apotemnophilia and amputee identity disorder do not necessarily co-exist in the same person.

²⁰³⁸ At least since Freud joined both terms it has been known that both 'poles' of this perversion are often linked; there is also a frequent association with fetishism and transvestic fetishism. What is included here is real sadism and masochism rather than simulated masochism.

²⁰³⁹ After the Marquis de Sade, a sadist, 1740-1814.

²⁰⁴⁰ After Sacher-Masoch, an Austrian novelist, 1836-95.

²⁰⁴¹ *Infantilism* refers to the wish to be treated as a baby, e.g. by wearing nappies. *Algolagnia* is the isolated love of pain.

²⁰⁴² 'The writings of harlots'. *Narratophilia* is the seeking of arousal from hearing sexual stories, *hybristophilia* is arousal sought from criminals, and *chrematistophilia* is arousal from being forced to pay for sex or from being robbed by the sex partner.

²⁰⁴³ Scopophilia or 'Peeping Tom'.

display during the voyeur's childhood. *Triolism* is the name given to the phenomenon whereby a man achieves sexual pleasure from watching his female partner having sex with another man. Voyeurism in women is rare, but this does not mean that think about or even peep!(Friday, 1975)

Transvestism: This is sexual arousal achieved by wearing hidden or visible (longstanding cases may feel confident enough to wear opposite sex attire publicly) female clothing. It can be normal and transient in adolescents. If persistent it becomes truly a fetish, i.e. it becomes essential before orgasm can be achieved. Masturbation is the usual accompaniment. Stealing clothes may lead to legal proceedings. Relapse may follow perceived rejection or other emotional stressors. Covert homosexuality may be present. Fenichel, the psychoanalyst, stated that the transvestite creates a 'phallic woman' of himself to allay fears of castration (cf. fetishism)! Aversion therapy has been used in the past. Clubs for transvestites have sprung up worldwide. Few people give up the practice completely despite any drawbacks they may encounter. Cross-dressing can be classified as follows. The *fetishistic transvestite*²⁰⁴⁴ is a male who wears female clothes as a fetish and masturbates while doing so; it is often associated with fetishism and masochism. The *transsexual* forms the second group.(*vide infra*) The double or dual role transvestite, usually male, spends part of his time as a heterosexual male and part dressed and passing as a female; unlike the transsexual, he has no desire for a permanent sex change. Lastly, the *homosexual transvestite*, who is of either sex, is attracted, of course, to members of the same sex. It is important not to assume that someone who engages in cross-dressing has something wrong with him. Some men, independent of sexual orientation, find the experience to be a calming one.(King, 2008, p. 703)

Sexual attraction to cross-dressed or anatomically feminised men is called *gynandromorphophilia*.

Stealing of used underwear from clothes lines is referred to as *snowdropping*.

*Transsexualism (gender identity disorder)*²⁰⁴⁵ was generally defined as involving the immutable belief, dating back to at least puberty, that the person is trapped in the body of the wrong sex. In fact, not every child with transsexualism retains this diagnosis into adulthood, although many boys who were transsexual as children will be homosexual or bisexual as adults. Many experts believe that gender identity disorder is part of a spectrum ranging from mild atypical gender behaviour through gender dysphoria to gender identity disorder. A collateral history is important to confirm the long-held belief of being trapped in a body of the wrong sex.

Primary - always considered himself as being female, even as a child; does see himself as homosexual; does not report homosexual fantasies; likely to cope well with surgical sex reassignment²⁰⁴⁶

Secondary - starts to feel that he is female at a later age, usually in adolescence²⁰⁴⁷; less likely to do well after surgery; described as essentially homosexual or transvestite

Transsexualism mimics – adolescence (a time of identity problems), effeminate homosexual males (transient wish for erotic reasons), borderline personality disorder (transient wish related to identity diffusion), and delusions (e.g. alien-induced incorrect genitalia)

Female children with the adrenogenital syndrome²⁰⁴⁸ may be boyish during childhood, but they do not become transsexual. Zhou et al (1995) found that the central subdivision of the bed nucleus of the stria terminalis in the hypothalamus was smaller in male-to-female transsexuals than in normal males and akin in size to normal females. The authors did not believe that this finding could be attributed to hormone therapy. Occasional cases of transsexualism following the onset of temporal lobe epilepsy have been reported and (generally uncontrolled) studies have reported an excess of EEG abnormalities in transsexuals. The transsexualism may disappear with anticonvulsant treatment.

²⁰⁴⁴ DSM-IV-TR limits this transvestic fetishism to males who are homosexual, which is patently not true.(Blanchard & Collins, 1993) Onset is very early in life. It was reported to occur at least once in 2.8% and 0.4% of Swedish males and females respectively.(Langstrom & Zucker, 2005)

²⁰⁴⁵ Gender identity disorder; eonism: Chevalier d'Eon de Beaumont, 18th century transsexual. Transsexual people, who naturally do not like the word 'disorder', prefer the term *transgender*. **Transgender Equality Network Ireland**, 085-1477166, www.teni.ie, info@teni.ie.

²⁰⁴⁶ Some non-transsexuals may seek sex reassignment, e.g. transvestites and effeminate homosexuals males.

²⁰⁴⁷ A small number of male cross-dressers may, after many years, cease to be excited by the activity and gradually become more certain that they are female.

²⁰⁴⁸ Excess androgen before and after birth.

Very rough estimates of prevalence for transsexualism are 1 per 30,000 adult males. The condition is very rare in adult females (1 per 100,000)²⁰⁴⁹. These figures refer to people seeking sex-reassignment surgery in the USA. (Becker & Johnson, 2003, p. 745) Transvestism and a desire for surgical re-sexing are integral components of the condition. It has been described in discordant MZ twins. Sex drive has been described as often being low and any sexual orientation is possible. Depression, substance abuse, personality disorder (borderline/dissocial/narcissistic²⁰⁵⁰), parasuicide, self-mutilation (often to force surgical intervention), and divorce are common. In one study, Dutch psychiatrists considered that gender identity disorder was an epiphenomenon of other psychiatric conditions (especially personality, mood, dissociative, and psychotic disorders) in 270 (75%) of 359 patients. (Campo ea, 2003) Female transsexuals are said to be more often homosexual than are their male counterparts. Rarely, chronic transvestism may change to transsexualism. If the patient can live as a woman for a certain number of years he can, in some countries, have a sex change (surgery and hormones). Over half of US States and most Western European countries allow birth certificate changes. In 2002, UK transsexuals received the right to marry a man or a woman and to have their gender changed on birth certificates²⁰⁵¹, whether or not sex reassignment surgery had been performed. A male-to-female transsexual was refused permission to change the name on the birth certificate in an Irish court in July 2002. In a case that divided medical opinion, a 13-year-old Australian girl was allowed hormone treatment as a possible prelude to later sex-change surgery. Some patients procure hormones via the internet or from abroad. (De Gascun ea, 2006) Many psychiatrists offer supportive psychotherapy only. Some patients view psychotherapy with suspicion, viewing it as a way of discouraging surgical intervention. (Becker & Johnson, 2003, p. 747) Patients can be determined to accept nothing short of surgery. Snaith (1987) reported that about 70% of patients are satisfied with the results of gender reassignment. Perhaps the strongest predictor of psychological problems following surgery is level of satisfaction with the results of surgery. (Barrett, 2008, p. 715) Some have sought surgical reversal to their former gender and others have committed post-reassignment suicide. Thorough evaluation and long-term support is required, and preliminary HIV testing has been advocated. Even in Britain, local services may be inadequate. (Murjan ea, 2002)

Female transsexuals require androgens (implant or IM injections). Oral androgens might be associated with increased risk of developing hepatocellular carcinoma. Surgical creation of a penis may fall short of expectations and such patients may need to accept non-penetrative sex.

Exhibitionism (flashing) is the commonest sexual deviation to involve legal proceedings²⁰⁵². About 20% appear in court on a second charge. A man (most often young, and can be married) exposes his penis, in any state of tumescence, to a female from a safe distance in lonely surroundings, and there is rarely any physical contact. He tries to shock her. Exhibitionism begins early in reproductive life and becomes most frequent when the perpetrator is under stress. The notion that such men are shy and immature has been undermined by research. (Brotto & Klein, 2007, p. 539) Cases that masturbate and shout at or touch the victim are more potentially dangerous than are those who simply expose themselves. Exposure to minors, a history of non-sexual crimes, a previous conviction for exhibitionism, and exposure of an erect penis suggests recidivism. Management has included aversion therapy (e.g. imagining the scene and dreadful consequences), group therapy (spousal involvement when feasible), and drugs. Rarely one comes across women who repeatedly expose their breasts, and very rarely one sees women who do the same with their genitalia. (Federoff ea, 1999) However, according to Blair and Lanyon, (1981) female exhibitionistic behaviour is usually performed for monetary gain rather than for any sexual pleasure experienced on their part.

Coprophagia - eating of faeces, as the preferred method of achieving sexual arousal; may be part of a masochistic ritual; masochist may have to lick the sadist clean; coprophagia and *coprophilia*, the storing of faeces²⁰⁵³ are usually associated with intellectual disability, the degenerative psychoses of childhood, and

²⁰⁴⁹ The De Gascun ea(2006) Dublin series consisted of 52 cases, 45 male to female, and 7 female to male.

²⁰⁵⁰ This is not necessarily an aetiological relationship. (e.g. Fossati ea, 1999)

²⁰⁵¹ The *Gender Recognition Act* requires backing of two doctors, one a specialist and the other usually the GP. The applicant must have lived in their assumed gender role for at least 2 years. Application is made to the Gender Recognition Panel in Leicester (www.grp.gov.uk). Of course, their birth certificate must be a UK one.

²⁰⁵² It does not include homosexual courting.

²⁰⁵³ Sometimes defined as thinking about or observing defecation.

schizophrenia; term coprophilia may also refer to the deriving of sexual pleasure from watching the act of defecation; these terms should not be confused with coprolalia (utterance of obscenities as in schizophrenia or Tourette syndrome)

Infundibulation (stigmatophilia) – making holes, piercing or inserting rings²⁰⁵⁴ in the skin

Partial asphyxia (hypoxiphilia, asphyxiophilia) - man dons feminine attire and suspends himself on stairway while masturbating; plastic bag may be placed over head; rope may be suspended around neck to alter consciousness; may meet their death this way by accident

Urophilia (undinism²⁰⁵⁵) - aroused by watching the act of urination, by being urinated upon (*golden shower* or *urolognia*), by urinating during sexual intercourse, or by drinking urine

Sexual urethrisms - usually a woman who is aroused by urethral stimulation; *urethralism* involves pleasure in inserting objects into the urethra, e.g. catheters (*catheterophilia*)

Klismania or *klismaphilia* - use of enemas as sole or chief source of sexual pleasure

Mysophilia - sexual arousal by filth or smelly, soiled clothes

Telephone scatologia - obscene phone calls replace orthodox sexual outlets

Frotteurism²⁰⁵⁶ (Fr. to rub) - man rubs up against unsuspecting female,²⁰⁵⁷ often on crowded public transport; usually fantasises about an exclusive, caring relationship with the female; said to be associated with Asperger's syndrome

Bestiality (Zoophilia) - sexual preference for intercourse with animals; stereotype is young, mentally subnormal shepherd; in *formicophilia* there is a preference for small creatures touching the genitalia

Sodomy (anal intercourse) – in medicine buggery²⁰⁵⁸ is synonymous with sodomy²⁰⁵⁹ but legally it refers to either sodomy or bestiality; an increase in the number of men practising anal sex in England was reported in 1991

Pederasty (paederasty) - anal intercourse practiced by adults with boys

Oralism - focusing on oro-genital contact to the exclusion of sexual intercourse

Management: It is insufficient to aim at removing the sexual variation/paraphilia. Conventional outlets should be boosted, e.g. *orgasmic reconditioning* (think of paraphilic behaviour whilst masturbating but switch to a more acceptable fantasy when orgasm becomes inevitable) and *covert sensitisation* (fantasise about the paraphilic behaviour but add a noxious element, such as imagining being caught or having diarrhoea), although the effectiveness of such approaches is unclear. In some cases it may be pragmatic to make a fetish more acceptable to a partner, e.g. by settling for the wearing of a leather armband instead of full leather gear.

Cognitive-behavioural approaches are useful. Group therapy, the effects of which are modest, aims include accepting responsibility, empathising with the victim, and nourishing true motivation for change/controlling behaviour. The aim is to reduce recidivism rather than cure.

Drugs used for excessive (uncontrolled, dangerous) sexual drive: These drugs may be best for paraphilia patients with a high sex drive rather than for antisocial paraphiliacs with a low sex drive. (Cooper, 1986) In one meta-analysis (Hanson and Morton-Bourgon, 2005), the best predictors of recidivism were sexual deviation and antisocial tendencies. Hormones do not guarantee absence of recidivism and they are not a stand-alone therapy. It is important that patients accept responsibility for their actions and that they become involved in psychotherapy. Luteinising hormone (LH) controls testicular androgen secretion. Progestogens inhibit LH secretion from the pituitary. Anti-androgens like cyproterone and medroxyprogesterone act to decrease testosterone levels and to block its receptors. Cyproterone (or ciproterone) acetate²⁰⁶⁰ (Androcur) is a synthetic, progesterone-like antiandrogen that caused a decrease in serum testosterone, LH and FSH levels and a rise in serum prolactin. It is a competitive inhibitor of testosterone and dihydrotestosterone at androgen receptors. 50 mgs b.i.d. p.o. is a reasonable average dose. It may cause a reversible atrophy of the

²⁰⁵⁴ An example would be a Prince Albert ring piercing the penis.

²⁰⁵⁵ Gk: water spirit.

²⁰⁵⁶ Also called frottage; if the hands are used to touch the other person the term *toucherism* (e.g. surreptitious touching or rubbing of another's genitals) has been applied.

²⁰⁵⁷ Frotteurism is excessively rare in females. (Federoff et al, 1999)

²⁰⁵⁸ This term arises from the Bosnian Bogomils, a tenth century heretical sect (e.g. God had 2 sons) that was said to practice sodomy.

²⁰⁵⁹ Called after Sodom (*Genesis* 18-20), the city of evil.

²⁰⁶⁰ This was synthesised in Germany by Wiechert, 1961.

seminiferous tubules or liver damage (check LFTs) and can also cause gynaecomastia (up to 20%, sometimes irreversible), sedation, tiredness, and depression. Cyproterone reduces sexual interest and activity but does not impair the erectile response to erotic films. Not all patients lose desire for sex or erections despite being on relatively high doses. There is oligospermia and loss of ejaculation. Cyproterone is considered to be most effective when the paedophile is focused on orgasm and to be less effective when the patient is more focused on forming a relationship with the victim. Cyproterone should not be given without an oestrogen (e.g. ethinyl oestradiol) to a woman during reproductive life because, if she became pregnant, there might be sex differentiation problems in the male foetus. Cyproterone acetate is found in low dosage in the contraceptive pills Dianette and Minerva²⁰⁶¹, which has been used in women who suffer from severe acne. The effects of cyproterone may take some months to disappear. Some patients show habituation to the drug and need a dosage increase.

Oestrogens can be given as depot injections (oestradiol undecylenate) or as an oestradiol implant. Oestrogens can cause breast enlargement and nodules, testicular atrophy, osteoporosis and, rarely, breast tumours. Medroxyprogesterone²⁰⁶² (Depo-Provera), a progestagen that induces hepatic testosterone reductase, was given IM before being taken off the market in 2003; it had many other uses, e.g. certain hormone-sensitive malignancies, endometriosis, and infertility. Goserelin (Zoladex), a long acting LH analogue, is given s.c. It is used for endometriosis, prostatic cancer, premenopausal breast cancer, and as an adjunct to surgery for uterine fibroids. A single injection reduces LH and testosterone levels for a month. It reduces sex drive. It can cause hot flushes, loss of libido, headaches, mood changes, and vaginal dryness²⁰⁶³. Triptorelin (Decapeptyl, Gonapeptyl depot) is a long-acting GnRH agonist that reduces testosterone levels that also seems effective. It can cause erectile failure, hot flushes, and reduced bone density in some men. Leuprolide²⁰⁶⁴ (aka leuprolerin) acetate (Eligard, Prostag), another LH agonist, is preferred to medroxyprogesterone or cyproterone by many therapists because it causes a greater fall in testosterone levels; also, being a peptide, it is safer than steroids.

Physical castration, a thorny ethical issue (Grubin & Beech, 2010), was practised as a voluntary treatment for sexual perversities on rare occasions in some countries, such as in Denmark until 1972. However, it is still carried out in psychiatric hospitals for sexual offending in the Czech Republic. It was introduced in California for convicted paedophiles in 1996. (Macready, 1996) Castration can reduce sex drive but some people persist in seeking sexual activity and may even achieve penile tumescence and a third can achieve sexual intercourse. Also, androgens are also produced by the adrenal glands. The present author has found records of one intellectually disabled female who received a leucotomy in early twentieth century Ireland for what was deemed to be promiscuous behaviour. Ablation of the temporal lobe has been used in Eastern Europe for paraphilias. People may agree to be castrated in order to gain release from confinement rather than because they truly wish to reduce the risk posed to others.

Preoccupation with castration (DSM-IV): Such persons, of either sex, are preoccupied with castration or penectomy. They do not wish to acquire the secondary sexual characteristics of the opposite sex but are uncomfortable with their assigned sex (contrast with transsexualism). They fantasise about being of a different gender, and are often asexual.

Aversion therapy consisted of the pairing of a noxious stimulus (agents such as ammonia, apomorphine, disulfiram, nalorphine, or emetine; electric shocks) with the response/behaviour to be weakened or extinguished (alcohol, morphine, pictures of men and women, etc). The results of aversion therapy for paraphilia were often transient. Also, patients often became socially isolated and depressed because of the lack of an alternative sexual outlet.

Entry of sexual offenders onto a *sexual offenders' register* has different implications in different jurisdictions. They may be required to live at a particular address, report at stated frequencies to police, avoid minors or schools, or wear an electronic tag. Horrific sex crimes during the 1980s in the US led a number of states (beginning with Washington in 1990) to enact laws leading to civil commitment after the

²⁰⁶¹ Do not use if there is a history of venous thromboembolism.

²⁰⁶² Medroxyprogesterone induces hepatic testosterone A reductase and thereby lowers plasma testosterone.

²⁰⁶³ Antihistaminic or anticholinergic drugs can cause vaginal dryness.

²⁰⁶⁴ Leuprolide acetate is usually used for hormone dependent advanced prostate cancer. Side effects include testicular atrophy and pain, infertility, breast tenderness, fatigue, hot flushes and night sweats, skin problems, myalgia, prolonged coagulation time/ecchymoses, increased CPK levels, and rigors. FSH and LH secretion is initially increased followed by a decrease because of downregulation of receptors.

predator finished his prison term. This could mean indefinite confinement in a specialised treatment facility. Such measures were held to be constitutional by the Supreme Court, although the APA (1999) was not happy with such statutes.

Sexual Dysfunction

Sexual problems are more often transient than persistent. Problems of sexual desire and interest often carry a poor prognosis, although one should realise that some people who are locked in a relationship in which they have no say develop lack of desire as a form of protest. (Ritvo et al., 2008, p. 1318) Problems of self-esteem (try individual counselling or cognitive therapy) and interpersonal problems are common. Sexual dysfunction occurs in at least 10% of psychiatric outpatients. Osborn et al. (1988) reported that one-third of women aged 35-39 had operationally defined sexual dysfunction in a community survey in Oxford, especially impaired sexual interest, vaginal dryness, infrequent orgasm, and dyspareunia. These were significantly associated with increasing age, psychiatric disorder, neuroticism, and marital disharmony. Rust et al. (1988) found that marital problems were more closely related to sexual dysfunction in men than in women.

*Classifying marital distress (MD) and sexual problems (SPs)*²⁰⁶⁵

SPs causes/adds to MD

MD causes/adds SPs

MD + SPs co-occur

SPs without MD

MD without SPs

'Spectatoring' refers to the habit of monitoring and observing one's own love making rather than simply participating. This can lead to a vicious circle of performance anxiety and dysfunction. Men's performance oriented approach to sex is inappropriate when applied to sexual intimacy. (Bignell, 1993)

'PLISSIT' refers to four steps (depending on the situation) in treatment: (P) permission giving, (LI) limited information, (SS) specific suggestion, and (IT) intensive treatment. The first three (PLISS) make up brief therapy. They are less applicable in practice as one moves from P to IT.

The concept of the 'core complex' can be mentioned here in passing. The person is torn between love and hate for the partner, between a need for closeness and a wish for escape. According to the theory, the person's mother had maintained her child in an excessively dependent state, causing the child to feel threatened, frustrated and aggressive toward the mother, but at the same time wanting her love and protection. He therefore represses his anger. The conflict is re-experienced in adult sexual relationships as a wish for proximity accompanied by fears of being overpowered.

The physical examination of a patient with sexual problems is discussed by Dean. (1998) Examples of what to look out for in males include the firm penile plaques of Peyronie's disease and the tender prostate in prostatitis²⁰⁶⁶. The woman should be examined while her bladder is full since detrusor instability may be associated with voiding during intercourse. Chlamydiosis is one cause of dyspareunia. Bacterial and chlamydial swabs may be taken from the vagina and the endocervical canal. In the case of both sexes, the examiner should consider cultural mores and offer a chaperone.

Sexual dysfunction is extremely common in schizophrenia. Macdonald et al. (2003) found that 82% of males (low desire, erection difficulties, premature ejaculation, and low intensity ejaculation) and 96% of females (low enjoyment) reported at least one sexual dysfunction. Sexual dysfunction in females was associated with negative schizophrenic symptoms and general psychopathology. Interestingly, the authors found no association between sexual dysfunction and the type of antipsychotic drug being taken. However, it was impossible to separate illness from medication effects since most patients were taking medication and few patients relative to controls had a partner.

*Hypoactive desire disorder*²⁰⁶⁷ (*sexual desire disorder*) refers to lack or loss of sexual desire. It is much common in females than in males. It often reflects relationship problems²⁰⁶⁸, daily hassles, and high stress

²⁰⁶⁵ Modified from Ritvo et al. (2008, pp. 1318-9).

²⁰⁶⁶ Prostatitis may cause perineal pain, painful ejaculation, or altered sensation.

²⁰⁶⁷ Some authors suggest combining desire and arousal disorders under the heading 'sexual arousability disorder'.

²⁰⁶⁸ E.g. loss of attraction due to obesity, dull sexual routines, too much or too little closeness, religious concerns, power issues.

jobs. Rearing children may encroach on 'couple time'. Occasionally there is a specific sexual problem due to longterm sexual inhibition or an intractable biologically based low sex drive. It may be secondary to depression,²⁰⁶⁹ but it doesn't always clear up when the depression is treated. OCD may interfere with sexual desire. (Meston & Frohlich, 2002) Gregoire (1999a) states that up to 10% of men presenting with inhibited sexual desire may have a prolactin secreting pituitary tumour! Ginseng²⁰⁷⁰ is an ancient oriental aphrodisiac and tonic. Tibolone²⁰⁷¹ (Livial) may enhance sexual function in post-menopausal women. (King, 2008, p. 701) although more evidence is needed. Flibanserin, originally developed as an antidepressant, is undergoing trials with some promise of success. The FDA in America approved EROS-CTD²⁰⁷² in 2000, a small vacuum pump that applies gentle suction to the clitoris in order to increase its blood supply and increase desire. In '*sexual aversion disorder*' the person hates genital contact; it is severe and persistent; and the causes may be the same or similar to hypoactive desire disorder. '*Sexual phobia*' is rare. There is avoidance of sexual experience because of a specific anxiety that is seen as excessive by the patient. The anxiety may be confined to an aspect of sexual activity (kissing, smells, nudity, etc) or it may be generalised.

Sexual compulsion/addiction is not found in the DSM but does exist. One partner constantly seeks sexual activity and becomes distressed if such desires are not fulfilled. Some people who engage in extramarital affairs have this problem. Various therapeutic approaches have been advocated (Ritvo et al, 2008, p. 1319): 12-step approach (modelled on Alcoholics Anonymous), group therapy, couple therapy (even if it involves helping to negotiate an ending to the relationship), and SSRIs.

Males

Premature ejaculation is especially found in younger men. An older definition was that on at least 50% of occasions the male is unable to delay orgasm long enough to satisfy the female. DSM-IV, in paraphrased form, states that the man ejaculates too quickly, before he wishes it. It is often learned from earlier experiences but organic causes include testosterone deficiency, prostatitis, and multiple sclerosis. Treatments include the squeeze technique, withdrawal of stimulation just before the build up to orgasm (*stop-go technique*²⁰⁷³), and the application of a local anaesthetic ointment to the coronal ridge and frenulum to reduce stimulation. In the *squeeze method* the woman grips the corona glandis for a few seconds between her thumb and forefinger and then releases it suddenly. This technique may lead to loss of erection or even of ejaculation when employed too close to the point of ejaculatory inevitability. SSRIs cause the opposite effect, delayed ejaculation, and therefore may be useful in depressed males with concomitant premature ejaculation, whereas nefazodone (Dutonin – no longer available) is unhelpful in this scenario. Mirtazapine may attenuate nausea and sexual dysfunction due to SSRIs. Low dose BZDs, TCAs (clomipramine 50 mgs), SSRIs, and thioridazine may be beneficial when taken an hour or so before sexual intercourse. Spontaneous ejaculation has been described in a patient receiving reboxetine. Dapoxetine, a short acting SSRI (30-60 mg; max. serum conc. c. 1 hr.; initial half-life 1.2 hr.; 24 hr. plasma conc. < 5% peak value) is taken 1-3 hours before sex and has been shown to be effective. (Pryor et al, 2006) Adverse effects include nausea, diarrhoea, headache, and dizziness. A particular problem associated with use of clomipramine and the SSRIs is that they may reduce desire to have sex! A topical lidocaine-prilocaine solution helps some sufferers as long as anaesthesia is not extreme and there is no allergic skin reaction. *Delayed ejaculation (ejaculatory incompetence or retarded ejaculation)* refers to a long delay in, or inability, to ejaculate. This is usually psychogenic if the patient is able to ejaculate outside the vagina. It may be due to fear of creating a pregnancy, negative feelings for the partner, religious taboo, etc. Physical

²⁰⁶⁹ Also, increased sexual interest is reported by a minority of people with depressive or anxiety states and many individuals with these disorders find no change in their interest in sex. Sex may act as a transient anxiolytic or as a source of comforting closeness for some people.

²⁰⁷⁰ **Ginseng** from *Panax* (Gk: panacea) *ginseng* contains terpenes and saponins and has antioxidant properties. It has oestrogenic (may cause vaginal bleeding and breast pain) and hypoglycaemic effects (affects on liver lipogenesis and storage of glycogen) and blocks reuptake of 5-HT, DA, noradrenaline and glutamate. It blocks production of thromboxane A2 and thereby inhibits aggregation of platelets (which can be problematic in people on warfarin). Other adverse effects include headache, anxiety, poor concentration, raised blood pressure, palpitations, and diarrhoea. (see Dunne, 2009)

²⁰⁷¹ Synthetic steroid that is oestrogenic, androgenic and progestogenic; used to treat menopausal symptoms. It has a number of adverse effects including thrombophlebitis, hypertension, and vaginal bleeding.

²⁰⁷² Clitoral therapy device.

²⁰⁷³ Described by J. Semans in 1956.

factors (drugs such as antidepressants, deficiency of androgens, etc) are less likely to be so situation-specific. Neurological disease (e.g. spinal cord lesions or prostatectomy²⁰⁷⁴) and drugs such as alpha-adrenergic blocking agents may lead to 'dry run' orgasm (i.e. orgasm occurs but semen blocked during passage) or retrograde ejaculation ('dry orgasm' - semen enters urinary bladder - sperm in post-ejaculatory urine - infertility units may centrifuge urine and collect sperm²⁰⁷⁵). Treatment involves masturbation of the male by the female externally. Eventually she places the penis in the vagina at the appropriate moment. This usually breaks the vicious circle in psychogenic cases. The female should kneel over the male. It should be noted that normal aged males often produce an ejaculate only every second or third time.

Intermittent use²⁰⁷⁶ of SSRIs, e.g. sertraline 50 mgs, has been recommended.

In diabetics, neuropathic involvement of the bladder neck may lead to retrograde ejaculation (cloudy urine). Ephedrine taken prior to sexual intercourse has been recommended but this can be dangerous, especially if combined with caffeine.

A morning or non-coital erection does not outrule orgasmic dysfunction. For example, people on beta-blockers or MAOIs may have drug-induced orgasmic dysfunction despite normal morning erections. (Fagan & Schmidt, 2000)

Painful ejaculation is a rare, often idiopathic disorder. There may be an inflammatory condition, such as urethritis or prostatitis.

Erectile dysfunction/disorder (ED, impotence; O'Shea *et al.*, 2001) is an inability to achieve or maintain penile erection until completion of sexual activity, affects about 7.5% of males (average of three studies). *ICD-10* tends to stress satisfaction and enjoyment in sexual relationships in its definition, whereas *DSM-IV* takes a more physiological approach²⁰⁷⁷. Diagnosis is based on a thorough history, including collateral information as necessary, and examination, supplemented by whatever investigations seem indicated and sensible. The *International Index of Erectile Function*, a validated questionnaire, has 5 domains: erectile function, orgasmic function, sexual desire, satisfaction with sexual intercourse, and overall sexual satisfaction.

Relevant physiology

Erotic stimulation may require activation of caudal thalamic intralaminar nuclei

Parasympathetic stimulation of erection does not seem to work directly via acetylcholine

Various chemicals are involved in causing penile smooth muscle relaxation: nitric oxide²⁰⁷⁸, vasoactive intestinal polypeptide (VIP), and prostaglandin

Cyproterone acetate reduces sexual interest and activity, but not erectile response to erotic pictures; the same phenomenon is seen with other causes of hypogonadism: *therefore androgens are not essential for erection*

Vomer nasal or Jacobson's organ of the nasopharyngeal septum secretes volatile chemicals called *pheromones* or *copulins*, and is linked to the olfactory system and hypothalamus, leading, when stimulated, to gonadotrophin release and, it is contended, to sexual arousal

Canine bitches secrete urinary substances at oestrus which stimulate the male to produce luteinizing hormone and testosterone

Certain genetic mutations that affect resting endothelial function carry an increased risk of developing ED, e.g. polymorphisms of the genes for nitric oxide synthase and Rho kinase

Whatever the primitive biological underpinnings, it is important to note that sexual arousal and potency have obvious perceptual and cognitive components in humans. A cross-section of the erect penile shaft, relative to the flaccid penis, reveals engorged veins, narrowed cavernous²⁰⁷⁹ and Helicine²⁰⁸⁰ arteries, and bloated sinusoidal spaces.

²⁰⁷⁴ Transurethral prostatectomy (TUR) may reduce orgasmic sensation and cause retrograde ejaculation. Radical pelvic, including prostatectomy, for cancer can impair erectile function. Erectile dysfunction is uncommon after TUR.

²⁰⁷⁵ 74 days are required for spermatogenesis. Therefore today's sperm reflect the man's health that many days ago.

²⁰⁷⁶ Less nausea and reduced libido.

²⁰⁷⁷ DSM-IV, as with all disorders, stresses the fact that ED causes marked distress or interpersonal difficulty.

²⁰⁷⁸ Also produced in the clitoris.

²⁰⁷⁹ In centre of corpus cavernosum.

Types of penile erection requirements, and effects of spinal cord trauma

reflex erections – not caused by thinking/seeing erotica

- results from penile stimulation
- requires S2-S4 nerve roots: sacral reflex arc
- mediated by parasympathetic fibres
- usually present with injury above L2 vertebra

psychogenic erections – caused by thinking/seeing erotica

- mediated by sympathetic fibres
- not caused by direct stimulation of penis
- thoracolumbar roots essential
- often lost with thoracic or cervical cord injury

Aetiology of erectile impotence

Drugs: alcohol²⁰⁸¹, tobacco²⁰⁸², lithium, antidepressants²⁰⁸³, antipsychotic drugs²⁰⁸⁴, barbiturates, benzodiazepines, opiates (may be reversed in some cases with naltrexone), psychostimulants²⁰⁸⁵, cannabis, anti-androgens, methotrexate, anticholinergic drugs²⁰⁸⁶, H2-blockers²⁰⁸⁷, antihypertensives (chiefly if centrally acting, such as guanethidine and alpha-methyldopa²⁰⁸⁸), digoxin, clofibrate, gemfibrozil, thiazides, spironolactone, interferon- α

*Physical*²⁰⁸⁹: multiple sclerosis, Parkinson's disease²⁰⁹⁰, Addison's disease, diabetes mellitus, hypo- or hyperthyroidism, acromegaly, temporal lobe epilepsy, syphilis, pituitary adenoma, peripheral vascular disease²⁰⁹¹, pelvic surgery (e.g. prostate) or irradiation, spinal cord trauma, bicycle riding²⁰⁹², Klinefelter's syndrome, hepatic cirrhosis, cardiac disease, chronic renal failure²⁰⁹³, malnutrition, etc

Psychological/psychiatric: anxiety, depression, organic brain syndromes, schizophrenia, etc

Causes of ED have been divided into the largely psychological²⁰⁹⁴, largely physical, or combined psychophysical. Older men are especially vulnerable. ED can be primary or secondary (former if an erection never achieved, latter if function is lost). The majority of cases are secondary. ED can be partner-specific. Fear, guilt, and drugs²⁰⁹⁵ are common causes of ED and alcohol is a testicular toxin. Diabetes mellitus (DM) causes erectile problems, especially in older men, probably via a combination of neuropathy

²⁰⁸⁰ Branches from cavernous artery to sinusoidal spaces.

²⁰⁸¹ The acute effects of alcohol ('brewer's droop') are well known. The chronic alcoholic with hepatic dysfunction may have hypogonadism, feminisation, and peripheral neuropathy.

²⁰⁸² Nicotine decreases blood flow in the corpus cavernosum and inhibits cavernosal venoconstriction.

²⁰⁸³ SSRIs, TCAs, and MAOIs.

²⁰⁸⁴ This is dose related: low doses of antipsychotic drugs facilitate erection, high doses impair erection. It also responds to sildenafil. (Gopalakrishnan et al, 2006)

²⁰⁸⁵ Cocaine.

²⁰⁸⁶ Disopyramide and anticonvulsants.

²⁰⁸⁷ Ranitidine, cimetidine.

²⁰⁸⁸ Also calcium-channel blockers, clonidine, reserpine, and beta-blockers; angiotensin II receptor blockers such as losartan (Cozaar) are said to be free of sexual side effects. Antihypertensives, by lowering systemic blood pressure, can reduce maximal penile filling capacity.

²⁰⁸⁹ See Rees et al (2007) and McVary (2007) for details.

²⁰⁹⁰ L-DOPA may facilitate erection.

²⁰⁹¹ The bore of the penile artery is tiny and any reduction in arterial diameter may lead to ED long before other cardiac symptoms (e.g. angina) occur.

²⁰⁹² This may damage the perineal nerve causing numbness of the penis and it may cause ED by reducing oxygen pressure in the pudendal arteries.

²⁰⁹³ Uraemia is accompanied by increased LH, oestrogen and prolactin and decreased testosterone levels. Erythropoietin may improve sexual function, probably by reversing some of these hormonal changes.

²⁰⁹⁴ This has been criticised as being overly simplistic since anxiety can also increase male and female sexual arousal. Is anxiety a problem only for those who already have a dysfunction? (King, 2008, p. 698)

²⁰⁹⁵ E.g. thioridazine, beta-blockers, nicotine, and alcohol ('brewer's droop').

and arteriopathy. Psychogenic factors may be the chief cause in many cases of DM. Diabetic women may have decreased sexual arousal, poor vaginal lubrication, reduced orgasmic capacity, or depression. Peyronie's disease²⁰⁹⁶ causes different degrees of deformity of the erect penis. Leriche's syndrome²⁰⁹⁷ and small vessel disorders²⁰⁹⁸ are other causes.

The search for physical causes of ED cannot replace a holistic, multidisciplinary approach to what is a complex problem. A thorough physical examination is essential. Cultural mores must be respected, and a chaperone has become essential in the current litigious climate. Physical investigation of the aetiology of erectile dysfunction has become less imperative with the introduction of effective oral treatments.

Measurement of penile arterial blood pressure involves a Doppler probe, a digital blood pressure cuff, and a sphygmomanometer. Nocturnal penile tumescence²⁰⁹⁹ can be monitored, but its usefulness in distinguishing between psychological and organic causes of ED may have been exaggerated. Cavemosography, wherein a contrast medium is infused to examine the corpora cavernosa and their drainage, can help to identify leaks. Pelvic arteriography is used to demonstrate arterial obstruction. Conduction latency in the dorsal nerve and bulbocavernous reflex latency are other tests that may be relevant.

Psychological treatment is usually a modification of the Masters and Johnson technique, although it has not proved possible to replicate the original high cure rates. Patients with organic impotence may be encouraged to explore other forms of sexual activity with their partners. Individual and interpersonal dynamic factors should not be ignored: for example, there is no point in focusing on sex in a relationship that is unhappy for other reasons. Individual, marital, couple or family approaches may be warranted in complex cases; separate attention to substance use disorders may be indicated. A problem may arise because the partner is not interested in seeking help.(King, 2008, p. 698)

Kegel's pelvic floor exercises are often prescribed for ED (or premature ejaculation) but there is only a little evidence that they are effective.(King, 2008, p. 699)

Testosterone has little effect on erectile dysfunction and is more important in sustaining sexual drive and the capacity for ejaculation. However, low sexual drive secondary to hypogonadism (older men with hypogonadism may suffer an excess of depression: Shores *et al*, 2004) would be an indication for employing this hormone. Low testosterone levels are treated with a series of depot testosterone injections.

Gonadotropin-releasing hormone²¹⁰⁰ can be used when hypogonadism is secondary to hypothalamic or pituitary disorders. Bromocriptine is indicated for those rare cases of hyperprolactinaemia (prolactin inhibits central dopaminergic activity and so reduces gonadotrophic hormone-releasing hormone secretion) due to idiopathic causes or secondary to pituitary adenoma. Yohimbine²¹⁰¹, an alpha-adrenoreceptor blocker, has been used especially in psychogenic cases. One group achieved a 38% success rate for situational ED. Topical nitroglycerine may produce a useful erection in some men; headache in the partner due to transvaginal absorption may be avoided by using a condom. One study found that topical creams²¹⁰² were best in psychogenic ED. However, topical preparations are generally not as successful as injections. Trazodone, which causes priapism²¹⁰³ in 1 in 6,000 treated males, has been used for (especially psychogenic) ED.(Fink *et al*, 2003) Various strategies employed to reduce the sexual side-effects of antidepressants include dose reduction, weekend drug holidays for short half-life agents, change of drug²¹⁰⁴, taking the drug after coitus, and various chemicals: cyproheptadine, bethanacol, amantadine, yohimbine, buspirone (withdrawn 2009), and bupropion. Some workers are not convinced that oral medications like yohimbine have efficacy (but see PDE5 inhibitors).

²⁰⁹⁶ Idiopathic fibrosis of corpus cavernosum with firm plaques.

²⁰⁹⁷ Large vessel obstruction.

²⁰⁹⁸ Obstruction of internal pudendal arteries or of the penile arteries in older men; arterial inadequacy or 'dysplasia' in primary cases; and venous incompetence where too much blood is lost by the penis to the general circulation.

²⁰⁹⁹ **Nocturnal penile tumescence** occurs during REM sleep. We know that it is androgen dependent. It is postulated that the brain normally inhibits erection via noradrenergic nerve cells in the locus coeruleus and that such descending inhibitory tone is turned off during REM sleep.

²¹⁰⁰ GnRH, luteinizing hormone-releasing hormone, LHRH, a decapeptide.

²¹⁰¹ Indole alkaloid found in many plants (e.g. root of *Rauwolfia* and bark of African *Pausinystalia yohimbe* tree). It can cause anxiety, headache, nausea, and hypertension.

²¹⁰² Combinations of aminophylline, isosorbide dinitrate, and co-dergocrine mesylate.

²¹⁰³ Priapus is seen weighing his huge penis in a fresco in the Villa dei Vetii, Pompeii, first century.

²¹⁰⁴ E.g. an SSRI to mirtazapine.(Gelenberg *et al*, 2000)

Advertisements for sildenafil (see below) and other similar drugs on the internet are ubiquitous and the products being sold may contain too little or too much of the active ingredient. They may also contain potentially toxic metals.

Phosphodiesterase type-5 (PDE5) inhibitors, which cause nitric oxide release, include sildenafil, tadalafil, and vardenafil. These are all taken orally. Sexual stimulation is required for these drugs to produce an erection because in the absence of sexual stimulation concentrations of nitric oxide and cyclic GMP are low. Sildenafil (Viagra; a PDE5 inhibitor): The usual starting dose is 50 mgs one hour before sex. The dose can be changed as needed: range, 25-100 mgs. It should only be used once daily. Side effects include painful erection (>17% of males), headache, dizziness, flushing, sweating, dyspepsia, nasal congestion, and a bluish tinge to vision (limited inhibition of phosphodiesterase type 6 in the retina), increased light perception or blurred vision. Driving may be a problem. Muscle aches follow frequent use. The incidence of priapism ranges from 0.35-4% (a similar problem with the female clitoris is possible), and fibrosis occurs in 1-23% of users. It may be abused alone or with 'ecstasy' (MDMA), the combination being called 'sextasy'. Abuse may lead to priapism with resultant sexual dysfunction! Mixing PDE5 inhibitors with drugs containing nitric oxide (e.g. "poppers", which contain amyl nitrate) can cause hypotension, with the potential for myocardial infarction or stroke²¹⁰⁵. Failure of sildenafil may lead to distress and exacerbation of low self esteem. (Tomlinson & Wright, 2004) Interestingly, the lotus flower²¹⁰⁶ contains, among other things, phosphodiesterase inhibitors: it was often sniffed or taken in wine!

Sildenafil citrate (Viagra)

Effective across full range of aetiologies²¹⁰⁷ (incl. serotonergic antidepressant-induced dysfunction) – overall effectiveness is 50% of cases; may reverse gastroparesis in diabetes

Increases hypotensive effect of nitrates: avoid amyl nitrite or any nitrates (sildenafil is used for pulmonary arterial hypertension)

Metabolism: P450 isoforms: mainly 3A4, less so by 2C9; inhibitors of these enzymes reduce clearance

Highly protein bound: dialysis unhelpful after overdose

Avoid if: severe hepatic impairment, BP <90/50, recent CVA or MI, known family history of degenerative retinal disorders²¹⁰⁸

Caution in: abnormal penis²¹⁰⁹ or risk of priapism²¹¹⁰ or concurrent use of dihydrocodeine²¹¹¹

Does not increase arousal in females (Basson et al, 2002)

Adverse effects of intracavernosal vasoactive injection

Mild, non-specific changes in liver function tests

Haematoma, bruising

Fibrosis, nodules

Priapism: necrosis if persistent

Local pain

Dizziness and faints: psychogenic?

Death if papaveratum used in error instead of papaverine

Abuse of, at sex shows

²¹⁰⁵ **Should a person who has taken a PDE5 inhibitor require medical attention (e.g. in an emergency department) the doctor should be advised of medication taken lest nitrates are administered!** There is concern over the sale of so-called 'herbal Viagra' products that may contain large amounts of PDE5 inhibitors such as sildenafil and tadalafil. Sibutramine, an MAOI, has also been found in such products. Internet sales of such products should be avoided.

²¹⁰⁶ Ubiquitous on Ancient Egyptian murals.

²¹⁰⁷ Effectiveness ranges from 43% (radical prostatectomy) via 59% (diabetes) to 84% (psychogenic ED). (Osterloh & Riley, 2002) Psychogenic cases who respond may develop renewed hope and get time to utilise psychological methods. King (2008, p. 697) suggests efficacy of 50% in diabetes and much lower after radical prostatectomy (esp. if nerves are not spared)

²¹⁰⁸ Some cases have genetic disorders of retinal phosphodiesterase.

²¹⁰⁹ E.g. Peyronie's disease: penile curvature due to plaque or scar; painful erection/difficult penetration; may improve spontaneously; advise continued sexual activity; delay surgery until condition stable. (Basson & Schultz, 2007)

²¹¹⁰ E.g. leukaemia, multiple myeloma, sickle cell anaemia. A post-mortem erection in men who are hung is technically a priapism and may be due to pressure on the cerebellum. Cimetidine increases sildenafil concentrations, erythromycin even more so; ketoconazole also inhibits enzyme; if necessary use low dose of sildenafil, e.g. 25 mgs.

²¹¹¹ Two case reports of prolonged erection (persisting beyond ejaculation) due to accumulation of cyclic guanosine monophosphate in peripheral nerve endings. (Goldmeier & Lamba, 2002)

Tadalafil (Cialis, 10 mg and 20 mg tablets) improves erection for *at least* 24 hours²¹¹² after taking a dose. The dose for adult (incl. elderly) men is 10 mg 30 minutes to 12 hours before intercourse. The maximum dosage frequency is once daily. It is contraindicated with organic nitrates or in the presence of significant cardio- or cerebro-vascular disease. Caution is required if used with potent CYP3A4 inhibitors, such as erythromycin. Grapefruit juice may increase plasma levels of tadalafil. Alpha-blockers should be avoided. Possible side effects include headache, dizziness, dyspepsia, flushing, nasal congestion, back/muscle pain, eyelid swelling, eye pain, and hyperaemic conjunctivae.

Vardenafil (Levitra, 5 mg, 10 mg and 20 mg tablets; PDE5 inhibitor) can be taken once daily. 10 mg (5 mg if elderly or impaired hepatic or liver function) is taken 25-60 minutes before sexual activity²¹¹³. The dose range is 5-20 mg, average 10 mg. Avoid vardenafil with nitrates/nitric oxide donors, contraindications to sexual activity (e.g. severe cardiovascular disease), severe hepatic impairment, end-stage renal disease needing dialysis, hypotension, recent CVA/MI, unstable angina, and known hereditary retinal degenerative states. Do not use vardenafil with grapefruit juice and, in the over 75s, do not use it with potent CYP3A4 inhibitors²¹¹⁴. Avoid vardenafil in patients with anatomical abnormalities or a proneness to priapism²¹¹⁵. Downward dose adjustment (5 mg) may be needed if vardenafil is co-prescribed with erythromycin. Risk-benefit analysis must be undertaken for cases with bleeding diatheses or active peptic ulcer disease. It is not recommended that vardenafil be given with alpha-blocking drugs. Adverse effects include dyspepsia, nausea, dizziness, syncope, headache, rhinitis, flushing, hypertension/hypotension, hypotonia, visual disturbance²¹¹⁶, photosensitivity reactions, and erectile disturbance. Apomorphine HCl (Uprima)²¹¹⁷, a central DA receptor agonist, was available for the treatment of ED up to 2006.

Local devices include vacuum condoms (vacuum constriction device²¹¹⁸) and penile rings may be used, although sensation may be compromised by these methods.

Alprostadil (prostaglandin E²¹¹⁹; MUSE²¹²⁰) can be used in intraurethral pellet ('stick') form²¹²¹, with erection after about 5-10 minutes; penile pain may occur. When prostaglandins (embryotoxic in animals) are used by the male and the female partner is pregnant it is advised that the foetus is protected by barrier contraception (e.g. condoms). Intracavernosal prostaglandin E1 (Alprostadil, Viridal - metabolised locally) gives a good erection (both it and papaverine produce erections lasting 30-60 mins). It may cause local pain or priapism, especially if there is no underlying vascular cause for ED.

Other local injections are also available. Self-injection of papaverine, phenoxybenzamine or phentolamine into the cavernosa at the penile base gives a normal erection, which lasts about forty minutes. Papaverine injections have been used to differentiate between neurological and vascular causes. It will not produce an erection where there is significant arterial obstruction. In males with an intact genital circulation, injections into the corpora cavernosa of either beta-blockers (phenoxybenzamine or phentolamine) or other smooth muscle relaxants (e.g. papaverine) usually produce erections sufficient for sexual intercourse. The patient or his partner is taught to give the injection. Potentially serious side effects include priapism (admit immediately, aspirate the corpus cavernosum and inject phenylephrine 5 mgs. intracavernosally – adrenaline and metaraminol are alternatives; if no success, call urologist) and penile fibrosis.

²¹¹² This 'weekend drug' has a 17.5-hour half-life.

²¹¹³ A high fat meal delays onset of action of both sildenafil and vardenafil and they should be taken on an empty stomach. This precaution is not necessary with tadalafil.

²¹¹⁴ Ritonavir, indinavir, ketoconazole, oral itraconazole.

²¹¹⁵ Leukaemia, multiple myeloma, sickle cell anaemia.

²¹¹⁶ A higher affinity for PDE5 vs. PDE6 may account for reduced visual side effects relative to sildenafil.

²¹¹⁷ One tablet was taken *sublingually* 20 minutes before the sexual act, being virtually ineffective if swallowed. According to Anonymous (2004) apomorphine improved ED to a lesser extent than sildenafil but was the only licensed oral drug for ED 'not absolutely contraindicated with nitrates'.

²¹¹⁸ Avoid these in cases of anticoagulant therapy, leukaemia, and sickle cell disease.

²¹¹⁹ Patients who do not respond to sildenafil (esp. Post-radical prostatectomy) may respond to alprostadil injected into corpora cavernosa (*Caverject*, *Viridal Duo*). King (2008, p. 696) suggests that transurethral prostaglandin E is less effective, particularly if there is poor blood supply.

²¹²⁰ Medicated Urethral System for Erection.

²¹²¹ Use applicator. Stick strength range from 125 to 1000 mcgs and the correct dose should be worked out under medical supervision.

Surgery may involve penile prostheses²¹²² (various types - inserted bilaterally in the corpora cavernosa) or vascular surgery (e.g. aorto-iliac surgery for thrombosis of a major vessel or surgery for leakage from the corpora cavernosa).

The only sexual dysfunction that can be (almost) cured completely is vaginismus: we are dealing with methods to alleviate the problem or to achieve better control. Departments of psychiatry, focused on serious mental illness as they are, rarely work with sexual problems, and special clinics are uncommon. According to some experts, up to 70% of venous leakage cases, where blood drains away from the penis too quickly, can expect improvement with surgery. However, other experts consider the results of this type of operation, and of revascularization of the corpora, to be poor.

Dyspareunia (painful intercourse) can be physical or psychological.

Priapism is the persistent, prolonged, uncontrolled and usually painful penile erection. It is a medical emergency. Half of cases are idiopathic. When due to drugs, phenothiazines are causative in 50% of cases. Diseases that can cause priapism include sickle cell anaemia, leukaemia, trauma, stroke (CVA), spinal cord injury, perineal trauma, nephrotic syndrome, multiple myeloma, and hyperviscosity states.

Some drug causes of priapism

Phosphodiesterase type-5 (PDE5) inhibitors - sildenafil, tadalafil, vardenafil.

Use and abuse of intracavernosal injections

Antipsychotics (? due to alpha 1-adrenergic antagonism) – chlorpromazine, thioridazine, mesoridazine, fluphenazine, pericyazine, promazine, thiothixene, perphenazine, clozapine, olanzapine

Butyrophenones – haloperidol

Benzisoxazole derivatives – risperidone

Antidepressants – trazodone²¹²³, phenelzine

Anxiolytics – buspirone, hydroxyzine

Anticoagulants – heparin, warfarin

Antihypertensives – prazosin, labetalol, guanethidine, hydralazine, phenoxybenzamine

Others – alcohol, cannabis, testosterone, phenytoin, black widow spider venom

Females

Dyspareunia is more common in females. It may lead to sexual dysfunction in the male partner. Vulval vestibulitis²¹²⁴ is one physical cause. Removal of a physical cause does not invariably remove the dysfunction because of conditioned anxiety (which may require couple therapy). Treatments consist of vaginal lubricants (e.g. Johnson's Baby Oil), vibrators, other sex aids, enhanced foreplay, psychotherapy aimed at improving the interpersonal relationship, family planning education, etc.

Anodyspareunia is pain from receptive anal sex and is common in gay men and may be persistent. It may lead to avoidance of anal sex or to the sole practice of insertive anal sex.

Vaginismus: The introitus tightens to prevent penetration. This is confirmed by digital examination. It can be associated with impotence or passivity in the partner (which may become obvious after treating the woman). It is often a learned phenomenon. Causes include arthritic conditions, vaginal surgery/tumour/trauma/atrophy, uterine prolapse, endometriosis, congenital problems, hymenal problems, pelvic congestion, and sexually transmitted infection. Vaginismus can cause dyspareunia and *vice versa*. Pelvic examination is performed in the presence of the partner. Hagar dilators are placed in the vagina, slowly increasing their size. However, King (2008, p. 705) states that there is 'no evidence of benefit' with dilator therapy – this does not necessarily mean that it doesn't help!

Orgasmic dysfunction is an inability to attain orgasm (*anorgasmia*) or an undue delay in attaining orgasm. Human orgasm is associated with electrical activity in the septum of the brain. As in male impotence, orgasmic dysfunction may be primary (never attained) or secondary (ability lost). The frequency and situation-behaviour (e.g. masturbation/coitus) specificity of orgasm in women is infinitely variable. About 20% never or hardly ever achieve unassisted orgasm during sexual intercourse; 30% almost always achieve

²¹²² Implants/prostheses are used less often nowadays than they were in the past.

²¹²³ Trazodone may cause pain upon ejaculation.

²¹²⁴ Multiple tiny red sores.

it, and 50% do so sometimes. The causes²¹²⁵, physical and psychological, are multiple. Studies of pudendal nerve conduction and evoked potentials can be performed if indicated. Treatment is aimed at education, reduction of fear, and enhancement of sexual arousal. Very many drugs can cause anorgasmia, e.g. SSRIs and venlafaxine. Antidepressant-induced anorgasmia may respond to cyproheptadine 2-16 mgs before sexual activity. Cyproheptadine is a serotonin antagonist and may sometimes cause a relapse of depression in individuals prone to develop it. There is no evidence to suggest that women possess a 'G spot' (Grafenberg spot) in the anterior vagina²¹²⁶.

Masters and Johnson²¹²⁷ technique: The full programme is expensive and elaborate. The basic idea is to get the couple relaxed. They avoid intercourse until everything else is satisfactory. They progress through mutual fondling (active and passive), eventually caressing breasts and genitalia (so-called *sensate focus*). This is all accompanied by therapeutic evaluation and attempts to improve general relationship problems. The initial ban on intercourse, the aim being to reduce performance anxiety, was first suggested by John Hunter in the 18th century.

Prognosis: Premature ejaculation and vaginismus do best with treatment. Impotence is less certain. Loss of libido is often refractory to help. Outcome studies are made difficult by problems of definition, reporting, and sampling as well as relationship variables (including the therapist's personality) and measurement problems.

Some unusual conditions

Pseudocyesis (phantom pregnancy), which is also found in other mammals, is basically a form of conversion hysteria with lordosis of the lumbar spine, depression of the diaphragm, and possibly aerophagy (air- swallowing). Breast changes occur in 80% of patients. The most common symptom is amenorrhoea or oligomenorrhoea. Most cases are in their twenties or thirties. Hippocrates first described the condition.

John Mason first used the term in 1923. Famous cases were said to be Mary Tudor, Queen of England (1515-1558), and Breuer's patient, Anna O²¹²⁸. The frequency of the condition is not known for sure (1 in 200/250 maternity clinic admissions). One neuroendocrine theory is that there is a dopamine deficiency²¹²⁹. Psychological explanations include an extreme desire to conceive or fear or guilt surrounding pregnancy.

Simulated pregnancy: A woman declares herself to be pregnant when she knows she is not.

Pseudopregnancy: This is due to a hormone-producing tumour.

Delusional pregnancy: A woman (or man) believes she is pregnant (even with the Messiah!) when she is clearly not. It has followed loss of a baby and rejection by the spouse in a schizophrenic Indian woman. (Shankar, 1991)

Couvade syndrome: The man has a swollen abdomen or complains of any other symptom of pregnancy or of the puerperium. The Couvade syndrome, strictly speaking refers to the swollen abdomen. It is not delusional, although delusions of male pregnancy may occur, as in schizophrenia. Similar delusions can occur in organic brain disease. The non-delusional form may be related to anxiety about the partner's pregnancy.

Spontaneous miscarriage/abortion

25% of women have a miscarriage at some stage of their lives. Relief, grief, or other psychiatric problems can follow spontaneous miscarriage. Social isolation may be an important factor in determining outcome. The role of counselling/debriefing is less certain as Lee et al (1996) found that debriefing a couple of weeks after the event had the same effect as no intervention at 4 months in a preliminary study.

32 out of 67 women interviewed 4 weeks after a spontaneous abortion were psychiatric cases (depression) as determined by the PSE. (Friedman and Gath, 1989) This was four times higher than in the general female population. All 'cases' were diagnosed as depressive. Unsurprisingly, many women had symptoms of grief.

²¹²⁵ This includes trauma (e.g. spinal cord), surgery (e.g. pelvic), peripheral neuropathy, BZDs, SSRIs, MAOIs, TCAs, D2-blocking drugs, alpha-blockers, etc.

²¹²⁶ Ernst Gräfenberg (1881-1957), German-born gynaecologist, suggested the existence of a highly excitogenic spot in 1950. One theory is that it is 1" to 3" inches above the anterior opening of the vagina. However, it has been 'discovered' at various other sites including the posterior vaginal and anterior anal walls.

²¹²⁷ William Masters (1915-2001), gynaecologist, and Virginia Johnson (b. 1925), psychologist, were married in 1969 but divorced about 30 years later.

²¹²⁸ Like many other famous people, she is said to have had numerous diseases! When Breuer tried to discharge Anna O she developed an hysterical parturition, which, according to Jones (1961), he handled by hypnosis of the patient and taking an anxious exit himself!

²¹²⁹ DA inhibits prolactin release - some workers have reported hyperprolactinaemia.

Oral contraception

Vessey ea (1985) looked at the incidence of serious psychiatric illness, as measured by first referral to hospital for specialist advice and treatment, among over 16,000 women taking part in the Oxford Family Planning Association contraceptive study. Their findings were 'reassuring with respect to oral contraceptive use'. Vessey ea (2003) found no effect of the contraceptive pill on overall mortality: however, if the patient also smoked the mortality rate was increased and more so if she smoked cigarettes heavily. The 'pill', because of the progestagen, inhibits drug metabolism. If it is stopped, the woman may need to increase the dose of a psychotropic drug. Because of increased progesterone levels during pregnancy, she may need less psychotropic drugs, but she may have an increased requirement following delivery.

Sterilisation

Females: Cooper ea (1982), in a prospective study, found that the operation does not significantly increase the likelihood of psychiatric disorder. Definite regrets were voiced in less than one in twenty cases. Certain categories of women require extra counselling prior to elective sterilisation: 0-1 children, youth, poor marital relationship, and personality disorder. Adverse factors include a poor interpersonal relationship, being pressured into having the procedure, refusal by the male partner to have a vasectomy, youthfulness, ambivalence, sterilisation hard on the heels of induced abortion, and regret when done soon after the birth of a baby that fails to survive.

Males: Men may develop cysts around the severed vas leading to post-coital pain. (Gregoire, 1999b)

Borderland of medicine and psychiatry²¹³⁰

Brian O'Shea

'...so long as are the seat of disease, and the physician disregards such disorder...he clearly fails to fulfil the first indication of treatment...' (Tuke, 1892, p. 1290)

'Skill in recognizing countertransference and transference of the psychiatrist's armamentarium in.....consultation-liaison psychiatry....' (Ursano & Silberman, 2003, p. 1182)

'The burden of mental disorders is likely to have been underestimated because of inadequate appreciation of the connectedness between mental illness and other health conditions'. (Prince ea, 2007)

Liaison psychiatry has taken many forms and has developed to different levels of sophistication²¹³¹ in different locations but within the same country and internationally. Lipowski and Wise (2003) set out five major models of psychiatric consultation in the general hospital setting: patient-oriented (diagnosis, assessment, psychodynamic formulation), crisis-oriented (rapid assessment, coping and problem evaluation, immediate intervention), consultee-oriented (what problem does the referring clinician have with this patient?), situation-oriented (analysis of team-patient interface), and the expanded variety (with the patient at centre stage the consultant takes cognisance of everyone who influences the patient or is influenced by the patient).

Psychiatric disorder

- Delays recovery from medical illness and *vice versa*
- Drives up cost of hospital care
- Increases number of procedures performed

²¹³⁰ DSM-I spoke of psychosomatic disorders, DSM-II referred to psychophysiological disorders, and DSM-III included psychological factors affecting medical condition, as does DSM-IV. ICD-10 avoids the terms psychogenic and psychosomatic as specific category titles for theoretical and practical reasons, e.g. psychological factors do influence other disorders as well as those traditionally categorised under such headings. In 1833, Ralph Fletcher pointed out that the brain could exert a malevolent influence on the body. In 1981, Lipowski defined psychosomatic medicine as 'a scientific discipline concerned with the study of the relationships of biological, psychological and social determinants of health and disease. It is a set of postulates and guidelines embodying a holistic approach to the practice of medicine and it encompasses consultation liaison psychiatry'. Some people attract psychiatric referral; others, equally in need, do not.

Franz Alexander (1950; lived 1891-1964), a Chicago-based psychoanalyst (b. Budapest), offered many interesting psychoanalytical 'explanations' for (7) 'psychosomatic disorders' (peptic ulcer, ulcerative colitis, bronchial asthma, thyrotoxicosis, rheumatoid arthritis, essential hypertension, and neurodermatitis), but there is little hard evidence to support these. While we can accept that psychological distress may lead to physiological changes (e.g. anxiety to tachycardia), we do not know how the latter are translated into pathological changes. Also, we do not know for sure if so-called psychosomatic conditions are truly such or whether they represent idiosyncratic reactions of organ systems.

In 1956, Hans Selye described the 'general adaptation syndrome', the hormonally mediated somatic stress response. Alexander believed that chronic overstimulation of the sympathetic nervous system was associated with stress related diseases. An intensive study of the US Navy circa 1970 found that men with the highest number of LCUs (life change units, a measurement of life events) developed more illnesses of all kinds. Some such events are independent of the individual (whole workforce is laid off) and others are probably dependent (only one is laid off out of a force of 6,000).

Rutter ea (1970), in their Isle of Wight study, found that conditions like asthma or diabetes doubled the likelihood of psychiatric disturbance in children, while neurological disorders such as epilepsy or cerebral palsy increased the risk five fold.

²¹³¹ In many cases only the psychiatrist who is on call on that day provides a consultation service, perhaps coming in from a different hospital. At the other extreme a consultation-liaison service is delivered on site by a dedicated multidisciplinary team.

- Increases number of discharge diagnoses

There is no direct relationship between a medical assessment of severity of illness and subjective distress

Find out what patient expects and believes is amiss

Patients may mask mood complaints

Somatic illness can mimic mood disorder

Adjustment disorders with subjective low mood in in-patients are common²¹³²

Treatment of depression in general medical or surgical inpatients shortens hospital stay

Many times more workdays are lost through mental ill health than through industrial disputes

Depressive and anxiety disorders significantly limit function independently of chronic somatic disorder

Depression comorbid with one or more chronic diseases have the worst health scores of all disease states²¹³³

Organic psychiatric disorder, especially quiet delirium, is missed more often than are mood disorders

GPs and house officers miss half of mood and anxiety disorders

Personal and social costs of mental and addictive disorders resemble those for major physical illnesses like cardiovascular disease and cancer, yet are relatively poorly funded when it comes to research

Organic brain disease increases the likelihood heightens the chances of psychiatric disorder

Children often complain of somatic symptoms like abdominal pain, headache, and limb pains

One-quarter of children with abdominal pains severe enough to warrant paediatric investigation develop chronic psychiatric problems

In a (non-random) community (cross-sectional) study, Surtees *et al.* (2003) found that chronic anxiety caused greater physical health limitations than chronic depression or a number of somatic disorders²¹³⁴. According to Pitt (1998) up to 30% of people over 65 years of age in general hospital wards are demented, a rate that is six times the community rate, and 10-20% of the same group have delirium.

In the US in particular, there is been a tendency to fully investigate patients for organic disorder before considering or tackling psychosocial problems. A positive psychological profile may reduce the mortality and morbidity associated with disease. (Earll & Johnston, 1993) O'Shea and Falvey (1991) and Williams *et al.* (1999) found a connection between large case notes and psychosocial deprivation and psychiatric problems in psychiatric and medico-surgical populations respectively.

Selected medico-psychiatric research finding

1818 Johann Heinroth uses 'psychosomatic' in reference to some causes of insomnia

1922 Felix Deutsch uses term 'psychosomatic medicine'

1939 Billings of Colorado General Hospital coins term 'liaison psychiatry'. (Morriss & Mayou, 1996)

1980 Use of opiate analgesia often inadequate because of exaggerated fears of inducing dependence.

1982 TCAs (tricyclics) as effective as H2 blockers like cimetidine for treating peptic ulceration.

1984 Neurologists miss almost ¼ of cases of psychiatric morbidity: don't ask, not told, miss cues, or not considered.

1986 At least 50% of patients with carcinoma of GIT are alcohol dependent

1988 Alcohol abuse in women increases risk of breast cancer (Longnecker *et al.*, 1988)

1990 UK: Liaison work is very variable in terms of level of development and in who provides it (sector team, junior doctors, special teams). Very often, because of the workload, liaison psychiatrists can only manage to see only emergencies. The psychiatry of old age is rather better developed than other liaison work in general hospitals.

Pre-exposure history of excess anxiety or depression and of excess unexplained somatic complaints made plastics workers more prone to become ill after exposure to chemicals.

Psychiatric diagnosis in A&E ward admissions associated with single status, low socioeconomic status, unemployment, not having a home, and not being registered with a GP.

1991 Many physical complaints have no discoverable organic cause; do not automatically attribute the to 'mental' mechanisms; do not overinvestigate; early recognition/management of emotional & cultural elements important.

Psychological stress increases risk for acute respiratory illness, but significant methodological problems.

Psychiatric basis of some general hospital admissions is missed and psychiatric referral does not follow.

Stress increases metastatic spread of rat mammary cancer via suppression of natural killer cell cytotoxicity.

Chronic pain increases risk of suicide to 2-3 times the general population rate (Fishbain *et al.*, 1991)

²¹³² Use of symptom checklists potentially over-diagnose formal depressive disorders when the correct diagnosis may be difficulty adjusting to somatic illness, pain, dyspnoea, other distressing symptoms, loss of familiar environment/relationships, and a depressing hospital milieu. (Winrow & Holmes, 2005) One should not ignore the possibility of abstinence phenomena, including withdrawal from nicotine, alcohol, and prescribed or illicit substances, or iatrogenic depression.

²¹³³ See Moussavi *et al.* (2007)

²¹³⁴ Except for stroke.

- Men and women with schizophrenia have life expectancies of 57 and 65 years, living a fifth less years than otherwise expected.
- 1993 Cancer of larynx: 40% of laryngectomy patients found to be depressed, but none who received radiotherapy (Irish pilot study).
- 1994 Unemployment in previously stably employed middle-aged men led to increased mortality from both cancer and cardiovascular disorder, even after adjusting for other variables such as alcohol, tobacco and weight.
- 1995 Patients with at least 10 admissions to non-psychiatric departments during 8 year period. Of persistent somatisers, 16% were learning disabled (low IQ), 48% dependent on drugs or alcohol, and 48% were personality disordered. Main ICD diagnoses: anxiety states (54%), depressions (30%), phobias (18%), and psychosis (20%).
- 1996 Overwork can kill, especially if combined with high physical & psychological demand, low control over decisions, and low social support, including meeting colleagues socially. Mechanisms require further research.
- 1997 Alcoholics have similar medical outcomes to other patients after liver transplantation, but they are still vulnerable to alcoholic relapse; little is known about predictors.
41% and 26% of 345 consecutive patients presenting to urban teaching hospital emergency department screened positive for substances of abuse and alcohol respectively.
- 1997 German general practice study of peptic ulcer: alcohol protects against and caffeine may promote *H. pylori*! Nicotine is neutral.
- 2000 Increased risk of breast cancer if mother died during patient's childhood and if patient had a history of chronic depression.
- 2001 Mortality rate in Massachusetts among cases of severe mental disorder in 2000 was 3 times expected rate (in 25-44 year olds the cardiac-related death rate was raised more than 6-fold); main cause was cardiovascular, followed by respiratory.
- 2002 Severely stressful life experiences do not increase risk of recurrence of breast cancer.
Retrospective study of cadaveric renal transplantation at Dublin's Beaumont Hospital suggests that with comprehensive pre-transplant multidisciplinary assessment psychiatric patients can do well.
- 2003 People with schizophrenia, esp. males, have a predicted increased risk of both coronary artery disease and stroke; they have a poor diet; most smoke; most are overweight/obese.
Large Danish study of breast cancer patients finds depression to be a negative prognostic factor.
Strong inverse relationship between social support and psychiatric morbidity in people with early breast cancer.
In March, American Board of Medical Specialities approves subspecialty of psychosomatic medicine.
The more depressed is the peritoneal dialysis patient the greater is the risk of peritonitis.
- 2004 Of 200 consecutive psychiatric admissions 48.5% and 22.5% scored 'hazardous/harmful use' and 'significant dependence' respectively on Alcohol Use Disorders Identification Test (AUDIT), with no significant gender differences; alcohol misuse was strongly associated with suicidality.
Oropharyngeal (22-57%), pancreatic (33-50%), and breast (1.5-46%) cancers often associated with depression.
- 2005 SSRIs might reduce cardiovascular morbidity/mortality in depressed patients after acute MI, but controlled study needed.
Folate might protect against increased risk of breast cancer associated with alcohol consumption.
World's first partial facial transplantation performed in France by Jean-Michel Dubernard.
Excess of suicides in men aged 65 years or older with prostate cancer in Florida.
- 2006 Using Alcohol Use Disorders Identification TEST (Audit), over 36% of subjects in medical and surgical wards of an Irish hospital screened positive for either an alcohol use disorder and/or for binge drinking; male sex and under 65s were risk factors.

International school-based survey (131 countries) of 13-to-15-year-olds showed relatively narrow gap in tobacco use between the sexes, a high willingness to take up the habit, and high levels of second hand smoke exposure at home and in public places.
- 2007 Preliminary evidence that increased folate intake decreases risk for Alzheimer's disease, or at least improve information processing and sensorimotor speed in the elderly.
UK GP research database: severe mental illness associated with increased risk of death from coronary heart disease/stroke (not fully explained by medication/smoking/social deprivation); no increase in non-respiratory cancer mortality.
Norwegian study finds that folate supplementation in early pregnancy reduces risk of isolated cleft lip by a third.
Stimulant drug abuse among young adults may increase the rate of hospital admissions for stroke and related morbidity.
2177 patients with MI evaluated for ICD-10 depression and randomised to intervention or care as usual:
antidepressant therapy did not affect likelihood of depression or cardiac events. However, study lacked statistical power.
Folate-fortified cereal food reduced rate of neural tube defects in Canada.
- 2008 Follow-up of entire Swedish population 1973-2004: rheumatic disease increased risk for psychiatric disorder; SLE and ankylosing spondylitis carried higher risk of psychiatric disorder than did rheumatoid arthritis (RA); SLE increased risk for dementia and delirium; only women with RA and SLE had increased risk of psychosis and severe depression.
Large randomised Belarussian trial suggests prolonged and exclusive breastfeeding improves children's cognitive development.
36% of referrals to Irish old age psychiatry services are consultation/liaison referrals but only 2 of 14 services have ring-fenced resources for consultation/liaison work.
12-year follow-up of civil servants: positive affect and affect balance (between positive and negative affects) do not predict future coronary heart disease if free of heart disease at start of study but negative affect is weakly predictive.
Prospective Irish study of surgical admissions at two institutions during 2005; used HAD scale; 12.5%, 18.5%, and 8.3% had significant depression, anxiety, and mixed anxiety-depression respectively and 22.9% warranted referral to liaison psychiatry services.
Medically certified absence from work among London civil servants was associated with 1.7 times increase in mortality, whereas absence for psychiatric reasons was associated with 1.9 times increase in general mortality and 2.5 times increase in cancer mortality. (Head et al, 2008)
17% of older patients admitted for heart failure had a mental illness diagnosis and this subgroup received poorer care and was at greater risk of death and readmission than were those without a psychiatric diagnosis (Medicare patients).
Young people with new onset of panic attacks/disorder at increased risk of coronary heart disease/MI; this may reflect initial misdiagnosis of CHD as panic attacks/disorder or underlying increased risk of CHD with panic in younger people.
- 2009 Patients with advanced cancer who had dependent children were more anxious, less likely to engage in advance care planning,

and had poorer quality of life in week before death (prospective cohort study).

Most kidney donors have a good quality of life in the long-term.

Only a small proportion of women planning pregnancy comply with recommendations re nutrition and lifestyle, e.g. 2.9% of those who became pregnant within 3 months of interview were taking 400 mcg or more of folic acid and consuming 4 or less units of alcohol/week

The EUROASPIRE surveys in eight European countries found that adverse lifestyle trends persist in patients one year after a cardiac event, and that a fifth of patients still smoked and the proportion of young women smoking actually increased.

Diet rich in fruit and vegetables, moderate drinking, tobacco avoidance, and exercising reduce risk of stroke

Smoking nullified women's otherwise large survival advantage over men

Depression is a risk factor for morbidity and mortality in patients with coronary heart disease, particularly following acute coronary syndrome; treatment-resistant depression may have even stronger implications

Woman in US has face transplant for repair of damage inflicted by gunshot

Healthy young volunteers watched comedy and stressful movie strips: laughter reduced pulse wave velocity, cortisol levels, and soluble P-selectin²¹³⁵; stress increased pulse wave velocity and decreased IL-6 status; positive cardiac effects of laughter last about half an hour

Breast and lung cancer death risk increased in schizophrenia females and males respectively during 11-year follow-up

Danish study suggests that treatment for heart disease offered to individuals with severe mental illness is poor

Women with schizophrenia in Manitoba are less likely to be screened for cervical cancer than are women without schizophrenia

Long-term cancer survivors not at increased risk for major depression but are more impaired if it occurs

In a Swedish twin study (mean age 57 years) comorbidity between major depression (MD) and coronary artery disease (CAD) have a modest relationship over the lifespan but a stronger relationship when time-dependent models are used; sustained effect of CAD on MD risk is much stronger than the other way about; effect of MD on CAD is chiefly acute (long-term effects seem to be mediated by recurrences of MD); in males the environment (often acute effects) play a significant role in comorbidity; in females chronic effects (partly genetic) are more important; and in males, genetics play a greater role in comorbidity in younger people

Persistent depression following hospitalisation for acute coronary syndrome increases mortality over 6.7 years follow-up

Junior doctors lack knowledge about QTc interval in relation to antipsychotic medication and fail to identify high-risk cases

Oestrogen plus progestin therapy in the postmenopausal female does not increase incidence of lung cancer but it does increase

Mortality from lung cancer, especially from non-small cell lung cancer

High lead levels reported in some children's cosmetics

Cross-sectional survey of over 65s in 11 sites in 7 countries with low/middle incomes: dementia was by far the main contributor to disability; other important contributors were stroke, limb impairment, arthritis, depression, sight problems, and GIT problems

Swedish follow-up study of males aged over 30 years finds that prostate cancer associated with threefold increase in risks for cardiovascular event and suicide; drawbacks are lack of tumour stage data and possible residual confounding

2010 Newcastle UK 85 year olds have significant levels of disease and impairment but good functional ability and self-rated health; percentages (M/F) with hypertension 53/60; atherosclerotic disease 55/43; osteoarthritis 43/57; cataract 39/52; ever diagnosis of cancer 20/12; and dementia 7/9

Giving up smoking during the early stages of lung cancer is associated with improved prognosis

Increased risk of acute MI in patients diagnosed with first hospital diagnosis of schizophrenia in Taiwan during a 6-year follow-up

In a 1-year Scottish neurology clinic follow-up of patients, those deemed unlikely to have a neurological disorder were

more likely to be those who didn't attribute symptoms to psychological factors or who were in receipt of illness-related payments

Among primary care patients in Catalonia, quality-adjusted life-year (QALY) losses from mood disorders came second to pain-related chronic medical conditions

World's first *full* facial transplant carried out in Barcelona, Spain by Joan Pere Barret (24-hour operation on a man with severe facial injuries)

Greater increase in testosterone may be associated with menopausal depression

Generalised anxiety disorder increases the risk for cardiovascular events in stable coronary heart disease outpatients

Heart failure is an independent risk factor for incident depression in elderly subjects in this Rotterdam population-based study and use of loop diuretics in such cases reduce the risk for depression

If the patient's ideas about illness are different from the doctor's ideas then the patient is unlikely to co-operate with treatment and management. In one study (Health Education Studies Unit, 1982) this lack of commitment to doctors' instructions was most pronounced among West Indian and Irish adult patients. The concept of long-term management is foreign to most folk medicine. Traditional healers would consider it an admission of failure to continue treatment once the client became symptom-free.

Screening for disease

Can have negative effects on mental health

²¹³⁵ A cell adhesion molecule on surfaces of activated endothelial and platelet cells.

Positive results may cause upset, mitigated by adequate counselling

False-positive results, later shown to be negative, may lead to adverse effects even when the later findings are known

Negative results could, potentially, reinforce adverse lifestyles (e.g. smoking)

Sifneos coined the term *alexithymia*²¹³⁶ in the 1970s to describe patients who go on interminably about symptoms but describe any psychological difficulty in a superficial way; they appear to be out of touch with feelings and fantasy. *Somatisation*, on the other hand, is a complex mixture of phenomena, such as conversion-type symptoms (e.g. seizures) and amplification of normal (e.g. palpitations) and abnormal sensations (e.g. pain, etc). Somatisation is common in Western primary care in the developed world and is not confined to the Developing World. There is no convincing evidence that alexithymia explains somatisation. Medically unexplained symptoms (MUS²¹³⁷) are common and should be taken seriously, a psycho-biological model should be proffered, and, where available, cognitive therapy should be offered. Organic underpinnings are often sought and rarely missed, but psychiatric problems (particularly anxiety and depression), although common, are often missed.(Hatcher & Arroll, 2008)

Malingeringophobia

Described by Issy Pilowsky of Adelaide, Australia in 1985

Irrational and maladaptive fear of being tricked into providing health care to individuals who masquerade as sick, but either have no illness at all, or have a much less severe one than they claim

Can get out of hand, with serious consequences for both patient and doctor

Miller et al (1985)²¹³⁸ looked at eleven ways in which people might react to stress. Subjects were asked if they had reacted in that way in general in the past 6 months and if they had reacted in that way in response to any specific life stresses. Being angry with one self or with others, rumination, use of alcohol or tobacco (see Spring et al, 2003), all discriminated between those who were well and those who were psychiatrically ill at initial interview. These items were formed into a 6-point scale of maladaptive reactions. They performed a follow-up analysis of 306 women who were well at the first interview. 35 suffered an episode of psychiatric illness (23 depression, 12 anxiety) within the subsequent year. Maladaptive reactions at the first interview predicted later illness inception, even after taking life stress into account. Such reactions seemed sometimes to lead to illness even when there was only minimal later life stress. Attempts to find coping reactions that afford protection against illness inception were unsuccessful.

Patients with chronic disease should be assisted to achieve emotional adjustment by remaining as active as possible, to accept and express feelings so as to win back control, to become involved in self-management, and to search for positive outcomes of their illness.(de Ridder et al, 2008)

In a survey of patients admitted to medical geriatric wards about 10% had an acute organic psychiatric syndrome.(Hodkinson, 1973) The chief predisposing factors were pre-existing dementia, defective hearing and vision, Parkinson's disease and advanced age. The next most common factors were pneumonia, cardiac failure, urinary tract infection, carcinomatosis, and hypokalaemia. Children develop acute organic syndromes more readily than do adults when physically ill, e.g. with fevers. Chronic disorders can cause intellectual disability, disintegrative psychosis or dementia.

Denial

Commonly reported defence mechanism in clinical medicine

²¹³⁶ This is also called somatothymia. In a small PET study of healthy female alexithymics the latter demonstrated a different pattern of cerebral activation to controls in response to emotional stimuli.(Karlsson et al, 2008)

²¹³⁷ 'MUS' represents an attempt to lump conversion, dissociative, and somatisation conditions together. Some might see this as hysteria resuscitated!

²¹³⁸ 576 Edinburgh women

Found, for example, in myocardial infarction (MI) patients, in renal transplantation and, for the graft and/or donor, in heart transplant recipients
 May have protective and adaptive functions
 Denial of fatal illness may help the patient but hamper preparation for bereavement in the spouse
 Organ transplants recipients may commit 'passive suicide' by stopping immunosuppressants
 Some kidney recipients stop immunosuppressants knowing that they can fall back on haemodialysis

Anxiety and some depression are very common for a few days after MI. Less than 20% develop a severe depressive reaction. Depressed patients may report angina²¹³⁹ more often than non-depressed cases. There is increasing evidence that post-MI depression increases the risk for subsequent coronary events. Among ninety-six unselected patients referred to a specialist clinic for recurrent or persistent abdominal pain (Gomez & Dally, 1977), only 15 were found to have organic disease.²¹⁴⁰ Individual cases may shed light on why physical problems cause psychological difficulties.²¹⁴¹ Trainee psychiatrists' case notes of are notoriously deficient in the area of physical examination, especially concerning neurological and locomotor systems.(Rigby & Oswald, 1987)

Bone-pointing syndrome

A form of giving up
 Seen in primitive societies and patients who are told of a terminal diagnosis
 Derives its name from witch doctors that point a bone at people upon whom they wish to place a spell
 Patient turns to the wall, gives terse answers, and dies quickly²¹⁴²
 Going to a prestigious treatment centre may cause a temporary, psychologically mediated remission, just as when a 'stronger' witch doctor revokes the spell of a lesser one

Biofeedback involves a measuring device and immediate delivery of feedback to the patient on his responses. It can be direct (feedback given about the disorder on symptoms to be controlled, e.g. blood pressure) or indirect (this does not measure the disorder or symptom directly). The patient is taught something which produces a desirable effect on the symptom, e.g. if you warm your hands it decreases the frequency of migraine headaches. He must convince himself of the effect through practice. There is no strong evidence to suggest that biofeedback is any better than any other form of relaxation or meditation for tension-related disorders. Focus on changing a specific EEG does not negate the fact that benefit accrues from 'repeated low-stress focused attention'.(Reeve, 2003, p. 116)

Psychoneuroimmunology

About 30% of people respond to inert placebos²¹⁴³ during clinical drug trials. The charisma of the therapist is also a significant element in treatment outcome (bedside manner). Depression commonly follows illnesses such as glandular fever, brucellosis, influenza and infectious hepatitis. Animal studies offer some evidence that the immune system can be taught to respond to simple learning techniques, as when saccharin is first paired with an immunosuppressant and then given alone with the same effect. Fawzy ea (1993) demonstrated improvement in employment of coping strategies and in immune function after a short-term group interaction in people with malignant melanoma. We all experience poor resistance to infection when tired or experiencing prolonged stress.(e.g. Cohen ea, 1999) Depressives also exhibit this tendency. Hostile marital reactions are associated with slower wound healing and muted local cytokine²¹⁴⁴ production at blister wound sites than occurs after supportive social interactions.(Kiecolt-Glaser ea, 2005) Stress may lower the rate of secretion of s-IgA.²¹⁴⁵ Even with removal of the cause the person who is unable to

²¹³⁹ It should be noted that angina can be precipitated by vivid dreams.

²¹⁴⁰ Thirty-one had depression; 21 had an anxiety neurosis; 17 had symptoms of 'hysterical' origin; and, not detected until the survey, 12 had alcoholism.

²¹⁴¹ E.g. in the case of a lady with a mastectomy, 'Her husband said to her in so many words that he wouldn't go to bed with a lopsided woman'.

²¹⁴² E.g. a tumour may not be seen to account for demise at autopsy.

²¹⁴³ Rightly or wrongly, placebo prescribing is common.(Tilburt ea, 2008)

²¹⁴⁴ IL-6, TNF- α , and IL-1 β . Depression is associated with decreased IL-6 and C reactive protein.

²¹⁴⁵ Salivary immunoglobulin A.

externalise aggression may show a continued fall in s-IgA levels. There is evidence to suggest T-lymphocyte suppression after bereavement and in major depression. These changes appear independent of variables like diet, activity, drugs taken, and alcohol and tobacco consumption. There may be impaired Type I/cellular immunity in schizophrenia.(Freudenreich ea, 2010)

Opiate abuse may directly affect susceptibility to HIV-1 infection because morphine induces a chemokine receptor that the virus utilises to enter T-lymphocytes.(Miyagi ea, 2000)

ACTH increases in response to CRF following acute stress. This leads to increased adrenal cortisol release. Raised cortisol levels temporarily suppress cellular immunity. Negative feedback reduces further CRF release, thereby stopping further cortisol release. Arginine vasopressin (AVP) is also partly responsible for adenohypophyseal ACTH release.

In situations of chronic stress, desensitisation of central and peripheral glucocorticoid receptors interferes with normal feedback. AVP and interleukin 1 activate the hypothalamico-hypophyseal axis with resultant persistence of hypercortisolaemia.

One theory of depression suggests that the activity of brain neurotransmitters change as a result of inflammatory changes.²¹⁴⁶ Pro-inflammatory cytokines lead to neural damage. In chronic cases, desensitisation of glucocorticoid receptors on neurones and immune cells leads to further damage via high cortisol levels. Antidepressants may affect cytokine release and modulate intracellular signals²¹⁴⁷ to alter pro-inflammatory cytokine synthesis.²¹⁴⁸ Raised interleukin-6 may be associated with major depression in cancer patients.(Sherman & Fisch, 2004) Fitzgerald ea (2006) found evidence for reduced cutaneous glucocorticoid receptor function in depression resistant to antidepressants, that circulating TNF-alpha²¹⁴⁹ may play an important role in this abnormality, and topical steroid efficacy is diminished in such cases. Tacrolimus (e.g. Prograf) and cyclosporine (e.g. Neoral) may cause a periventricular leucoencephalopathy with sudden change in mental state.

Observing the face

The face is normally the most accessible part of the body. The acromegalic may become unrecognisable to friends and scleroderma may mimic excessive use of Botox. Brown pigmentation may be due to a holiday in the sun or to Addison's disease but the latter is associated with greying of the oral lining.²¹⁵⁰ Vitiligo, an autoimmune-based depigmentation (especially affecting face, hands, and genitalia) with loss of melanocytes, may have severe psychological consequences, particularly in coloured patients. Specialist advice about camouflage is helpful. Hypomania and depression may be betrayed by excessive and diminished display of engagement respectively. Down's syndrome is unmistakable. Tremor of the lips may suggest dependence of alcohol and tongue protrusion and smacking of lips may point to tardive dyskinesia. The face is screwed up on one side in tic douloureux (trigeminal neuralgia). A hairless face in hypopituitarism, puffy eyelids in hypothyroidism, a look of 'surprise' (prominent eyeballs and retracted eyelids) on the face in hyperthyroidism or the expressionless facies in Parkinson's disease, the moon facies of Cushing's syndrome is accompanied by hirsutism²¹⁵¹, the intended smile replaced by a sneer in myasthenia gravis, the long thin face of dystrophia myotonica or the *tire en travers* (transverse smile) of facioscapulohumeral dystrophy, and the head may move in synchrony with the pulse in cases of aortic incompetence. Incongruous affect or blunted emotions may prompt a search for other symptoms of schizophrenia. Facial palsy may spare emotional movements or, rarely, emotional movement may be lost²¹⁵² with retained voluntary activity.

Neuroendocrinology & psychoneuroendocrinology

While neuroendocrine axes are abnormal in some patients with certain psychiatric disorders, (Arce ea, 2003) these often normalise on recovery from an illness episode, suggesting state rather than trait markers. As yet, such findings have limited clinical application.

²¹⁴⁶ IL-1 → increase in prostaglandin E2 and NO.

²¹⁴⁷ E.g. cyclic AMP and BDNF.

²¹⁴⁸ Examples of pro-inflammatory cytokines include IL-1 and -6 and TNF- α . Anti-inflammatory cytokines include IL-4, -10, and -13.

²¹⁴⁹ Depressed patients with congestive cardiac failure have raised levels of TNF- α and soluble apoptosis mediators.(Parissis ea, 2004)

²¹⁵⁰ Phenothiazines and a number of other drugs (antimalarials and anovulants) and toxins (e.g. lead) can cause oral pigmentation.

²¹⁵¹ **Hirsutism** due to ovarian causes is associated with very high serum testosterone levels whilst dehydroepiandrosterone (DHEA) levels are raised in cases associated with disease of the adrenal glands. Idiopathic/familial, polycystic ovaries, and the menopause are the most frequently encountered causes of hirsutism. There are many other causes, e.g. anorexia nervosa, acromegaly, Cushing's syndrome, congenital adrenal hyperplasia, glucocorticoids, ACTH, anabolic steroids, minoxidil, and phenytoin.

²¹⁵² With lesions affecting temporal lobe or pons.

Hypothalamico-pituitary-end organ axes

Gonadotrophin releasing hormone (GnRH) stimulates release of luteinising (LH) and follicle stimulating hormones (FSH)

GnRH controls the menstrual cycle in females (in males, secretion of testosterone and spermatogenesis)

Growth hormone releasing hormone (GHRH) stimulates growth hormone (GH) release

Somatostatin inhibits release of GH and TSH (it also has effects on various GIT structures)

Thyrotropin (TRH) releasing hormone releases TSH and prolactin

Dopamine (DA) inhibits prolactin and TSH release

DA blocking drugs such as metoclopramide and antipsychotic drugs increase the TSH response to TRH

Corticotrophin releasing hormone (CRH) stimulates release of ACTH and other POMC-related peptides

ACTH regulates adrenal cortisol secretion

Acromegaly

In acromegaly there is excess growth hormone (GH) secretion by a pituitary somatotroph adenoma or, less often, hyperplastic adenohypophyseal eosinophil cells. Growth hormone acts via insulin-like growth factor-1. Most cases are insulin resistant and one-fifth is diabetic. Facial disfigurement (e.g. widely spaced teeth) is an important issue. Macroglossia and hypertrophic pharyngeal soft tissues lead to obstructive sleep apnoea. Patients may lack spontaneity and state this may alternate with periods of elation and impulsiveness. The patient may become uncaring of others and self-centred. Eventually thinking becomes slowed. Respiratory, cardiovascular and cerebrovascular problems shorten life expectancy. Surgical interventions involve removal of small tumours via the sphenoid sinus with the addition of radiotherapy and medical therapy for partially removed larger adenomas. Bromocriptine and other dopamine agonists that inhibit GH secretion via certain somatostatin receptors have been replaced by long-acting somatostatin analogues (e.g. octreotide), and novel medications like pegvisomant (Somavert), a GH receptor antagonist. (Schreiber et al, 2007)

Metabolic syndrome (Reaven's syndrome, syndrome X, insulin resistance syndrome)

Human obesity with insulin resistance²¹⁵³, dyslipidaemia, and hypertension; measurement of abdominal obesity and fasting blood sugar are good screening tests; and weight reduction, increased physical activity, and medication review are the main indicated interventions. (Eckel et al, 2005; Straker et al, 2005) Yevtushenko et al (2008) found that leptin genotype and smoking were associated with metabolic syndrome in schizophrenia. Interacting with diet, a polymorphism in the multi-PDZ domain-containing adaptor protein (PDZK1)²¹⁵⁴ is associated with the metabolic syndrome. (Junyent et al, 2009) Low levels of vitamin D may also be important. (Reis et al, 2009) Lower levels of adiponectin²¹⁵⁵ and gain in weight after taking atypical antipsychotic drugs increased the risk of metabolic syndrome in patients with schizophrenia. (Bar et al, 2009) Metabolic syndrome is associated with stress at work (Chandola et al, 2006) and with clozapine. (Lamberti et al, 2006; Ahmed et al, 2008) Metabolic syndrome is 2-4 times more common in schizophrenic cases v controls. Type II diabetes is more common in schizophrenic patients (even before atypical antipsychotics) and in unaffected relatives of schizophrenic patients than in controls. About 15% of drug-naïve first-episode schizophrenic patients have impaired fasting glucose levels and hyperinsulinaemia. First episode schizophrenic patients have three times as much intra-abdominal fat as do matched control subjects. Meyer and Stahl (2008) reviewed the literature on metabolic syndrome in schizophrenia and found strong evidence for significant cardiometabolic risk differences among antipsychotic agents. They point out that H1 and 5-HT2C antagonism are associated with weight gain, but receptor targets for dyslipidaemia and insulin resistance (both of which may occur without weight gain with some antipsychotic drugs) are as yet unidentified.

²¹⁵³ Insulin resistance may explain most, if not all, of the syndrome. (Eckel et al, 2010)

²¹⁵⁴ This protein regulates the HDL-receptor scavenger-receptor type B class 1.

²¹⁵⁵ This is a hormone derived from adipocytes and it is involved in the control of lipid and carbohydrate.

Weight gain is highest with clozapine and olanzapine, somewhat less with risperidone and quetiapine, and lower again with ziprasidone and aripiprazole.²¹⁵⁶

The clinical relevance and predictive power of the metabolic syndrome *per se* has been questioned.(Kahn, 2008; Sattar ea, 2008; Eckel, 2010; Bayturan ea, 2010) Does it really hang together, i.e. is it no better than the sum of its parts? It may be better to simply treat each abnormality appropriately.

Sensory deprivation

D. O. Hebb researched the role of prolonged sensory isolation during brainwashing.

With visual, auditory, and tactile deprivation for periods up to seven days there may develop

Increased suggestibility, anxiety, tension

Poor concentration and ability to organise thoughts

Somatic illusions

Physical complaints

Intense subjective emotional distress

Vivid (usually visual) sensory imagery

Hallucinations and delusions (sometimes)

Weaning from mechanical ventilation

A minority of patients find this difficult to tolerate. Reasons include fear of dying, depression and other negative affects such as anger, and conflicts with others. Interventions include slow, gradual weaning, dealing with conflicts, and cautious use of medication.

Hypothermia

Psychiatrists should be aware of this disorder for many reasons. A reduction in heat production may follow overdose when a patient lies on a cold floor for a long time before being discovered. A depressed or demented patient may not eat properly or attend to domestic heating. Hypothyroidism is also associated with decreased heat production. Excess heat loss may be associated with alcoholic intoxication. Giving alcohol will cause vasodilatation and increased heat loss. Failure of the brain to regulate body temperature may follow overdose with phenothiazines, barbiturates or TCAs. Drug screening should be performed. In hypothermic subjects the ECG may show rounded waves rising above the isoelectric line (J waves) where QRS complex and ST segment meet and prolongation of QT interval and QRS complex. Death is usually due to ventricular tachyarrhythmia/fibrillation/asystole. Hypothermia may simulate brain death.

Lyme disease

This is a tick transmitted spirochaetal infection caused by *Borrelia burgdorferi*.²¹⁵⁷ It is the most common European tick-borne disease. Most cases are benign and self-limiting. Delusional disorder, schizophrenia-like disorder, bipolar disorder, major depression, panic disorder, anorexia nervosa, OCD, and dementia have been reported in association with Lyme disease. 26-66% of cases develop a depressive state.

Acute pancreatitis

The most common causes are bile stones and alcohol abuse, although cigarette smoking is an independent risk factor for acute recurrent pancreatitis.(Yadav ea, 2009) Other causes are idiopathic (15-25% of cases),

²¹⁵⁶ All 6 of these drugs carry an FDA diabetes warning although the latter 2 drugs probably have the least risk of the 6 in practice.

²¹⁵⁷ **Lyme disease:** Burgdorfer described this tick-borne spirochaete in Lyme, Connecticut in 1975. The vector is the tick *Ixodes ricinus*. Any bodily organ can be affected. In most parts of Europe it is the deer that is the common carrier of the tick the main Irish reservoir is the woodland population of birds.(Cullen, 2010) Rodents are important in Central Europe. Because of rising temperatures there may be an increase in the incidence of the disease. Three stages have been described. *Erythema chronicum migrans* (rash develops days/weeks after bite and is an annular erythema that slowly spreads outwards; usually found on trunk/limbs), with or without systemic symptoms (pyrexia, headache, backache) constitutes stage one. In stage 2 there may be a fluctuating meningoencephalitis, cranial and peripheral radiculoneuropathies, mononeuritis multiplex, Guillain-Barré syndrome, and myositis. Stage 3 may develop after months to years and include oligo-articular arthritis or a chronic neurological syndrome including meningoencephalomyelitis, spastic paraparesis, seizures, ataxia and dementia. Diagnosis depends on finding raised titres. Lyme disease and syphilis may give false positive tests for each other. Early cases respond to doxycycline. Treatment with IV centrally-penetrative antibiotics such as ceftriaxone is used if there is involvement of the nervous system. Feder ea (2007) are very critical of the concept of chronic Lyme disease.

toxic (scorpion bite, organophosphates), surgery, genetic (e.g. PRSS1), infection (bacteria, viral, parasites), hypercalcaemia, hyperlipidaemia, SLE, Sjögren's syndrome, pregnancy, trauma, ischaemia, and numerous drugs, e.g. steroids, opiates, valproate, carbamazepine, lamivudine, and paracetamol. (Frossard et al, 2008)

Chronic pancreatitis

The classic sufferer is a middle-aged alcoholic male. Drinking alcohol, bending forward, and opiates (risk of addiction) relieve the pain. Despite advice, most sufferers continue to drink.

Aetiology of chronic pancreatitis

West – alcohol and cigarette smoking²¹⁵⁸

India – malnutrition, cassava

Diabetes mellitus (DM)

Maternal glucose can cross the placenta whereas insulin cannot do so. Many oral anti-DM drugs cross the placenta but are generally avoided because of potential foetal damage.

On being told of the diagnosis, patients may exhibit anger, anxiety, depression, social withdrawal, or denial. In a study of 50 insulin-dependent diabetics common symptoms were marked anergia, excessive fatigue, irritability, depression, and delayed psychosexual maturation. DM often makes the patient feel uncomfortable, reduces his functional capacity, disrupts family life, and disturbs the adolescence of those affected at an early age. Family dysfunction is associated with poor control of diabetes in juvenile-onset cases and the latter correlates with reading problems and psychiatric in child and/or parent. 10-20% of chronic cases may have cognitive impairment²¹⁵⁹ due to diseased large and small vessels. However, an (average of) 18-year follow up of 1114 cases of type I diabetes revealed no substantial²¹⁶⁰ cognitive dysfunction despite relatively frequent attacks of severe hypoglycaemia. (DCCT/EDIC²¹⁶¹ Study Research Group, 2007) Mean age of entry to the study was 27 years. Ohmann et al (2010) examined executive function and other neuropsychological and psychosocial variables in adolescents with type I diabetes and did find cognitive deficits that were independent of quality of metabolic control and disease duration. The authors suggest such deficits are due to the disease, especially when the condition has a early onset.

The diabetic way of life has its own intrinsic stresses, and the disease has direct effects on the nervous system. Abnormal eating attitudes are common in young insulin-dependent female diabetics, but are less likely in their male counterparts. Hyperglycaemia and glycosuria (which cause weight loss) and the emphasis on diet may promote eating disorder; reducing insulin intake also reduces weight (and increases the chance of complications such as retinopathy and diabetic ketoacidosis). (Goebel-Fabbri et al, 2007, p. 92) Kawakami et al (1999) followed up 2,764 male employees in a Japanese company for eight years. They were screened at entry with the Zung (self-rating) depression scale. Each year they were screened for DM. 43 developed type II DM over the study period and of these 9 have moderate/severe depression at study onset. Various factors, such as activity, alcohol, and obesity were controlled for. The 9 cases with moderate/severe depression at study onset had a 2.3 times increased risk for type II DM at follow-up relative to non-depressed/low level of depression at entry to the study. Atlantis et al (2009) in Melbourne found that depressive symptoms doubled the risk of developing diabetes on follow up in the elderly independent of antidepressant drugs. In a community follow-up study, Campayo et al (2010) reported that clinically significant depression is associated with a 65% increased risk of DM. Type A behaviour pattern in childhood DM may be associated with an increased likelihood of a hypoglycaemic response to stress. A psychiatric diagnosis was recorded in 50% of patients being assessed for pancreatic transplantation, and 25% of patients had a lifetime history of major depression. (Popkin et al, 1988) Henry Maudsley noted an excess of DM among patients with schizophrenia. (Farmer, 2003) This connection was certainly discussed before the introduction of antipsychotic drugs. (Kooy, 1919; Braceland et al, 1945) All schizophrenic patients,

²¹⁵⁸ See Yadav et al (2009).

²¹⁵⁹ Sometimes multi-infarct dementia.

²¹⁶⁰ Caveats: Higher glycated haemoglobin values were associated with moderately reduced motor speed and psychomotor efficiency. Pre-study test results on the small number diagnosed during childhood and information on elderly cases or those with over 30 years of illness cannot be provided by this study.

²¹⁶¹ Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications.

regardless of medication status, should be screened for diabetes.(Smith, 2008) Poor control, as illustrated by glycosylated haemoglobin levels, is more common in diabetics with a psychiatric illness. Even when compliance is controlled for, stress seems to adversely affect control. However, compliance to diet and exercise is reduced by depression.(Katon ea, 2009) Psychological factors appear to play some role in 'brittle' DM, but it should be recalled that the diabetic adolescent whose DM is difficult to control and who acts out also has labile diabetogenic hormones because he is an adolescent.(Kay & Tasman, 2006, p. 813) Psychosocial stress may play a role in precipitating the disease and in non-compliance in some cases of DM. Significant fears may develop in patients concerning blood sugar dyscontrol and complications such as blindness or amputation. Over enthusiastic control by obsessional patients may lead to persistent hyperglycaemia (to avoid low blood sugar), excessive blood sugar monitoring, and episodes of hypoglycaemia²¹⁶². Emphasis on building a relationship with the adolescent diabetic may prove better in terms of disease control than a rigid insistence on acceptable blood sugars.

Diabetes in women may cause reduced arousal, diminished vaginal lubrication, and reduced capacity for orgasm. Bulimia nervosa patients who are also diabetic may deliberately omit their insulin. Logroscino ea (2004) found that elderly women with type II DM had an increased likelihood of having poor cognitive function that gets worse over time and that oral hypoglycaemic drugs may reduce this risk. Drugs like beta-blockers may reduce arousal (and erection in the male). Sexual dysfunction may be associated with depression.

Autonomic neuropathy affecting the vagus nerve in diabetics

Tachycardia and loss of sinus arrhythmia

Later on there may be cardiac denervation²¹⁶³

Impaired reflexes, e.g. Valsalva

Postural hypotension (loss of peripheral sympathetic tone)

Polyneuropathy – warm foot with bounding pulses (vasodilatation)

In a systematic review and meta-analysis, Gillies ea (2007) found that lifestyle interventions are at least as effective as drug treatment in reducing the rate of progression to type 2 diabetes in people with impaired glucose tolerance.

Apart from universal precaution with alcohol²¹⁶⁴, the diabetic must be aware of certain facts (see table).

Alcohol

High in energy and carbohydrate

May potentiate the hypoglycaemic action of oral hypoglycaemic drugs and insulin

Produces hypoglycaemia by directly inhibiting gluconeogenesis and hepatic glucose output

Predisposes to lactic acidosis²¹⁶⁵ if taking biguanides

Can induce a disulfiram-type reaction in people on sulphonylureas

Abstinence should be the rule if the patient is obese, hypertensive, has hypertriglyceridaemia, or is alcoholic.

Aripiprazole and ziprasidone are the antipsychotics of choice in people with DM.

Use of exogenous insulin results in low C-peptide levels; oral hypoglycaemic drug use may raise C-peptide levels (mimicking insulinoma) by stimulating beta islet cells; oral hypoglycaemic drugs can be detected in blood or urine.

Nocturnal hypoglycaemia

This is common in Type 1 diabetes. It is often not detected, as it usually does not waken the patient.

Complaints include unrefreshing sleep, vivid dreams/nightmares, hangover/morning headache, and

²¹⁶² Some patients become unaware of the physiological symptoms of hypoglycaemia or cannot distinguish them from anxiety. Shame or helplessness may complicate attacks. Patients may keep their blood sugars too high so that attacks are avoided. A potentially dangerous scenario is where a diabetic ends up in an Emergency Department with hypoglycaemia but is mistaken for a fighting drunk.

²¹⁶³ This is similar to the transplanted heart.

²¹⁶⁴ E.g. alcohol is a relative contraindication to warfarin therapy – risk of bleeding.(Bloomfield ea, 2006)

²¹⁶⁵ So does paraldehyde.

tiredness. A bed partner may notice diaphoresis, restlessness, and twitching/seizures. The cause may be insulin regimen. If the patient's blood glucose level is < 6 mmol/L on retiring a carbohydrate snack should be taken. A fast-acting insulin analogue can be employed for the evening meal or depot intermediate-acting insulin can be delayed until going to bed.

Reactive (postprandial) hypoglycaemia (RH)

There is sudden weakness and faintness with anxiety 1-4 hours after a meal. Blood sugar levels rise and then fall. It can occur in otherwise healthy individuals or it can be due to rapid carbohydrate absorption as in post-gastrectomy patients. Treatment consists of a low carbohydrate diet. Often such patients are anxious and irritable between meals, and the relationship of these symptoms to RH is controversial.

Factitious hypoglycaemia

This may be induced by insulin or by oral hypoglycaemic agents. The pancreas secretes C-peptide along with insulin, so that high insulin and low C-peptide levels indicate exogenous insulin, and high insulin and high C-peptide levels indicate endogenous insulin. (Scarlett *et al.*, 1977)

Plastic/cosmetic surgery

Cosmetic procedures in the US rose from 2.9 million in 1997 to 11.9 million in 2004. About £200 million is spent each year in the UK on cosmetic procedures and one-quarter of bank loans are procured for this purpose. (Veale, 2007, p. 617) Procedures vary from Botox injections to rhytidectomy (face-lift).

Factors associated with worse outcome after plastic surgery

Unrealistic expectations

Delusions

History of dissatisfaction with prior surgery

Suicide rates are increased in women after cosmetic breast augmentation. (Sarwer *et al.*, 2007) Psychiatric disorders to consider body dysmorphic disorder (BDD), amputee identity disorder (AID), body sculpting, and delusional states. The first three of these phenomena are usually 'explained' as fixed (overvalued) ideas. The factitious SHAFT syndrome consists of patients who manipulate plastic surgeons into performing surgery. They patients are described as being sad, hostile, anxious, frustrating, and tenacious. (Kasdan *et al.*, 1998)

BDD cases with multiple complaints may shift focus to other body parts. They have rarely been known to attack their surgeons. BDD patients are often unhappy with previous surgery and may state that the wrong procedure was carried out or that the end result is worse than the original 'defect'. BDD patients may practice DIY surgery, e.g. by filing down teeth or using a staple gun on the face. The milder the symptoms and the lower the expectations of the BDD patient the safer is it to allow surgery to proceed. The attempted suicide rate is increased. (Veale *et al.*, 1996)

AID involves the wish to have a limb(s) or digit(s) amputated. The patient may injure the body part in order to force surgery, or they may amputate the limb themselves. Such cases will often live as 'disabled' persons, e.g. residing in a wheelchair. They (unlike BDD) do not see the part to be amputated as ugly but they believe (like gender identity disorder) that will cope better without it. It should not be confused with apotemnophilia (sexual attraction to disabled persons). Psychiatric treatment is ineffective. (Smith & Fisher, 2003)

Body sculpting cases change their bodies for 'artistic' reasons or desire to take the form of an animal, e.g. the famous 'Tiger man': Dennis Smith, a San Diego computer programmer spent a small fortune on tiger-like tattoos and plastic surgery and had his name changed by deed poll to 'Cat Man'; he claimed to 'feel like a tiger'.

Facial transplantation has become a reality.²¹⁶⁶ As with other transplants, rejection is possible. (Guo *et al.*, 2008) The psychological impact of this procedure needs to be anticipated, planned for and managed. Lay people worry lest the donor's identity is transferred with the face, but modelling procedures suggest otherwise. (Butler *et al.*, 2005)

²¹⁶⁶ There were 13 cases up to August 2010.

Cosmetic genitoplasty for women who want a flat vulva (no protrusion beyond the labia majora) has become a 'booming business'!(Liao & Creighton, 2007) This may represent a lack of knowledge of normal variation or idealisation of a particular physiognomy.

Post-operative cognitive dysfunction

Apart from cardiac surgery (see below), this area has received little research endeavour, findings conflict, and adequate controls are needed to take variables such as disability, pain, and depression into account.(Selwood & Orrell, 2004)

Cardiac problems²¹⁶⁷

Risk factors for QTc prolongation include psychiatric drugs (e.g. thioridazine), drug-drug interactions, congenital long-QT syndrome, pre-existing heart disease, bradycardia, and low potassium or magnesium levels. Mitral regurgitation has been associated with dopamine agonists like cabergoline and with anorectic drugs such as fenfluramine.

A person whose same-sexed relatives died at a certain age may greatly fear death at that age and may take excessive precautions to prevent it, e.g. taking no exercise.

Higher baseline depressive symptoms are associated with increased progression in carotid intima-media thickness²¹⁶⁸ over the next three years.(Stewart ea, 2007) Patients with coronary artery disease who become depressed excrete increased amounts of noradrenaline in the urine.(Otte ea, 2005) Also, such patients when in possession of the s allele of 5-HTTLPR may be more vulnerable to poor outcomes.(Otte ea, 2007)

Patients in receipt of a heart transplant do not experience palpitations with anxiety because the denervated heart does not increase its rate in response to anxiety. This may change with new techniques for restoring sympathetic innervation aimed at improving cardiac response to exercise.(Bengel ea, 2001) Mai ea (1986) found a high prevalence of preoperative anxiety and depression in heart transplant patients. Transient confusional states may occur in the first days after this procedure, as can anxiety, social and behaviour problems. Higher scores on the somatic scale of the GHQ predicted a higher mortality postoperatively. The same authors suggested that certain 'preliminary' and 'tentative' psychiatric requirements before surgery should be addressed. Anxiety and depression secondary to a serious medical disorder is not a contraindication to operation. Severe personality disorder, especially if associated with recent alcohol or drug abuse, may contraindicate surgery. Less severe personality problems are a relative contraindication. Druss ea (2000) reported that patients with schizophrenia are relatively less likely to receive cardiac catheterisation after MI.

Mai (1993) reviewed the subject of heart transplants and that 45% returned to wholetime work and family and sexual problems were common after surgery. Good family and social supports are important requirements. Sound, informed motivation is needed. And, it is important that no serious cognitive dysfunction exists. Chacko ea (1996) found that DSM-III-R Axis I diagnoses predicted post-transplant hospital utilisation and Axis II diagnoses predicted post-transplant behaviour.

Psychiatrists are becoming more involved in the selection of recipients for organ transplants, the prediction of non-compliance with anti-rejection therapies (carrying ethical implications if surgery is denied), and the assessment of post-transplant rehabilitation.

*Psychiatric screening before transplant surgery*²¹⁶⁹

Picture of patient as a person

Capacity and informed consent

Coping skills

Collaborative and adherence abilities

Social supports²¹⁷⁰

Baseline mental functioning

Comorbid psychiatric disorder²¹⁷¹

²¹⁶⁷ The interface between psychiatry and the heart is reviewed in detail elsewhere.(O'Shea, 2006a,b,c) The methodological flaws (such as use of self-reports) in studies purporting to demonstrate a connection between psychological stress and heart disease have been addressed by Macleod ea.(2002)

²¹⁶⁸ Measured by ultrasound.

²¹⁶⁹ Various instruments may be employed, e.g. Psychosocial Assessment of Candidates for Transplant or PACT.(Olbrisch ea, 1989)

²¹⁷⁰ According to Dickens ea (2004) people who do not have a confiding relationship before an MI were at greater risk of further cardiac events.

Substance abuse and ability to stay of substances long-term
 Ability to modify behaviours such as exercise and smoking
 Patient and family requirements during various stages
 Plan services to meet needs

Patients sometimes worry that someone had to die so that they could receive an (cadaveric) organ or that they will somehow take on the characteristics of the donor.

Bass (1986) considered that most patients derive psychological and social benefit from coronary artery bypass grafting (CABG). Those who fare badly are likely to have evidence of pre-operative psychological maladjustment, and to suffer forced retirement (for whatever reason) following surgery. Some develop CNS complications, at least in the short term, (Walzer ea, 1997) especially with a long duration of extracorporeal circulation, microemboli (calcific plaque, platelet aggregates, air from oxygenator), hypotension, a low haematocrit, and metabolic disturbances. Depression following CABG is an important independent predictor of death. (Blumenthal ea, 2003) Post-CABG depression may respond to CBT. (Freedland ea, 2009)

Possible causes of neurological damage from heart surgery (Swain, 1993)

Damage to diseased vessels or intracardiac entrapment of air or particles
 Microemboli produced by interactions between blood and artificial surfaces in cardiopulmonary bypass circuit
 Changes in blood flow and distribution
 Other factors, such as sleep deprivation, neuroleptics, anxiety, pain, and isolation from family

Open-heart surgery, such as valve replacement, may cause more neurological insults than closed surgery, such as CABG.

Factors associated with:

Failure to return to work after operation

Socio-demographic - low socioeconomic status²¹⁷²; age > 55 years; unemployment for 6 months or more before operation; receiving disability pension preoperatively

Clinical - more medical problems and more frequent hospitalisation in previous 5 years; less improvement in cardiac symptoms after surgery; injudicious medical advice

Attitudinal - patient blames coronary disease on work stress; refuses to enter rehabilitation programme after operation; employer has a negative attitude

Return to work

Working before surgery

Short wait for operation

No dyspnoea

Low physical morbidity

Shaw ea (1986) found neurological disorders not to be a major cause of failure to return to work by six months after coronary artery bypass surgery. The long-term prognosis for early postoperative neurological disorders was found to be favourable, except in those patients who had sustained major perioperative stroke.

Bodily change of any variety requires adjustment, and the actual changes appear to be less important than our perception of such changes. (Abram, 1970; Cohen ea, 2009) The wearing of external devices may cause increased vigilance, overdependence on caring staff, fear of being far from the hospital, anxiety and panic, as well as acting to distance the partner from sexual involvement with the patient. CABG or MI are not

²¹⁷¹ Do not use St John's Wort in depressed transplant patients as it may lead to decreased immunosuppressant drug (cyclosporine) levels with consequent graft rejection.

²¹⁷² Pagano ea (2009) looked at over 44,000 adults undergoing heart surgery in part of England during 1997-2007 and found that smoking, extremes of BMI, and diabetes were associated with poor survival after surgery but that social deprivation was an important predictor of mortality risk independent of these variables.

uncommonly associated with PTSD symptoms and intra-aortic balloon pumps or frequently discharging automatic implanted cardiac defibrillators can cause anxiety.(Huffman ea, 2004)

A lower incidence of cardiac problems was found in the early 1960s among Irishmen in Ireland versus their brethren who had gone to Boston, Mass. Other factors incriminated in the genesis of heart disease are well known, e.g. cigarette smoking. Alcohol intemperance is strongly associated with sudden death post-MI. Up to 45% of patients with coronary heart disease (CHD) may become depressed.(Dowlati ea, 2010)

Depression increases the likelihood of developing CHD (Bass, 2007, p. 367) and also increases mortality after infarction.(e.g. Frasure-Smith & Lespérance, 2003) possibly due to increased platelet activation and responsiveness as a result of serotonergic dysfunction; increased platelet binding has reversed during paroxetine treatment. Failure to take exercise is a factor in the exacerbation of pre-existing heart disease in depressed individuals.(Whooley ea, 2008) A meta-analysis of 4 placebo-controlled RCTs of reasonable duration using mirtazapine, citalopram, fluoxetine, and sertraline in patients with documented CHD and DSM-IV depression (Dowlati ea, 2010) found that antidepressants were superior to placebo for decreasing Hamilton and Beck depression scale scores and produced more responses and remissions than did placebo and with no significant differences in overall dropouts or in dropouts due to adverse events.

Type A personality²¹⁷³ has been stressed as having an important aetiological role in the genesis of heart disease, although evidence is lacking.(Bass, 2007, p. 367) Stress and change are important here. Intense anger may precipitate MI. Hostility seems to be risk factor not only for CHD but for nearly every somatic disorder! Just to confuse the reader, a *type D personality* (D for distressed) has been described that may be associated with poor survival in CHD, as well as (with cardiac history and prior depression) persistence of depressive symptoms during the year following MI.(Martens ea, 2008) Such people are worriers, gloomy, unhappy, irritable, socially avoidant, and inhibit their feelings. There is a need for studies to tease out state from trait markers in this population. In post-MI depression, somatic affective symptoms are more closely linked to MI severity and cardiovascular prognosis than are cognitive affective symptoms.(Martens ea, 2010)

Factors suggested by Cohen (2003, p. 154) as increasing cardiac mortality in depressed people

Poor medication and exercise compliance

Changes in autonomic tone (with risk of fatal arrhythmia)

Increased tendency of platelets to aggregate (reduced by antidepressants – platelets contain 5-HT²¹⁷⁴)

Unfavourable changes in lipid metabolism

Presence of subclinical cerebrovascular disease

Osborn ea (2006) found that excess risk factors for CHD in people with severe mental illness were not completely explained by medication or socio-economic deprivation; such cases need to be medically screened and to have relevant interventions for diet, exercise, diabetes and smoking.

Many different illnesses have reportedly followed in the wake of significant life events. In the early 1970s it was reported, after questioning close relatives, that patients who died after MI had higher LCU scores in the half to 1 ½ years before infarction than did those surviving a similar incident. Earlier, it was reported that widowers over the age of 55 years died at 40% above the expected rate for people of the same age during the 6 months following bereavement. The excess mortality was attributed to heart disease. If they survived this time their mortality rate fell back to that found in the general population. Depression may be an independent risk factor for ischaemic heart disease in men. Different studies found this to be so for both sexes (Ford & Mead, 1998), if more so for men, but other research did not come to this conclusion for women.(Hippisley-Cox ea, 1998)

Should a person view their first MI as the start of a longterm disability he is less likely to return to work and more likely to develop sexual dysfunction. Sexual intercourse following MI can commence, gradually and gently, when the male patient can climb a flight of stairs without symptoms. Strenuous activity is best avoided. Intercourse after a heavy meal or alcohol may cause problems. Isosorbide dinitrate taken 10 minutes before sex has been recommended for those experiencing angina during intercourse. A follow up of patients with coronary artery disease who had ischaemia induced by mental stress at baseline showed

²¹⁷³ In this context there are, or rather were, only two types - A and B, B not having A's characteristics.

²¹⁷⁴ SSRIs reduce risk of re-infarction and death in depressed post-MI patients.(Taylor ea, 2005)

that they had significantly higher rates of subsequent fatal and non-fatal cardiac events that could not be explained by a number of other variables.(Jiang ea, 1996)

Anxiety is very common in cases of coronary artery disease and it negatively influences outcome. High levels of anxiety following an MI significantly increases morbidity and mortality.(Moser & Dracup, 1996) Marital stress in middle-aged women who had been hospitalised for MI or unstable angina tripled the risk for recurrent coronary events compared to women with no marital stress.(Orth-Gomér ea, 2000) Serious ventricular arrhythmia may be more likely after major stressors, e.g. the World Trade Centre attack²¹⁷⁵.(Steinberg ea, 2005)

Psychological interventions to help prevent cardiac morbidity and mortality should be individually tailored²¹⁷⁶. Cognitive-behavioural and pharmacological (e.g. antidepressants) approaches may be employed.(Mayou, 1996) All TCAs prolong cardiac conduction. There is also some evidence that the SSRI citalopram may prolong the QTc interval in dogs with resultant ventricular arrhythmias.(Brown ea, 2000) Stopping TCAs suddenly can lead to cardiac arrhythmias and influenza-like symptoms. Relatively safe antidepressant drugs in the face of cardiac conduction problems include trazodone, fluoxetine, and bupropion.

The Irish Medicines Board (2007) issued conclusions regarding use of haloperidol, pimozide, sertindole or ziprasidone (avoid with significant cardiovascular disease, QTc interval prolongation, history of ventricular arrhythmias or *torsades de pointes*, uncorrected hypokalaemia, or patient on other drugs known to prolong QT interval).

Myocarditis has many causes (infective, radiation, autoimmune, idiopathic) including drugs such as clozapine, modafinil, sulphonamides, penicillin, methyl dopa, and anti-TB drugs. Among secondary causes of cardiomyopathy are alcohol, cocaine, and cobalt.

*Tako-tsubo*²¹⁷⁷ (or *stress*) *cardiomyopathy* (Kurusu ea, 2002) is an acute, reversible condition occurring mainly in middle-aged or elderly women that may follow severe psychic stress. There is ballooning of the apex of the left ventricle. The coronary arteries are normal.

Stokes-Adams attacks

Complete heart block, Mobitz type II second-degree atrioventricular block, or sick sinus syndrome (sinoatrial disease) *with* episodic ventricular asystole

Sudden unconsciousness +/- falling

Seizures (ischaemia) in prolonged cases

Pale and death-like

Flushing during recovery (recovery much faster than in epilepsy)

Differential diagnosis: vasovagal attacks, carotid sinus syndrome

Atrial fibrillation (A Fib)

Alcohol is associated with A Fib

Multiple factors often contribute e.g. an alcoholic hypertensive with CHD

Chest pain

At least half of cardiology outpatient referrals for chest pain have a non-cardiac aetiology.(Bass & Mayou, 2002)

Common causes of chest pain

Oesophageal reflux or dysmotility

Musculoskeletal, e.g. chondritis and muscle tension

Thoracic spine disorders

Hyperventilation

Psychiatric, e.g. panic attacks²¹⁷⁸ and depression

²¹⁷⁵ The patients had implantable defibrillators.

²¹⁷⁶ When angina patients' friends have negative views of damage caused by this symptom and believe that work should be avoided it is necessary to challenge such views.(Petrie ea, 2002)

²¹⁷⁷ Japanese: *octopus trap*.

It is important not to create an invalid out of the patient by giving a false diagnosis of angina. Exercise should not be prohibited. A firm non-cardiac diagnosis should be made when appropriate and advice between treating agencies should be co-ordinated.

Deafferentiation pain

Central (due to damaged somatosensory pathways) pain

Follows injury to peripheral or central nervous systems

Associated sensations include dysesthesia (unpleasant sensations), causalgia²¹⁷⁹ (continuous, burning pain – allodynia, glossy skin and sympathetic dysfunction may be associated features), allodynia, and/or formication

Hypertension

It is possible that prolonged stress may produce a reactive hypertensive state that causes secondary changes in the vessels and kidneys leading to permanent hypertension. Transient stress is postulated by some to cause changes in renal function that may interfere with blood pressure (BP) regulation. However, the diagnosis of hypertension and its treatment may account for much of the excess of psychiatric symptoms described in this population. EPI (Eysenck Personality Inventory) scores are generally high for extraversion in hypertensive populations. Findings of ‘positive affect’ in hypertensive community-based elders were based on a single evaluation of small numbers.(Jorm, 2001) Various psychosocial upheavals, such as migration, are also associated with an increased risk of developing high BP.

Some environmental correlates of hypertension

Excess alcohol intake

Obesity (use a wide cuff) +/- sleep apnoea

Hugh dietary sodium (migration to cities is associated with increased intake)

Acute rise in BP associated with pain or psychosocial stress

One primary care study found an increased prevalence of panic attacks in hypertensives compared to normotensives, panic usually postdating a diagnosis of hypertension.(Davies ea, 1999) A prospective study found that symptoms of anxiety and depression predicted lower systolic BP eleven years later.(Hildrum ea, 2008) A family history of hypertension, or a tendency to hypertension (borderline hypertension), may be associated with retention of sodium and water whilst competitive tasks are being undertaken. Mild to moderate hypertension, with a diastolic BP of less than 110 mmHg was said to be associated with only uncertain benefit from drugs.

Raised BP appears to be associated with white matter brain lesions on MRI.(Kuller ea, 2010)

Advice to the patient

Reduce weight

Reduce alcohol intake (alcohol acutely raises BP; intake of alcohol is higher in people with raised BP; and BP falls by 5-10 mm Hg on reducing or stopping regular alcohol intake²¹⁸⁰)

Stop smoking

Restrict dietary salt

Undertake relaxation-training, e.g. breathing exercises, deep muscle relaxation, biofeedback, stress management, and cognitive strategies

²¹⁷⁸ Nocturnal (in slow wave sleep) panic attacks may fuel fears of sleep if they are misinterpreted as being cardiogenic.

²¹⁷⁹ Also called complex regional pain syndrome (CRPS) type II. CRPS I is another name for reflex sympathetic dystrophy.

²¹⁸⁰ Cervilla ea (2000) suggest that reducing systolic blood pressure and taking moderate amounts of alcohol may improve late-life cognitive outcome. Extrapolations from studies showing a correlation between moderate drinking and better health may be hazardous, e.g. there may be something about moderate drinkers that offer a better explanation for good health, such as personality, genes or exercise.

Whilst the clinician is encouraged to follow up hypertensives and encourage the continued practice of relaxation, the evidence that relaxation therapies significantly reduce BP is controversial. (Littman & Ketterer, 1999)

Drugs such as TCAs that block catecholamine reuptake reduce the antihypertensive effects of clonidine and guanethidine. TCAs increase circulating catecholamines and can therefore exacerbate the features of a phaeochromocytoma. ECT should be avoided in a patient with phaeochromocytoma.

Hypertensive encephalopathy

Rare

Associated with accelerated phase (malignant) hypertension

High BP

Neurological symptoms (usually reversible on achieving BP control) – confusion/coma, transient speech/visual dysfunction, paraesthesiae, seizures

Commonly have papilloedema

CT – may have bleeding around basal ganglia

Hypotension

A strong relationship between low systolic blood pressure and minor psychological dysfunction on the 30-item GHQ has been reported among London civil servants. Also, associated physical symptoms, like dizziness, were attributed to mental disturbance. (Pilgrim *et al*, 1992) In fact, low blood pressure may present as fatigue, 'low positive affect', (Jorm, 2001) reduced motivation, or falls. It may be orthostatic or non-postural. When due to MAOIs it may be mistaken for an exacerbation of depression. Barrett-Connor and Palinkas (1994) found an association between low diastolic blood pressure in older community-dwelling males and non-drug-related depression but the direction of causation was unclear. Hildrum *et al* (2007) found an association between low blood pressure and anxiety and depression in elderly people regardless of whether they had cardiovascular disease. Postural hypotension and electrolyte imbalance in the infirm elderly during hot weather may respond to a reduction in diuretic dosage.

Paradoxical hypotension may occur when adrenaline is given with a low potency antipsychotic drug: the beta-adrenergic stimulating vasodilator action of adrenaline is unopposed by its expected pressor action because the antipsychotic drug is occupying alpha-1 adrenergic receptors. The same result occurs when a low potency antipsychotic drug is given to a patient with phaeochromocytoma. Low potency antipsychotic drugs may cause hypotension when combined with various anaesthetics, e.g. halothane.

Urinary system

Numerous psychological issues can affect the patient with renal disease: losses (e.g. of health or transplant), guilt (e.g. re donor), uncertainty (e.g. waiting lists), mortality (e.g. death of other patients), medical care (e.g. availability of transplants, fluid restriction), phobia (of needles), and other people (e.g. getting time off work for dialysis or kidney donation from a live relative). (Butler, 2007, p. 509) Renal transplants eventually fail despite compliance with immunosuppressive therapy (a quarter at 5 years and over half at 10 years). This may not be a major issue with geriatric recipients.

Should a patient in renal failure require sedation a drug that is chiefly metabolised by the liver should be used, such as nitrazepam or chloral betaine (cloral betaine). Drugs such as ephedrine and indinavir are rare causes of renal stone formation. Acute renal failure has been reported after an alcoholic binge. In cases of benign prostatic hypertrophy, sudden urinary retention with a distended and painful bladder can follow excess alcohol intake (or constipation or prostatic infection).

Focal segmental glomerulosclerosis – some associations

Severe obesity

Heroin abuse

HIV

At least one-half of males with advanced chronic renal disease or on haemodialysis experience erectile dysfunction/decreased sex drive. (Goddard *et al*, 2006)

There is no evidence for a psychogenic mechanism in the *urethral syndrome*²¹⁸¹ (usually a female with symptoms suggesting cystitis/urethritis and a sterile urine).

Causes of syndrome of inappropriate antidiuretic hormone secretion (SIADH)

Idiopathic

Drugs – TCAs, SSRIs²¹⁸², carbamazepine, haloperidol, hypoglycaemic drugs (e.g. chlorpropamide), opiates, vincristine, cyclophosphamide

Psychotic disorders

CNS disorders – infection, trauma, CVA

Lung disorders – TB, pneumonia

Neoplasia – small-cell carcinoma of lung

Post-surgery

Acute porphyria

Other causes of continuous nausea/pain/stress

Renal dialysis is of no therapeutic benefit in schizophrenia.(Carpenter ea, 1983)

Aristolochic acid is found in fungus-contaminated Chinese herbs used for slimming purposes and severe nephropathy and associated tumours of uroepithelium. Balkan nephropathy, found in the flooded plains of the Balkans, probably has the same aetiology although the acid probably comes from shallow wells in this instance.

Uroepithelial tumours are associated with cigarette smoking, phenacetin, cyclophosphamide, bilharzia, industrial (e.g. rubber) poisons, and aristolochic acid.

Prostatodynia²¹⁸³, a somatoform disorder, occurs in males and is characterised by urogenital pain and urinary symptoms. It may respond to fluvoxamine.(Turkington ea, 2002) However, persistent prostate pain may follow bacterial prostatitis despite resolution of active infection and such cases have been known to respond to amitriptyline and carbamazepine.

Myoglobin levels are raised in NMS and in patients in restraints or in those taking LSD, PCP, or cocaine. Myoglobinuric acute tubular necrosis (ATN) may follow muscle injury from heroin abuse. Lithium may also cause ATN.

The urine of chronic stimulant abusers may have a stale smell due to the ammonia used in illegal manufacturing processes.

Haematology

Non-specific symptoms of anaemia²¹⁸⁴ may mimic psychiatric or neurological disorder. Macrocytic anaemia, which may be associated with dementia, may be due to vitamin deficiency, hypothyroidism, or alcohol. Haemolytic anaemia²¹⁸⁵ may be due to drugs such as methyl dopa, L-DOPA, chlorpromazine, and phenytoin. Leucopaenia/agranulocytosis or thrombocytopaenia may follow use of such agents as phenothiazines, clozapine, and carbamazepine whereas leucocytosis is found with lithium or solvents and in the DTs and the neuroleptic malignant syndrome (NMS). The prothrombin time is elevated in cases of severe liver damage. Serum amylase levels may be increased in bulimia nervosa (BN). Bicarbonate levels may also be increased in BN, psychogenic emesis, or patients abusing laxatives. Bicarbonate levels are decreased due to hyperventilation, panic disorder, and abuse of anabolic steroids. Low calcium levels occur during chronic laxative abuse. CPK is raised in rhabdomyolysis (e.g. in substance abuse), NMS, dystonia, restraint, intramuscular injection, and asymptotically with antipsychotic medications. The level of alkaline phosphatase is raised in various bone, liver, and cardiac disorders and in patients taking phenothiazines and it is decreased in pernicious anaemia.

²¹⁸¹ Causes likely include intermittent or scanty bacteriuria, difficult to grow organisms like *Chlamydia* or some anaerobes, reactions to chemicals, sexual intercourse, and atrophic vaginitis.

²¹⁸² Especially in the elderly: SSRIs can cause or exacerbate SIADH.

²¹⁸³ This is also spelled prostatodynia.

²¹⁸⁴ Malaise, apathy, confusion, self-neglect, reduced mobility, falling, etc. Of course, significant anaemia may follow bruising due to falling, particularly if warfarin or anti-platelet drugs are being taken.

²¹⁸⁵ Test: direct and indirect Coomb's test.

Porphobilinogen deaminase²¹⁸⁶ is decreased in patients with acute intermittent porphyria. Porphyria may be mimicked by plumbism and by hereditary tyrosinaemia.

The effects of haemophilia A are usually only noticed when children start to move about and can easily be mistaken for child abuse. Haemophiliac children, some of whom may have HIV infection, may have less behavioural problems than diabetic children.(Logan ea, 1990) Recombinant erythropoietin may be associated with visual hallucinations and leucoencephalopathy.(Bent ea, 1999)

The Irish Blood Transfusion Service (IBTS) currently does not accept blood donations from gay people.

Liver failure

Asterixis involves a sudden loss of muscle tone followed by its quick recovery. It can occur with encephalopathic states, neurodegenerative diseases, and with drug (e.g. opiate, anticonvulsants) poisoning. Steatosis (fat deposition in hepatic cells) is nearly always present in heavy drinkers of alcohol, even those with liver function tests with normal limits. Alcoholic hepatitis, even in the absence of cirrhosis, can lead to fatal hepatic or renal failure or bleeding from varices. Elevated INR in alcoholics may be due to hepatic insufficiency or vitamin K deficiency.

Haemochromatosis is an autosomal recessive disorder characterised by excessive absorption of iron. Abuse of alcohol, which is said to be common in patients with haemochromatosis, increases iron absorption further.²¹⁸⁷ Iron is deposited in the tissues and it probably precipitates fibrosis. Serum ferritin levels are high. A combination of melanin and iron confers a slate-grey discolouration on the skin. Complications include hepatic cirrhosis, diabetes mellitus (*bronze diabetes*), gynaecomastia, atrophy of the testes, hypopituitarism, loss of body hair, cardiac failure and arrhythmias, and (in 30% of cirrhotic cases) hepatocellular carcinoma. Also, chondrocalcinosis (calcium pyrophosphate) deposition causes arthropathy. Liver biopsy is the main investigatory tool.

Alcoholic liver disease is sometimes associated with a prolonged QT interval with attendant risk of sudden death.(Day ea, 1993)

Anabolic steroids can cause cholestatic jaundice and a severe acute hepatitis with hepatocellular necrosis can follow abuse of ecstasy or cocaine.

Reducing pack sizes of paracetamol following 1998 legislation in the UK reduced liver transplant rates for poisoning by that drug by two-thirds.(Hawton ea, 2001) The older TCAs were probably safer in liver disease than lofepramine or the MAOIs. Acute alcoholic intoxication may reduce hepatic TCA metabolism (increased blood levels) but chronic alcohol intake may induce liver enzymes and speed up TCA metabolism (reduced blood levels). Haloperidol is safer than the phenothiazines. Clozapine, which should be avoided in cases of severe hepatic failure, may cause reversible hepatitis, eosinophilia, and a rise in aspartate aminotransferase levels. Chlormethiazole (clomethiazole) dosage should be kept low. Lithium distribution is affected by ascites, and *higher* doses of lithium are needed to produce desired plasma levels.(Leipzig, 1990) Pemoline should be avoided in people with liver disease. It can cause an asymptomatic increase in liver enzymes or, in 2% of patients, an unpredictable and perhaps autoimmune fulminant liver failure. Nefazodone (withdrawn, 2003) caused catastrophic hepatic failure in a few people with no known risk factors. Lower protein levels associated with hepatic disease may increase (unbound) drug potency; venlafaxine is relatively safe in this regard because relatively little is protein bound. Hepatic enzyme induction (e.g. by nicotine, carbamazepine, phenytoin, and barbiturates) increases drug metabolism and necessitates dosage increases.

Drug metabolism – phases

- | | |
|-----|--|
| I. | Isoenzymes of the mixed-function oxidase (cytochrome P450) system – deamination, sulfoxidation, dealkylation, hydroxylation, etc |
| II. | Conjugation – sulphonation, acetylation, glucuronidation, methylation, etc |

Oxidation by microsomal enzymes decreases with increasing age. Glucuronide conjugation (spared in most liver disease) renders compounds water soluble and hence excretable by the kidneys. Oxazepam,

²¹⁸⁶ Erythrocyte uroporphyrinogen-1-synthetase.

²¹⁸⁷ Indeed, lesser degrees of iron deposition in other cirrhosis cases (especially alcohol-related) may lead to diagnostic confusion. Secondary iron overload (haemosiderosis) spares the pancreas.

temazepam and lorazepam (short acting benzodiazepines [BZDs], conjugated only) are safer than other, long acting, BZDs such as diazepam (oxygenated and conjugated).

Non-alcoholic fatty liver disease (NAFLD)

NAFLD affects rich societies and is usually associated with insulin resistance. It is becoming more common as we become more obese. It is classified into simple fatty liver disease (relatively good prognosis) and non-alcoholic steatohepatitis (associated with fibrosis and cirrhosis). Most cases present with no symptoms but raised LFTs. Liver cancer may complicate NAFLD cirrhosis.

It should be noted that alcohol consumption and a raised BMI, both of which are related to liver disease, appear to have a super-additive effect when combined, i.e. their combined effect in producing hepatic disease is greater than the sum of their separate effects.(Hart et al, 2010)

Liver transplantation

Paracetamol overdose is a common reason for this procedure. Because patients with liver transplants do as well as other transplant patients²¹⁸⁸, Lloyd (2007, p. 423) argues that they should not be excluded from such programmes. However, allocation of transplant liver should be on the basis of likelihood of best outcome. Most centres require 6 months abstinence from alcohol before transplantation, which sometimes makes transplantation unnecessary. Previous substance misuse or current methadone maintenance, as long as the patient can be expected to stick to the immunosuppressive regimen, are not contraindications. Live donors are often emotionally invested in the recipient. It is important to ensure that the liver tissue is freely given: no threats and no payment.

Thyroid

Globally, iodine deficiency is among the most common preventable causes of intellectual disability (mental retardation: Hetzel, 1988; Haddow et al, 1999) Loss of weight is common to primary anxiety and hyperthyroidism but appetite is usually increased and reduced in hyperthyroidism and primary anxiety respectively. Rarely, cases of hyperthyroidism in middle age or the elderly may present with lassitude, slowed mentation, depression (*apathetic* or *lethargic hyperthyroidism*), weight loss, atrial fibrillation and congestive cardiac failure. Eye signs may be absent. Younger patients may present with agitated depression. The tremulous patient with unstable emotions may be mistakenly assumed to be drinking to excess. The psychiatric manifestations are likely to result from central metabolic effects of excess T4 and the actions of catecholamines since beta-blockers alleviate psychiatric symptoms without affecting thyroid hormone concentrations.(Trzepacz et al, 1988) T4 levels may be raised by anovulants or other oestrogen-containing drugs, phenothiazines, clofibrate, or by pregnancy²¹⁸⁹. The anti-epileptic drug tiagabine is a rare cause of goitre. In the presence of hypothyroidism plus depression, antidepressants tend not to be effective. Pregnancy often necessitates an increase in dosage of thyroid hormone to maintain a normal TSH level and to prevent adverse cognitive outcome in offspring.

In the case of gravid women taking lithium, a foetal goitre may compress the trachea during delivery.

‘Myxoedematous madness’, a global term for a wide variety of psychotic manifestations (affective, schizophreniform, delirious, etc) of hypothyroidism, was coined by Richard Asher.(1949)

Pendular reflexes (delayed relaxation phase) are found in hypothyroidism, diabetes mellitus, and anorexia nervosa.(Larner, 1995)

Postpartum thyroiditis, a lymphocytic thyroiditis, may cause hyperthyroidism, hypothyroidism, or one followed by the other following pregnancy. It can be misdiagnosed as postpartum depression. While it is usually transient it can give rise to permanent under-activity of the thyroid gland when antibodies are present. It is probably due to necessary immune changes associated with being pregnant.

²¹⁸⁸ Less than 5% of grafts are lost within 5 years due to alcohol.(Lloyd, 2007, p. 426) Personality disorder, not keeping appointments, and non-compliance with medication may predict a return to drinking.(Gish et al, 2001)

²¹⁸⁹ Increase in binding globulin – free thyroxine index will correct for this.

Congenital hypothyroidism (1 in 3500 births) is routinely screened for at birth in developed countries. Early thyroid hormone replacement will prevent cretinism²¹⁹⁰ (neurological and intellectual damage).

Parathyroid glands

Depression is found in about a third of cases of primary hyperparathyroidism, severity of depression and cognitive problems roughly correlating with serum calcium level²¹⁹¹. In most cases depression abates on correcting the calcium level²¹⁹², but an antidepressant is sometimes required.

There are a number of causes of hypoparathyroidism. Of particular interest to psychiatrists, two related syndromes involving rearrangements and microdeletions on chromosome 22, DiGeorge and velocardiofacial, affect the development of third and fourth branchial arches. This leads to various degrees of hypoplasia of thyroid and parathyroid glands.

Burns

Most burn victims adjust relatively well.(Altier ea, 2002)

Children

Burns associated with psychiatric problems in child (e.g. mental retardation or hyperactivity) or with parental factors (e.g. abuse or neglect)

Adults

Many burn victims have pre-existing psychopathology, substance abuse, or medical illness (Stoddard & Fricchione, 2004)

Healthcare workers

Latter when they were exposed to severe burn cases following air disaster were at risk for PTSD (Epstein ea, 1998)

Burned children are more likely to develop PTSD than are burned adults. In adults, burns may be associated with alcohol or drug use, dementia, epilepsy or deliberate self-harm. Self-immolation is typically a female problem in Israel. Severe psychological problems may be associated with severe burns and their protracted treatment, especially if they involve the face. PTSD may not develop until after discharge from hospital. Organic syndromes and denial may complicate the early course.

Determinants of psychological needs of patient in burns unit

Ability to cope with stress

Event factors e.g. degree of trauma

Environmental factors e.g. family support

Painful treatment procedures

Protracted hospital stay

Disfigurement

Pre-existing problems e.g. epilepsy, dementia, intellectual disability, and alcoholism

Dermatology

²¹⁹⁰

A child with cretinism. Features include hypotonia, coarse facial appearance, macroglossia, and umbilical hernia. The derivation of the word is disputed, e.g. *creta* (Latin for chalk – pallor) or *creatus* (Latin for creature) or the island of Crete or a reference to iodine-poor soil.

²¹⁹¹ Hoogendijk ea (2008) found an association between being depressed and severity of depression on the one hand and low serum 25-hydroxyvitamin D levels and increased parathyroid hormone on the other hand in Dutch older adults (community-based 65-95 years).

²¹⁹² It should be noted that lithium may cause hypercalcaemia.

Dermatitis artefacta (factitious dermatitis): A of people with self-inflicted skin lesions have long-term psychiatric disorders that tend to respond more to change in life circumstances than to formal treatment. At least some cases of psychogenic purpura²¹⁹³ are cases of dermatitis artefacta²¹⁹⁴.

Psychogenic excoriation (dermatotillomania): The patient induces skin damage by picking at areas that can be reached either because of sensations or a felt need to remove irregularities. Suggested treatments include doxepin, SSRIs, clomipramine, antipsychotics, naltrexone, and behaviour therapy.

Delusional parasitosis: The patient believes that the skin is infested with parasites. It typically affects females and people 40 or more years of age. (Sheppard et al, 1986, found an excess of males). It may be secondary to a variety of psychiatric illnesses or organic disorders (e.g. B12 deficiency, pellagra, and multiple sclerosis). It is difficult to treat. Supportive psychotherapy and pimozide (Orap) may help.

'Dermatological non-disease' (Meador, 1965): The absence of diagnosable symptoms and signs does not necessarily indicate an absence of significant problems. Symptoms are commonly confined to three areas: face, scalp and perineum. Facial burning, itching, and hairiness are common complaints. Scalp complaints include hair loss and irritation. Genital itch, redness, burning and discomfort are also common. The most frequent psychiatric diagnosis is depression. Other diagnoses include dementia and schizophrenia. Suicide and attempted suicide may occur.

Classification of patients with psychological/psychiatric problems attending skin clinic (Cotterill, 1989)

Depressed because of skin disease

Skin disease results from stress, strain or conflict (controversial)

Factitious disorders

Dermatological delusional disease (e.g. a physical complaint relating to skin/hair is common and most often related to depression)

Delusions of parasitosis (seen by dermatologists and environmental health officers)

Skin problems due to/exacerbated by psychotropics (e.g. lithium inducing acne or psoriasis*)

*Avoid tetracyclines in lithium-treated acne patients, but retinoids are allowed. Beta-blockers can exacerbate psoriasis. Both groups of drugs might exacerbate psoriasis by inhibiting cAMP formation.

Dermatological presentations of delusional disorder* (Munro, 1999)

Skin infestation (on and/or in/under skin)

Subcutaneous foreign bodies (eggs, seeds, minerals)

Bromosis²¹⁹⁵ (with/without hyperhidrosis)

Chronic cutaneous dysaesthesia²¹⁹⁶

*The patient may go to extreme lengths to remove 'objects'.

Hot flushes/flushes: The patient feels hot, there is cutaneous vasodilatation, and the core temperature drops subsequently. She may experience sweating, flushing, palpitations, anxiety (even panic), and irritability. Females may have nocturnal diaphoresis. Attacks usually last for a few minutes but may be longer or shorter than this, and the frequency of episodes varies enormously. Risk factors include low oestrogen levels (e.g. perimenopausal), low body weight, lack of exercise, and cigarette smoking.

Causes of hot flushes

Perimenopause

Systemic disorders e.g. pancreatic cancer, carcinoid syndrome

Neurological e.g. anxiety, migraine, cerebral neoplasia, spinal cord lesions, Parkinson's disease

Alcohol/drugs e.g. chlorpropamide, metronidazole, nicotinic acid, bromocriptine

²¹⁹³ Gardner-Diamond syndrome. Some authors believe that most cases are factitious. (Arnold, 2007, p. 248)

²¹⁹⁴ One theory was that there was sensitisation to own red cells after injury.

²¹⁹⁵ Delusion of smell emission.

²¹⁹⁶ Abnormal skin sensations +/- glossodynia or vulvodinia: may be more often related to personality disorder, anxiety disorder, or OCD.

Treatments include oestrogen, progestagen, and SSRIs. (Loprinzi et al, 2000; Stearns et al, 2002; Stearns et al, 2003)

General: Imipramine was discovered in the search for antihistamines. TCAs reduce skin blood flow, skin temperature, and sweating (they can also increase sweating). They are also sedatives, antiemetics, muscle relaxants and local anaesthetics. They are often effective in a variety of skin disorders (such as chronic urticaria, nocturnal pruritus in atopic eczema, etc.) and neurological disorders (e.g. postherpetic neuralgia, pain of diabetic neuropathy, unilateral itch after strokes, etc.). These facts hold irrespective of the affective status of the patient. TCAs and other newer antidepressants may reduce pain by causing an increase in noradrenaline and 5-HT that in turn inhibits nociception in the dorsal horn of the spinal cord. Gabapentin is effective also for postherpetic neuralgia (and for diabetic neuropathy) and it may be more efficacious for neuropathic pain if combined with nortriptyline. (Gilron et al, 2009) Mexiletine, a lidocaine-like drug, is sometimes effective for neuropathic pains, including that associated with diabetes, but GIT side effects may limit tolerability; patients with cutaneous hyperpathia may be helped by topical lidocaine. (Rowbotham et al, 1995) Pregabalin (Lyrica) is used as adjunctive therapy for partial seizures and for neuropathic pain of diverse aetiologies.

Psychogenic pruritus

Aetiology²¹⁹⁷ may be metabolic (e.g. icterus) or psychogenic

May be local or general

Scratching may excoriate skin

Depression and anxiety are common; chronic cases may be associated with repressed hostility/self-damaging behaviour with rise in tension that is relieved transiently by attacking skin

SSRIs, TCAs (H1-blockade), token economy, and aversion techniques may help

Chronic scratching may cause special forms of pruritic disorder: neurotic/psychogenic excoriation²¹⁹⁸, chronic lichen simplex²¹⁹⁹, and prurigo nodularis²²⁰⁰

Atopic dermatitis

Aim is to stop vicious circle of pruritus and scratching

Non-drug approaches: relaxation, habit reversal, stress management, CBT

Drug treatment (histamine antagonism): doxepin 5% cream, trimipramine²²⁰¹

Adrenergic urticaria

Emotional distress leads to acute onset of urticaria

Increased levels of adrenaline and noradrenaline

Treat with beta-blockers

Psoriasis

Highly heritable

Certain factors appear strongly associated with psoriasis: alcohol, smoking, exposure to streptococci, trauma, drugs such as lithium, beta-blockers and antimalarials²²⁰², and emotional stress (Williams, 1994)

Depression, subjective health and perceived stigma are stronger determinants of disability than are aspects of the disease (e.g. Richards et al, 2001)

Porphyria cutanea tarda

²¹⁹⁷ **Itching**

(a) *Psychogenic* – psychiatric disorders, e.g. delusional parasitosis

(b) *Pruritoceptive* – due to skin changes such as dryness or inflammation

(c) *Neuropathic* – lesion of sensory pathways, e.g. MS, spinal neoplasms, post-herpetic

(d) *Neurogenic* – arising centrally, e.g. cholestasis. Cholestatic pruritus is due to neuropeptide action on opioid receptors. (Wiesner et al, 2007)

²¹⁹⁸ Compulsive, ritualistic picking/digging into skin, often secondary to acne; groups of reachable lesions of same shape and size; crusts and scars (often white with pigmentation around edges).

²¹⁹⁹ Repetitive, pleasurable scratching leads to thick plaque with accentuated dermal lines in various parts of the body; interventions include occlusion, steroids, naltrexone, CBT, and habit reversal training.

²²⁰⁰ Hard, irregular, nodular limb lesions.

²²⁰¹ Trimipramine (50 mg/day) reduces sleep fragmentation and duration of stage I sleep.

²²⁰² Also, withdrawal of systemic or potent local corticosteroids can exacerbate psoriasis.

Alcohol abuse is important in aetiology

There is also a genetic element

Bullae on face, back of the neck, and dorsum of hands, and scarring

Discoid eczema²²⁰³

May be associated with alcohol excess in young males

Alopecia areata

Cutaneous T cell-dependent autoimmune disorder occurring in genetically susceptible individuals

Excess of exit (e.g. divorce), social (desirable or otherwise) and uncontrolled events during 6 months before onset

TCA's (e.g. imipramine 75 mg/day) may help hair growth independent of any influence on anxiety or depression

SSRIs helped in people with comorbid depression and anxiety

Psychotherapy and relaxation therapy may help

Acanthosis nigricans²²⁰⁴

Often associated with obesity and regresses with weight loss

Vulval lichen sclerosis²²⁰⁵

This affects infants and children and may falsely suggest abuse

'Speed bumps'

Excoriations of skin found in chronic users of stimulant drugs

Teeth

May be abnormal in many disorders e.g. eating disorders (erosion), schizophrenia (caries), congenital porphyria (pink fluorescence)

Loose teeth may require removal/special protection pre-ECT

Dental appliances should be removed before ECT unless required to protect oral structures from injury

Drugs causing dry mouth²²⁰⁶ predispose to dental decay

Patients may go to many dentists with a delusional abnormal bite ('phantom bite syndrome') or 'facial pain' and undergo many procedures, including extractions, without relief (Munro, 1999)

They may even have delusions about their dentures (Mack, 1985)

Nails

Clubbing occurs in a number of circumstances, e.g. bronchial carcinoma in nicotine dependent individuals

Blue lunulae in Wilson's disease

Blue-black colouration of nails, often worse in summer, may be due to phenothiazines

Acquired melanonychia, a dark discolouration of all or some (e.g. the thumbs) nails due to drugs such as hydroxyurea, zidovudine, minocycline, cyclophosphamide, and doxorubicin

Brown nails in chronic renal disease

Yellow nails may occur with congenital lymphatic hypoplasia

Green nails may be caused by *Pseudomonas aeruginosa* infection, e.g. in gardeners

Fingernail hypoplasia may follow first trimester exposure to carbamazepine or valproate

'Habit-tic dystrophy', due to picking at proximal nail fold of thumb, causing a ladder of transverse ridges/furrows up centre of nail

Beau's lines²²⁰⁷ are due to a temporary arrest of growth, and may be associated with arrest of hair growth and subsequent fall (telogen effluvium)

Mees' lines are white lines across the nails due to arsenic, thallium, other heavy metals, or renal failure

Lithium may cause diffuse hair loss as well as altered skin texture and golden discoloration of distal nail plates

²²⁰³ A common form of eczema associated with coin-shaped limb lesions. Not confined to this age group. With many skin conditions it may be difficult to determine if skin problems, such as psoriasis, lead to drinking or *vice versa*.

²²⁰⁴ Velvety thickening and pigmentation of flexures occur. Also associated with primary (e.g. gastric) and metastatic malignancy (regresses with tumour excision) and with insulin resistance.

²²⁰⁵ The vulva is porcelain-white with purpura and scars.

²²⁰⁶ Xerostomia.

²²⁰⁷ Transverse lines related to acute physical or psychiatric illness or cytotoxic drugs.

Mees' lines

Patients with delusional parasitosis may tear away at their nails to get at subungal 'bugs'

Irritable bowel (colon) syndrome²²⁰⁸ (IBS)

Some proposed causes of this idiopathic disorder (Sibartie & O'Mahony, 2005)

Life stresses (especially if sustained)

Exaggerated colonic response to CRF

History of physical or sexual abuse²²⁰⁹

Genetic factors (2 MZ to 1 DZ)

Cognitive bias (emotional/physical symptoms = somatic disease)

Reactions to infection²²¹⁰

Altered gut motility

Abnormally overactive gut-CNS interaction

Indicators suggestive of a disease other than IBS (Spiller, 2007)

Age > 50 years

Male sex

Short history

Weight loss

Night time symptoms

Familial history of colonic cancer

Bleeding per rectum

Recent use of antibiotics

Lifetime diagnoses of depressive, somatoform, anxiety, panic and phobic disorders are increased. Creed ea (2005) looked at severe IBS and found that depressive, panic and neurasthenic disorders contribute to poor outcome. In fact, depression and depressive coping style are better at predicting subjective disability in IBD than is inflammation. (Cuntz ea, 1999) Common symptoms are diarrhoea, abdominal cramps, or alternating constipation and diarrhoea. Speed of onset is variable and the course is chronic and relapsing. Mucus may be found in large quantities in the stools. It is commoner in women in the West, and in men in India. It is a common bowel motility disorder that is non-inflammatory and often precipitated by stress. Sexual dysfunction has been reported to be common. This might be due to spasm of the bowel causing pain during sexual intercourse. Mast cell number and secretions are increased in IBS. (Spiller, 2007) Psychotherapy,

²²⁰⁸ IBS can be diagnosed in the patient from pain/discomfort for the past year with 2 of (a) relief following defecation, (b) looser/more frequent stools, and (c) harder/less frequent stools. The relationship between IBS and psychiatric disorder is complex.

²²⁰⁹ An increased incidence of child sexual abuse has been reported in specialist clinics (see Drossman ea, 1995) but not in population-based studies. (Levenson, 2005, p. 298) Also, as pointed out by Guthrie (2007, p. 403) high rates of sexual abuse are reported in other chronic pain syndromes and are not specific to functional GIT disorders.

²²¹⁰ Patients with acute gastroenteritis who developed IBS-like features were found by Gwee ea (1996) to have higher scores (that persisted over 3 months) for anxiety, depression, somatisation, and neurotic traits, than those who did not develop these features. According to Gwee ea (1999) a third of cases of acute enteric infection develop IBS-like symptoms. Page and Wessely (2007, p. 130) point out that although prospective research suggested that more neurotic, anxious and depressed individuals are at increased risk for IBS following gastroenteritis such findings might only hold true in the rarefied atmosphere of the specialist clinic. Hamilton ea (2009) also found that gastroenteritis was a risk factor for IBS in general practice patients.

especially CBT (Mayer, 2008), may benefit those cases that fail to respond to medical measures²²¹¹, although the fact that a psychological approach helps does not prove psychogenesis. Also, Kennedy *et al* (2005) found that although CBT delivered by primary care nurses offered additional benefit over mebeverine the effect waned by twelve months. The evidence for CBT for IBS in primary care is at a 'preliminary' stage. (Moss-Morris, 2010) Gut directed hypnotherapy²²¹², although not readily available, may help severe cases. (Hayee & Forgacs, 2007) No drug controls all of the symptoms of IBS. TCAs have been found to help some IBS cases and SSRIs may improve more global symptoms. (Spiller, 2007) Low dose TCAs may be quickly effective which suggests that they may be acting as analgesics or anticholinergics²²¹³. (Creed & Olden, 2007, p. 65) Various drugs acting on the serotonergic system²²¹⁴ are being tried but controversy surrounds the possibility that they may be associated with ischaemic colitis, a condition that may be more common in IBS anyway. (Farthing, 2005) Spiller (2007) suggested trying 5-HT3 antagonists (e.g. alosetron) for global symptoms, diarrhoea, and pain, and 5-HT4 agonists (e.g. partial agonist tegaserod) for global symptoms, constipation, and bloating. However, the promise offered by the latter drugs do not seem to have been fulfilled. (Fairclough & Silk, 2009, p. 312) Kaptchuk *et al* (2008) found that the positive effects of placebo treatment in IBS correlate best with the patient-practitioner relationship.

Adult²²¹⁵ acquired megacolon

It may be a symptom of depression or dementia, various neurological disorders, scleroderma, or hypothyroidism. It may be due to antidepressant medication or prolonged overuse of stimulant laxatives²²¹⁶ (e.g. senna).

Crohn's disease

Some cases have been mistakenly diagnosed as having anorexia nervosa. Genetic factors are important in this and ulcerative colitis. The risk for Crohn's disease is tripled in smokers (Palmer *et al*, 2006, p. 912 & 919) and the disease is exacerbated by smoking. The most effective intervention is to stop smoking. Ileostomies are associated with psychosexual problems, male infertility (surgery involving rectum), mechanical difficulties, dehydration (high ambient temperatures), and may be the site of disease recurrence.

Ulcerative colitis

Engel wrote about these patients' dependency needs and fear of failure and rejection during the 1950s. However, there are serious methodological flaws in much published research purporting to find a psychogenic basis for this disease. Chronic stress and depression might have a role in increasing the likelihood of relapse in both this disorder and in Crohn's disease. It is more common in non- and ex-smokers than in smokers. (Palmer *et al*, 2006, p. 912) Nicotine patches may reduce the intensity of flare ups. (Fairclough & Silk, 2009, p. 286)

Insulinoma²²¹⁷

Very rare episodic disorder, occur at all ages, and slight female preponderance
Usually benign adenomas in pancreatic islet cells, usually in body or tail of the pancreas
Some ectopic tumours near duodenum or porta hepatis
A small number are malignant (> 10%)
May be part of multiple endocrine neoplasia syndrome type 1 (MEN 1) with adenomas of other endocrine gland such as pituitary and parathyroid glands
Tumour may be present for years before correct diagnosis

²²¹¹ Reassurance, antispasmodics like mebeverine, high fibre diet, etc. Soluble fibre (ispaghula, sterculia) is a reasonable first choice. In a systematic review and meta-analysis, Ford *et al* (2008) found fibre, antispasmodics, and peppermint oil (antispasmodic) more effective than placebo.

²²¹² E.g. patient places hands over abdomen to induce a sense of warmth and comfort.

²²¹³ TCAs and SSRIs may worsen constipation and diarrhoea respectively in IBS.

²²¹⁴ E.g. cilansetron and tegaserod.

²²¹⁵ Children may develop acquired megacolon because they hold on to faeces.

²²¹⁶ Such laxatives cause degeneration of the myenteric plexus.

²²¹⁷ Some large sarcomatous tumours secrete insulin-like growth factor-1 with resultant hypoglycaemia.

Associated with diplopia, tremor, sweating, hunger, fatigue, weakness, dizziness, anxiety, palpitations, depression, agitation, confusion, loss of consciousness, grand mal seizures and, eventually, brain damage. Memory for content of attacks is absent or hazy. May be confused with personality disorder, panic attacks, depression, dissociative fugues, conversion disorder, epilepsy, or with alcoholic intoxication. Blood sugar levels may be low or normal during acute attacks. Whipple's triad: fasting/exercise induces symptoms²²¹⁸; hypoglycaemia (with inappropriately raised insulin levels²²¹⁹) during attacks; and symptoms respond to glucose. Removal of the tumour is the ideal intervention but (if it evades detection or if the patient is old and only mildly affected) octreotide or another somatostatin analogue is useful.

Peptic ulcer (PU)

During the 20th century the sex ratio for PUs changed from one of female to that of male predominance. PUs developed in Brady's 'executive monkeys' following electrical brain stimulation during the late 1950s. Monkeys who could avoid electric shocks by pressing a lever (having to make a decision) showed increased secretion of gastric acid and developed peptic ulceration more often than did monkeys who had no method of avoiding shocks. Studies on people with chronic gastric fistulae²²²⁰ have shown that emotional changes are paralleled by dynamic changes in the stomach. Anger led to a prolonged increase in gastric blood supply, whereas fear or sadness reduced gastric secretion, motility and blood flow. Alcohol and tobacco adversely affect the stomach and duodenum. Outdated psychodynamic theories stressed the aetiological role of oral gratification problems and subsequent proneness to excesses of rage. PUs may run in families. The role of acute stress in human populations is conflictual, although goal frustration has been reported before the onset of peptic ulcer. Creed (1992) reported no preceding excess of severe life events in straightforward peptic ulcer, but he did find an increase if the patient was psychiatrically ill. Stress and *Helicobacter pylori* may interact at times of upheaval, e.g. earthquakes. (Creed & Olden, 2007, p. 56) Magni et al (1986) found that the 16PF questionnaire divided 79 duodenal ulcer patients into three homogeneous subgroups: 32 dependent and anxious patients; 31 neurotic and anxious patients; and 16 patients with a 'balanced' personality. The authors felt that these findings upheld the concept of heterogeneity in peptic ulcer disease. In the 'balanced' group there was a non-significant increase in pepsinogen values. In a study by Walker et al (1988) serum pepsinogen correlated positively with increasing personality scores for hostility, irritability, and hypersensitivity. Some personality traits, such as hostility or dependency, may contribute to the pathogenesis of PU via increased smoking or alcohol intake. Subthreshold psychiatric disorders among PU patients impair quality of life and worsen prognosis. (Creed & Olden, 2007, p. 56) Alcoholism is very common among gastroenterology clinic attenders. Stress increases use of alcohol and tobacco. Indeed, nicotine-dependent and psychiatrically ill individuals consume 70% of all cigarettes smoked in the USA. (Grant et al, 2004) The exact role of alcohol (cause or exacerbation) is still debated. *Helicobacter pylori* infection only came into prominence in recent times. Antacids tend to reduce phenothiazine absorption by up to 45%. Interestingly, due to their strong antihistamine properties, trimipramine and doxepin have anti-peptic ulcer effects. Cholinesterase inhibitors increase gastric acid secretion, increasing the risk of bleeding in high-risk cases. SSRIs and venlafaxine increase the risk of GIT bleeding, especially in the presence of NSAIDs, and this risk is reduced by acid-suppressing agents. (de Abajo & Garcia-Rodriguez, 2008)

Non-ulcer dyspepsia

This consists of mainly stress-related symptoms: indigestion, wind, nausea, early satiety, and heartburn. There is no ulcer. Nocturnal pain is unusual and antacids are ineffective. Pain is diffuse, not of a recognised pattern, it is long lasting, is unaffected by food or fasting, and vomiting has no influence. Over-investigation should be avoided, particularly in young people. Treatment is by reassurance. Metoclopramide may help some cases.

²²¹⁸ It should be noted that propranolol can cause hypoglycaemia in non-insulinoma cases that are fasting or undertake vigorous exercise.

²²¹⁹ This was not one of Alan Oldfather Whipple's (1881-1963, US surgeon) original criteria for insulinoma.

²²²⁰ E.g. Beaumont's observations of Alexis St Martin (gunshot wound) in the 1830s and Harold and Stewart Wolff's observations of 'Tom' (their laboratory assistant) in the 1940s. Engel studied the infant Monica.

Burning mouth syndrome

Patients complain of a burning sensation in the tongue or other parts of the mouth, typically being absent on waking but increasing as the day goes on. There may also be complaints of dryness and altered taste sensation. There is usually no abnormal clinical or laboratory finding. Females, especially postmenopausal, outnumber males. Suggested treatments include vitamins, benzodiazepines, tricyclic antidepressants, anticonvulsants, topical capsaicin, and CBT.

Vomiting

A psychiatrist may occasionally be asked to give an opinion in a case of vomiting.

Aetiology of emesis

Gastrointestinal ('functional', inflammatory, obstructive)

Non-gastrointestinal (e.g. psychogenic, drugs²²²¹, radiation, migrainous, increased intracranial pressure, motion, pregnancy, infective, metabolic)

Important brain centres involved in vomiting are the chemoreceptor trigger zone²²²² and the (controversial) vomiting centre²²²³. Psychogenic emesis (or that due to pyloric canal ulceration) tends to occur whilst eating or just after a meal, whereas organic gastrointestinal disorders usually cause delayed postprandial vomiting.

Early morning vomiting associated with

Pregnancy

Metabolic disorders (e.g. renal failure)

Gastric surgery (may contain bile)

Alcohol consumption

Projectile vomiting (effortless, forceful, without retching) associated with

Pyloric stenosis

Increased intracranial pressure

There may be altered blood in the vomitus (coffee grounds). Undigested food suggests a pharyngeal or oesophageal problem. Distal obstruction may be associated with faecal vomiting. There may be abdominal distension or a succussion splash when the stomach is not emptying. Visible peristalsis denotes obstruction. 'Psychogenic vomiting' covers a multitude, e.g. eating disorders, factitious disorder, and stress-related (e.g. school examinations). Serum aldolase may be elevated in ipecac abusers.

Cyclical vomiting

Syndrome in young children

Idiopathic recurrent attacks of vomiting of widely varied frequency that may last for days

May have headache, abdominal pain, or fever

Most children 'grow out of it'

Post-prandial cholecystokinin levels can be relatively blunted in bulimics, and active purging may cause metabolic alkalosis (with raised bicarbonate), hypochloraemia, and hypokalaemia. Serum amylase levels may be raised due to chronic vomiting. Ipecac raises serum aldolase levels. Chronic laxative abuse may present as hypocalcaemia.

²²²¹ Tardive dyskinesia-related oesophageal dysmotility can cause emesis and weight loss.

²²²² Floor of fourth ventricle within the vascular appendage called the *area postrema*.

²²²³ Medullary lateral reticular formation.

Diarrhoea

Rahman et al. (2004) looking at a rural community in Pakistan, found that maternal depression before and after parturition predicted poorer growth and higher risk of diarrhoea in their infants.

Stomas

A distorted body image or *paraschemazia* may be due to hallucinogens, epilepsy, migraine, a stoma or amputation of part of the body. In addition, ostomies may cause occupational, dietary, and sexual difficulties as well as low self confidence and respect, disgust and shock. (Guthrie, 2007, p. 407)

Lung diseases

Chronic hypercapnia

This may cause problems sleeping, memory disturbance, diurnal drowsiness, lack of coordination, tremor, asterixis, myoclonus, and change in personality.

Pulmonary hypertension

There are many causes of pulmonary hypertension, the most common being COPD. However, of direct interest to psychiatrists are those cases caused by appetite suppressing drugs and talc inhaled with cocaine.

Chronic obstructive pulmonary disease (COPD)

The classical history is of smoking in excess of 20 pack years²²²⁴. Breathing retraining and CBT have been proposed as useful interventions for subjective distress. Propranolol causes bronchospasm. Sertraline possibly relieves dyspnoea to some extent (Smoller et al., 1998) and fluoxetine appears to be safe. Benzodiazepine (BZD) drugs cause respiratory depression. Short-acting BZDs, zolpidem and buspirone²²²⁵ particularly the latter two drugs are relatively safe.

Asthma

Asthmatics often have a personal or family history of hay fever or infantile eczema. There is evidence for a psychological element in asthma. Asthmatics may be particularly prone to a variety of comorbid anxiety and affective disorders. (Goodwin et al., 2003, 2004) However, proving direction of causality may be a problem: an asthmatic attack or the threat of such an attack is a frightening experience. The threat of infection with the plant pathogen *Burkholderia cepacia* has led to the breakup of self-help groups with resultant distress.

Precipitants of asthma attacks

Allergies, e.g. pet animals, pollen, dust, *Dermatophagoides pteronyssinus*²²²⁶

Cold air

Emotional problems²²²⁷

Dust/vapour/fumes/pollutants, e.g. cigarette smoke, strong perfumes, ozone, sulphur dioxide

Occupational exposure, e.g. glutaraldehyde, nickel, and manufacture of 'biological' washing powders

Physical exertion

Respiratory infection

Medication – beta-blockers and NSAIDs

Anticholinergic drugs (e.g. tricyclic antidepressants [TCAs]) dry bronchial secretions which may have implications for asthma sufferers. Panic disorder may mimic asthma and lead to the inappropriate prescription of bronchodilators.²²²⁸

Adrenaline (epinephrine) stimulates both alpha- and beta-adrenergic receptors. Orthostatic hypotension²²²⁹ due to antipsychotic drugs results from alpha-adrenergic blockade and giving adrenaline will only stimulate

²²²⁴ 1 pack year = 20 cigarettes/day for 1 year.

²²²⁵ Buspar was withdrawn, December 2009.

²²²⁶ The house-dust mite.

²²²⁷ The classic situation is the individual who was allergic to rose pollen but who also had asthmatic attacks when presented with an artificial rose.

²²²⁸ Interestingly, due to their strong antihistamine properties, trimipramine and doxepin have anti-allergy effects.

²²²⁹ **Orthostatic/postural hypotension** is defined as drop in blood pressure of > 20 or > 10 mmHg systolic or diastolic pressure respectively on standing from supine. Causes include prolonged bed rest, reduced extracellular volume (e.g. haemorrhage, burns, GIT

beta-adrenergic receptors leading to a further fall in blood pressure, a point to keep in mind if considering the use of adrenaline in acute asthma. Even 'selective' (beta-1) blockers such as atenolol may induce asthmatic attacks.

Lung cancer

This is the commonest cancer killer in Ireland (1 and 5 year survival = 23.7% and 8.6% respectively) and such deaths in women are catching up on breast cancer deaths. (Brennan *et al*, 2008) Lung cancer is the third most common cancer in both sexes in Ireland. The role of smoking in the genesis of lung cancer is incontestable.

*Cystic fibrosis*²²³⁰ (CF)

Patients with CF are living longer than before. Most men with CF are infertile²²³¹. (Chotirmall *et al*, 2009) Women tend to be subfertile, probably because the cervical mucus is abnormal, and pregnancy may be complicated. Parents need expert counselling. There are societies for interested parties and patients. Many affected children are small for their age and enter puberty late. Older children often become rebellious and need encouragement to continue with physiotherapy and medication. Adolescents may develop eating disorders. Educational abilities are normal in most cases. They can do most types of work except heavy manual labour. Those unfit for work need the help of a social worker. The finding of *Pseudomonas cepacia*²²³² in sputum of CF cases unhelpfully led to the admonition that such patients avoid one another. This led to the break up of self-help and educational groups with understandable distress.

Psychiatric contraindications to lung transplants (Coffman & Levenson, 2007, p. 42)

- Active alcoholism, drug abuse, smoking
- Severe mental disorder
- Treatment non-adherence

Drug interactions in the pulmonary patient

The anti-TB drug rifampicin, metabolised via P450 3A4, may compete with TCAs, SSRIs, bupropion, trazodone, and venlafaxine and compete through the same site with benzodiazepines, zolpidem, haloperidol, tiagabine, valproate, and carbamazepine. The leukotriene receptor antagonist montelukast²²³³ (Singulair) is metabolised via 3A4 and 2C9 and may lead to similar interactions to those associated with rifampicin.

Smoking, unlike nicotine gum, reduces theophylline levels by at least 50% and alcohol reduces theophylline clearance by almost a third. Prolonged seizures may occur if theophylline is given with ECT.

Multiple allergies

Some people believe that they are allergic to many things when this cannot be borne out objectively. A wide variety of psychiatric disorders have been reported in such cases. Arrogant confrontation has no place in management. Any underlying condition should receive attention. Encouragement to return to active living and discouragement of social withdrawal and disability are the mainstays of management.

Cancer

Adjustment disorder is the commonest psychiatric difficulty experienced by cancer patients. Excessive stress and a sense of helplessness have been postulated, but not proven, to promote cancer growth. It was generally held that relapse was more likely in breast cancer patients in the presence of severely threatening life events and difficulties, but a prospective study did not bear this out. (Graham *et al*, 2002) One systematic review (Petticrew *et al*, 2002) found that coping styles had no consistent effect on survival or recurrence in cancer patients.

losses such as vomiting or ileus, kidney losses such as diuretic drugs or analgesic nephropathy), drug-induced failure of peripheral vasoconstriction (e.g. alpha-adrenergic or calcium channel blockers, and nitrates), autonomic failure (e.g. diabetes mellitus and old age), and vasodilatation in septicaemia. Plasma is lost in such circumstances as peritonitis and burns.

²²³⁰ About 1 in 2,000 babies born in Britain have CF. It is the commonest lethal inheritable disease of Caucasians (autosomal recessive).

²²³¹ Atresia of vas deferens and epididymis.

²²³² A plant pathogen, often multiply resistant to antibiotics and associated with a rapid downhill course.

²²³³ E.g. used as add-on therapy for poorly controlled mild to moderate asthma.

Type C personality

Emotionally suppressed, compliant, conforming, stoical and unassertive
Suggested by Cull (1990) as being linked to cancer

It has been suggested that breast cancer may be particularly common in chronic psychiatric patients (Halbreich *et al.*, 1996) but the contribution of antipsychotic drugs to breast cancer, possibly by causing increased prolactin levels, is relatively small²²³⁴, if true. (Wang *et al.*, 2002) However, some research findings suggest a reduced likelihood of breast cancer in women with serious mental illness. (Bark *et al.*, 2008) Tumour growth rates may be accelerated in animals by uncontrollable stress. Chemotherapy and radiotherapy can cause cognitive and affective symptoms. Carcinoma of the lung (16% of cases), ovary and stomach can cause brain syndromes in the absence of metastases. Children educated about their cancers have good psychological outcomes if they happen to survive.

Despite undoubted medical progress, parents of children with leukaemia may have great difficulty accepting the diagnosis, the children often develop behaviour problems, and leukaemic children may feel that they have a foreshortened future. Diagnostic and therapeutic procedures, as well as frequent hospital admissions can be emotionally challenging. Cognitive problems are associated with irradiation of meninges and intrathecal methotrexate.

Psychological complaints in cancer patients

E.g. anxiety, depression, sexual problems, and fear of recurrence²²³⁵

Common

Often untreated

Lassitude is also a major difficulty

Patient may not inform doctor of such difficulties

Sexual problems include fear that pregnancy will spread the cancer or that the baby will be abnormal

May fear spreading disease to healthy partner

Fear of being repulsive because of body image or unpleasant smells

Guilt may follow avoidance of sexual activity

Continued sexual activity is important and helps in coping with hopelessness

Loss of hair from therapy causes embarrassment

Patients should be referred for hairpiece fitting before hair loss starts

Family is greatly affected by cancer

Graded use of photographs and other preparatory measures help people facing surgery to adapt to the aftermath

Depression is more common after breast cancer with:

- Past psychiatric history
- Treatment toxicity
- Lymphoedema
- Pain
- Body image problems
- Lack of a confidant
- Low self esteem
- Unresolved concerns

²²³⁴ 14% chance of getting it from the drug.

²²³⁵ Fear of recurrence was the main concern in Canadians who had been treated for cancer at least 6 months before the study: 42% admitted to this concern. (Charles *et al.*, 1996) Patients may be embarrassed by symptoms (e.g. unpredictable diarrhoea) and this may lead to anticipatory anxiety/agoraphobia. According to Massie (2004) rates of depression vary with cancer type: oropharynx (22-57%), pancreas (33-50%), and lung (11-44%) have high rates; lower rates are associated with colon (13-25%) and lymphoma (8-19%).

Depression in cancer patients should not be dismissed as 'expected' or 'understandable' – it should be treated appropriately with psychotherapy and/or medication. Venlafaxine may help reduce hot flushes in survivors of breast cancer,(Loprinzi ea, 2000) as may citalopram and paroxetine. Mirtazapine reduces physical symptoms such as pain, nausea and anorexia.(Sherman & Fisch, 2004) Depression secondary to interferon-alpha can be prevented or treated by SSRIs such as paroxetine²²³⁶.(Musselman ea, 2001) In a study employing a patient-completed questionnaire,(Frost ea, 2000) most American women who underwent bilateral mastectomy as a prophylactic measure because of a strong family history of mammary carcinoma were happy with the procedure, although a minority was dissatisfied with bodily appearance. Some felt less emotionally stable, felt more stressed with reduced self-esteem, had unsatisfactory sex lives and felt less feminine. In other work, women who regretted prophylactic mastectomy felt that the decision to operate had come from the surgeon.(Payne ea, 2000)

Gynaecological cancer treatments may lead to sexual problems²²³⁷, but successful treatment may be complicated by psychosexual problems in the either partner, e.g. fear of transmitting or 'catching' cancer, problems from disfigurement, or attribution of cancer to past sexual activity. Such issues need airing before and after treatment.

Some anti-cancer drugs, especially the alkylating agents²²³⁸, can cause sterility that may be irreversible. In males, the storage of sperm should be considered when chemotherapy is given with curative intent.

Corticosteroids may induce manic symptoms, as rarely may diencephalic tumours.

Doctors may see themselves as 'tellers' or 'non-tellers'. They should, however, individualise information and find out what the patient is really asking. We cannot prognosticate accurately for individual patients. We should tell them that 'life may be short but its length remains uncertain'. The patient should be given the information requested but not bombarded with facts. There is some evidence that doctors may try to keep the patient alive or to cure cancer to too great an extent. There may be more pressing indications for a greater emphasis on the care and comfort of the terminal cancer patient, with more use of analgesics and psychoactive drugs and less use of radiotherapy and chemotherapy.

Imparting bad news

Problems in the doctor – untrained²²³⁹ (how and where to tell and how to answer questions), uncertain (of patient's reaction or if the therapeutic relationship will suffer), and unsure (if patient will be upset)

Preparation – consider patient's prior knowledge and supports/resources, likely questions and types of reaction and appropriate responses, knowledge of patient's previous responses to adversity

When to tell – this is based on a consideration of many issues, e.g. ensuring a safe journey home or the return of a next-of-kin from holidays

Who to tell – does the patient want a friend/relative present, consider capacity/minors/Wards of Court issues

Where to tell – privacy, seated patient and doctor

What to tell - ask what is/wished to be known, give information stepwise, gently make sure you are understood, be realistically hopeful

Arrange further appointment and share relevant information with those professionals who have to know

CBT may help cancer patients cope better if it is brief, problem-focused, and modified to meet individual need. Imagework,(Kearney, 1992) where the patient focuses on mental images in his mind and asks himself questions that allegedly helps him to work through repressed material, has been advocated for pain, including cancer pain, that is inadequately responsive to physical interventions and which is considered to have a significant emotional component. Denial is not confronted during this procedure.

About one in four patients receiving combined chemotherapy develop nausea and vomiting if reminded of the treatment (Watson ea, 1992) and this response may lead to treatment avoidance. The newer antiemetic drugs like ondansetron are of help here. Also, infusions may be covered with an anxiolytic, e.g. lorazepam 2 mg T.I.D. for 48 hours before and during therapy. Tamoxifen may reduce TCA serum levels and thus interfere with the therapeutic efficacy of these antidepressants; and induced menopause (surgical,

²²³⁶ Interferon causes fatigue, neurocognitive dysfunction, and various degrees of depression.

²²³⁷ Loss of vagina, or radiotherapy damage to sacral nerves.

²²³⁸ Muscarine, cyclophosphamide, chlorambucil, etc.

²²³⁹ Delegation of this duty to the most junior member of the team is unacceptable.

tamoxifen) may lead to vasomotor symptoms. Also, SSRI antidepressants may reduce blood levels of tamoxifen metabolites and their use in women taking tamoxifen for breast cancer has therefore been questioned. (Jin et al., 2005) The combination of paroxetine and tamoxifen may worsen prognosis in breast cancer patients. (Kelly et al., 2010)

Paraneoplastic syndromes (PS) involving nervous system

PS (Darnell & Posner, 2003) refers to symptoms or signs due to organ or tissue damage at sites remote from primary or secondary neoplasia. There are many such syndromes, e.g. hypercalcaemia, Cushing's syndrome, and wasting. Most PS is due to tumour-derived substances that mimic normal hormones or interfere with circulating proteins. One²²⁴⁰ or many²²⁴¹ parts of the nervous system may be involved. A single cell type, such as cerebellar Purkinje cell, may be affected. Involvement of the spinal cord can lead to various inflammatory disorders, stiff person syndrome, amyotrophic lateral sclerosis, or sensory (dorsal root) neuropathy.

Other potentially affected areas

Peripheral nerve - various neuropathies

Neuromuscular junction - Lambert-Eaton myasthenic syndrome²²⁴², myasthenia gravis

Muscle - polymyositis, dermatomyositis, necrotising myopathy, myotonia

Neurological disorder usually precedes overt malignancy by months, even years. Many patients have serum and CSF antibodies that react with nervous tissue and the neoplasm.²²⁴³ Underlying pathology varies widely.

Spinal cord injury

Migliorini et al. (2008) examined mental health status in cross-section among 443 community-based adults with injured spinal cords. 48.5% had mental health problems (over twice the general population rate) and 60% had more than one problem. 37% were depressed, 30% were anxious, 25% were clinically distressed, and 8.4% had PTSD.

Most patients with spinal cord injury fail to ejaculate, or if they do, it is either non-orgasmic or with only an awareness of some altered feeling. Most male paraplegics with spinal cord injury put resumption of sexual function at the top of their wish list. Patients with spinal cord injury often say that they develop an area of arousal lying superior to the level of the lesion leading to sexual satisfaction ('phantom orgasm') from tactile experiences such as caressing.

Sensory deprivation follows acute high cervical cord injury. This is due to lack of sensory information from the environment and from immobilisation. This may lead to apathy that can be misconstrued for depression. Also, steroids may be used to reduce cord oedema. It is better to observe such cases for about four weeks than to rush in with antidepressants.

The spinal cord-injured patient who still feels (but does not believe) as if he/she is in/on the vehicle in which the trauma occurred may think he is losing his mind. He/she needs to be reassured that such persisting perceptions are a recognised complication of cord injury.

Vermiform appendicitis

Patients with a normal appendix at laparotomy have been found to have experienced more severely threatening life events in the weeks before the onset of abdominal pain than did those found to have an acutely inflamed appendix. (Creed, 1981) Similarly, severe life events or chronic problems may be associated with so-called functional acute abdomens of other varieties. Patients with a normal appendix at laparotomy are at increased risk of future hospital visits, particularly for self harm and for being seen by the liaison psychiatrist. (Dummett et al., 2002) Schizophrenic patients tend to have raised pain thresholds and may

²²⁴⁰ E.g. limbic encephalitis (amnesia, dementia, seizures; CSF raised protein and pleocytosis; anti-Hu antibodies), brainstem encephalitis, cerebellar degeneration, optic neuritis, retinopathy, Parkinsonism, chorea.

²²⁴¹ E.g. encephalomyelodisplasia.

²²⁴² Eaton-Lambert syndrome: Myopathy of cancer (small-cell carcinoma of lung) or thyrotoxicosis with myasthenic-like syndrome but, unlike myasthenia gravis, there is no response to IV edrophonium chloride (Tensilon). Anti-calcium channel antibodies are found.

²²⁴³ For example, Anti-Ma1 antibody reacting with neurones and, for example, lung cancer, and associated with brainstem encephalitis and cerebellar degeneration.

sometimes not complain of pain with acute appendicitis, perforated peptic ulcer, MI, or other serious medical events.(Dworkin, 1994; Marchand, 1955)

Amputation

Surgeons have traditionally delayed surgery for chronic disorders so that people might feel sufficiently relieved after intervention that they put up with the inconvenience caused by surgery. Amputation may be an acute or planned event. Those amputees who realistically appraise their situation and who work hard with rehabilitative measures do best. Late onset phantom limb pain may indicate a depressive illness. It seems to take some amputees many months before they appear as such in their dreams, although the dream content and changes therein varies widely between individuals.

Phantom and supernumerary limbs

Experience of possessing a limb that does not exist - in the first case the limb was amputated whereas in the second instance an extra limb is experienced

Phantom limb

Described in 1649 by Ambrose Paré

Tactile (often painful) rather than visual phenomenon, usually disappearing a matter of days after amputation²²⁴⁴

Usually the 'limb' is 'absorbed' or telescoped into the body, although some patients have a permanent phantom

Very young children rarely experience phantoms

Congenital limb absence may occasionally be associated with replacement phantoms

Preoperative anaesthetic block does not reduce the likelihood of phantom limb pain (Bach et al, 1988; Birbaumer et al, 1997; Flor, 2002)

Supernumerary limb

Experiencing an extra hand, fingers or limb, the number and site of such extra parts varies between patients

May occur with anosognosia for a left-sided hemiplegia

Usually there is retained insight

Looking at the limb may cause the extra part/phantom to disappear

Disorders of body schema

Abnormal awareness of spatial characteristics of the person's own body

Partially paralysed limb may feel excessively heavy or large (*hyperschemazia*) – found in multiple sclerosis, vascular disease, spinal cord lesions, toxic states, conversion states, hypochondriasis, dreaming, and in states of depersonalisation

Aschemazia and *hyposchemazia* (part of body seems smaller or absent respectively) may occur when the cord is divided, with parietal lobe lesions (e.g. right middle cerebral artery thrombosis), or in depersonalised states or in healthy people who are under water

Paraschemazia (distorted body image) can be due to hallucinogenic drugs, epilepsy, migraine, with a colostomy, or following amputation of a body part; however, rare cases of amputation-seeking people tend to say that they experienced a mismatch between anatomy and the self before amputation and to feel very well follow the procedure (First, 2005)

Strokes²²⁴⁵

CT is better than SPECT in distinguishing between haemorrhagic and non-haemorrhagic stroke. Overall, 20-40% of patients develop depression in the months following a CVA, and about half of these have major depression with the remainder suffering less severe (minor) depression.(Robinson, 2000) House et al (1991)

²²⁴⁴ Similar phenomena may follow nerve plexus, thalamic, or brainstem lesions. Breast, eye, or genital phantoms may follow removal of the relevant organs.

²²⁴⁵ Eventual level of **functioning achieved after a CVA/stroke** depends on many interconnected factors, e.g. amount and area of brain damage, quality of remaining brain tissue (CVA may unmask underlying Alzheimer disease), specific organic deficits (dysphasia, hemianopia, etc), psychological adjustment, length of immediate confusional state, extracerebral complications (e.g. cardiac failure), support offered by family and society, and facilities available for assessment and rehabilitation.

found a high post-stroke cumulative incidence of psychiatric disorders, but little of this persisted. However, Morris *et al.* (1993) found that depression following CVA was associated with greater mortality (particularly if accompanied by social isolation). Other workers have confirmed this finding. Various polymorphisms of the serotonin transporter gene (SERT) may be associated with post-CVA depression. (Kohen *et al.*, 2008) Various associations have been suggested between the site of a cerebrovascular lesion and psychiatric disorder, e.g. depression/left hemisphere (especially anterior/basal ganglia: Vataja *et al.*, 2001), mania/right hemisphere (especially limbic-connected and thalamus), and bipolar/right basal ganglia or thalamus. Robinson (2003, p. 730) argues that the association of post-stroke depression with proximity to the left anterior lobar pole and left basal ganglia may be an acute phenomenon, i.e. holding true in the first 1 to 2 months after a cerebrovascular accident.

Antidepressants, especially SSRIs, can be used to treat or prevent post-stroke depression and they may improve cerebral recovery and improve long-term survival. Executive dysfunction is common after stroke, an outcome that may be ameliorated by antidepressant drug therapy. (Narushima *et al.*, 2007) Antidepressants may be augmented with calcium channel blockers in post-stroke depression.

Psychostimulants, such as methylphenidate, are sometimes used to treat post-CVA depression, especially in the USA. (Lazarus *et al.*, 1994)

Anxiety is common post-CVA. Understandably, many patients are worried lest they develop further strokes (e.g. during sexual activity). Agoraphobia and misinterpretation of anxiety symptoms as premonitory symptoms of CVA may follow. OCD symptoms may follow CNS infarction, especially one involving the basal ganglia.

Emotional lability (emotionalism) can occur early or late in the history of stroke and it may respond to SSRIs or TCAs. (Robinson *et al.*, 1993) Laughing or crying occurs with no relation to internal mental state. The term 'silent' infarct means different things to different people. The infarct is either so small or in an area of brain that allows its effects to go unnoticed. It could mean that there are no discernible physical signs (see strategic infarct in box). However, such cases can be psychiatrically 'noisy' and present in a manner ranging from delirium to a pseudo-'functional' psychosis²²⁴⁶. MRI population-based work from Rotterdam (Vermeer *et al.*, 2003) suggests that these cases are at increased risk for dementia.

Strategic infarction

Unexpectedly severe cognitive impairment (dementia +/- specific signs such as paralysis) following an infarction in certain 'strategic' areas:

- Inferior genu of internal capsule
- (Medial) thalamus
- Left angular gyrus (with Gerstmann's syndrome)
- Basal ganglia
- Basal forebrain
- Area supplied by posterior cerebral artery

MELAS syndrome

Rare maternally inherited mitochondrial encephalopathy

Lactic acidosis and stroke-like episodes

Usually seen in children

May present in adults with migrainous headaches, deafness, stroke-like episodes, and a progressive dementia (Clark *et al.*, 1996)

Concerns have been raised concerning an association between the cough cure agent phenylpropanolamine and CVA in young women. Higher doses used in America and methodological flaws may have partly led to this finding. Phenylpropanolamine should be avoided in certain circumstances, e.g. acute cardiac ischaemia, hypertension, hypotensive therapy, MAOIs, anticholinergic therapy, and phenothiazine therapy.

²²⁴⁶ The prevalence of psychosis specifically due to stroke is low and may be more common with right-sided lesions. (Bourgeois, 2007)

SSRIs are the drug treatment of first choice for depression following stroke, except for haemorrhagic stroke (risk of bleeding: Robinson, 2000). A meta-analysis (Antithrombotic Trialists' Collaboration, 2002) found low dose (75-150 mg/day) aspirin reduced the risk of vascular events (at least 150 mg/day in acute setting) but that adding dipyridamole to aspirin did not significantly improve outcome. Blass and Ratan (2003) appear to disagree.

Olanzapine and aripiprazole are 'contraindicated' in elderly patients with dementia-related psychosis and/or behavioural disturbance because of evidence for an association with an increased mortality rate and a greater likelihood of stroke. Similar concerns have been raised for risperidone²²⁴⁷ and other atypical agents. One UK GP database study suggests that the risk of stroke is increased with *all* antipsychotics, more so for atypical drugs than for typical agents, and more so for dementia patients than for those without dementia.(Douglas & Smeeth, 2008) However, decisions need to be based on a case by case basis. Also, there is also evidence against an association between stroke and atypicals in elderly subjects with dementia!(Gill ea, 2005)

Active and passive smoking are risk factors for stroke.(Bonita ea, 1999) as may be hormone replacement therapy in postmenopausal women.(Bath & Gray, 2005) Eating fruit and vegetables reduces the risk of stroke,(He ea, 2006) possibly by supplying potassium, folate, fibre, and antioxidants like ascorbic acid, flavonoids, and betacarotene.

Deafness²²⁴⁸

At least one in seven people have some loss of hearing²²⁴⁹, one in every thousand being very deaf from early life.(Du Feu, 2010) Hysterical deafness is rare, accounting for 4% of hysteria cases in an American series in the early 1960s. People who are born deaf have no increase in psychiatric illness, although they may be prone to behaviour problems. The latter may stem from parental over-protection, separation in institutions, adverse reactions of third parties, excess emphasis in teaching on speech at the expense of sign language, or associated brain damage. Deaf children of deaf parents do particularly well. Intellectual disabilities are commonly associated with deafness. Desensitisation to wearing a hearing aid may be needed. High frequency hearing loss is common in early middle age in Down's syndrome patients and may account for apparent deterioration in cooperativeness. Whilst persecutory states are the classical psychiatric problem in the elderly with hearing impairment depression is more common in practice. Also, because hearing impairment is so common in the elderly, no accurate deduction about a role for deafness in psychiatric disorders can be reached with using a matched control group.(Gloag, 1980) There is cross-sectional evidence that high ambient noise, as when schools are close to airports, can affect cognitive development in children, specifically reading comprehension.(Stansfeld ea, 2005)

Tinnitus

'Phantom auditory sensation without an acoustic generator'²²⁵⁰ is common and often chronic. Tinnitus becomes more common with age. Onset may follow negative life events such as retirement, redundancy or divorce. Over one-tenth of cases seen by specialists have good or reasonable hearing. About 5% of adults have their sleep regularly disturbed by buzzing or other noises in their ear(s). Affective disorder is a common accompaniment. IV lignocaine abolishes or ameliorates tinnitus. Management must be holistic and includes supportive psychotherapy, treatment of depression (nortriptyline has been recommended), tinnitus maskers, etc. It is important to distinguish tinnitus from crude auditory hallucinations, e.g. in schizophrenia. Objective tinnitus²²⁵¹ can be caused by such problems as tumours, arterial abnormalities,

²²⁴⁷ Risperidone is the only antipsychotic licensed in Ireland (for up to 6 weeks) for use in dementia if other approaches fail and following a risk-benefit analysis. Risk increases if risperidone is combined with furosemide.(Irish Medicines Board, 2009)

²²⁴⁸ Francisco Goya (Spanish, 1746-1828) may have become suddenly deaf from Harada's disease (retinal detachment plus deafness, a variant of Vogt-Koyanagi disease), a fact that might explain his change from painting happy and coloured pictures of attractive people to a much more pessimistic output, e.g. '*Saturn Devouring His Son*' (1819).

²²⁴⁹ Presbycusis, due to cochlear degeneration, is the most common cause of deafness. It is usually associated with ageing but chronic noise exposure is also implicated. Higher frequencies are most affected. Because consonants are high frequency sounds (vowels are the opposite) speech becomes difficult to decipher and using a hearing aid that increases volume only makes vowels louder ('Stop shouting. I'm not deaf!'). An aid that is specific for high frequencies is ideal.

²²⁵⁰ There may in fact be a generator, i.e. pathology like glomus tumour, carotid body tumour, or essential palatal myoclonus.(Walshe ea, 2002)

²²⁵¹ Tinnitus that is audible to examiner.

myoclonus, insects, temperomandibular joint abnormalities²²⁵², and a patulous Eustachian tube.(Walshe ea, 2002)

Ophthalmology²²⁵³

Environmental light appears to influence the time of onset of the menarche: completely blind girls reach menarche earlier than partially sighted girls, the latter achieving this developmental milestone before the normally sighted; and girls are more likely to have their first menstrual period during autumn/winter than during spring/summer.(Steiner ea, 2002)

Hypernyctohemeral (or non-24-hour-day) syndrome

Resembles normals in time-free environment

Common in totally blind people; some cases live isolated lives

Retires and rises to/from bed 45 minutes later each day

Sleep-wake cycle of 24.5-25 hours

Over about 21 days a cycle is completed

Management: morning bright light, vitamin B₁₂

Usher's syndrome²²⁵⁴ was said to be associated with schizophrenia in about 15% of cases.(Hallgren, 1959) William's syndrome²²⁵⁵ includes a stellate or starburst pattern in the iris. A cherry-red spot on fundoscopy may be found in Tay-Sachs disease²²⁵⁶ and in sialidosis.²²⁵⁷ The X-linked disorder oculocerebrorenal dystrophy (Lowe's syndrome)²²⁵⁸ consists of generalised aminoaciduria, abnormal skull shape, congenital cataracts, intellectual disability, and hypotonia. There is a Fanconi-type proximal renal tubulopathy. Nystagmus may be secondary to drugs such as BZDs or barbiturates. It must be distinguished from nystagmoid jerks, which are normal and occur when the examiner forces the patient to follow an object beyond the natural sweep of the eyes. Eyelid myoclonia with absences is an epileptic phenomenon wherein there is jerking of eyelids, the eyes may jerk upwards, and there is retropulsion of the head. Macular degeneration²²⁵⁹ is more likely to occur in smokers.(Mitchell ea, 2002; Kelly ea, 2004) Black-patch psychosis (delirium²²⁶⁰) may follow eye surgery where the eyes are covered for a prolonged period of time. Its occurrence may be greatly diminished by putting pinholes in the patches or by removing one patch at a time during recovery. A perception of the world as tilting has been found in people with a lateral medullary infarct. Upside-down reversal of vision, usually transient, results from posterior circulation ischaemia (e.g. vertebral artery dissection: Evans & Mathew, 2005, p. 259). Hallucinations in a blind visual field have been explained as release phenomena. The Charles Bonnet²²⁶¹ syndrome consists of poor sight and visual hallucinations. Other causes of 'positive' visual disturbances include migraine (e.g. fortification spectra), retinal damage such as detachment (phosphenes or simple flashes of light)²²⁶², drugs, epilepsy, and primary visual cortical lesions. Phosphodiesterase inhibitors may cause a following day green visual tinge.

²²⁵² Temperomandibular joint dysfunction is often viewed as a functional somatic syndrome. The use of splints in this disorder is not supported by the evidence.(Page & Wessely, 2007, p. 141)

²²⁵³ Grief in blind people, eye poking and tunnel vision are discussed in O'Shea. (2002)

²²⁵⁴ Early onset of deafness and blindness (retinitis pigmentosa), autosomal recessive, described in 1852 by Albrect Von Graefe, and named for a British ophthalmologist Charles Usher.

²²⁵⁵ There is a deletion on chromosome 7, variable levels of intellectual disability between cases (verbal IQ may be high enough to be misleading), 'cocktail party speech' (loquaciousness) elfin facies, supraaortic stenosis, renal artery stenosis, hypertension, anxiety, and depression.

²²⁵⁶ *Tay-Sachs disease* is a sphingolipid storage disorder of infants with excessive startle response, extreme motor and cognitive delay, visual loss, spasticity, seizures and death before age 5 years.

²²⁵⁷ *Sialidosis* is a storage disorder with facial dysmorphism.

²²⁵⁸ A mutation is found in the gene OCRL1 at Xq26.1 which codes for phosphatidylinositol (4,5) biphosphate 5 phosphatase.

²²⁵⁹ The most common cause of blindness in developed countries according to Anonymous.(2008b) Failure of regulation off both classic and alternative pathways of complement activation appear to operate.

²²⁶⁰ Postoperative delirium is associated with being very old and heavy preoperative benzodiazepine use.(Inouye, 1998)

²²⁶¹ Charles Bonnet (1720-1793), Swiss naturalist, described this condition in his grandfather (Charles Lullin) who had bilateral cataracts and saw visions of people, birds, carriages, etc when he was almost 90 years old. Before Bonnet himself died (age 73 years), when he was almost blind, he developed the same syndrome himself!

²²⁶² Severe, early onset bilateral retinal disease (e.g. CMV retinitis) may cause the child to poke an eye to elicit visual sparks or *phosphenes*.

Cataract surgery performed with topical or regional anaesthesia is often associated with seeing light or colours (usually yellow and red) or (less commonly and clearly) aspects of the environment (e.g. a surgical instrument). This is frightening to a small minority of cases. Preoperative explanation and holding the patient's hand during cataract surgery appear to help. (Moon & Cho, 2001)

Oculogyric crises are dystonic reactions classically associated with encephalitis lethargic/post-encephalitic Parkinsonism, neurosyphilis and (particularly older/typical) antipsychotic drugs. However there are many other organic causes of this phenomenon, e.g. head injury, herpes encephalitis, MS, Tourette syndrome, infarcts of both thalami, lesions of fourth ventricle, cystic glioma of third ventricle, and juvenile Parkinson's disease. Reported iatrogenic causes include reserpine, lithium, carbamazepine, metoclopramide, TCAs, L-DOPA, nifedipine, chloroquine, and cisplatin. Cases have been recorded in patients taking (surprisingly) benzodiazepines and following influenza vaccination.

Conjunctivitis secondary to faecal contamination (ano-ocular spread by hand) is common in the behaviourally disturbed elderly. Dysthyroid eye disease (ophthalmic Grave's disease) is more common and more severe in people who smoke.

The drug of choice for depression in glaucoma patients is an SSRI. Avoid TCAs in narrow angle glaucoma, but they can be used in cases of open angle glaucoma. The actual situation is more complicated than these simple rules suggest. TCAs have sympathomimetic, anticholinergic, and sympatholytic (alpha-1-blocking) actions. Desipramine, despite weak anticholinergic effects, is likely to increase the risk of glaucoma because the balance of its effects causes mydriasis. However, amitriptyline, a powerful anticholinergic TCA, is unlikely to provoke glaucoma because it has little effect on pupil size because of the counterbalancing effect of sympatholysis.

Bitemporal hemianopia (outer half of each visual field affected²²⁶³) is usually due to tumours of, or near, the pituitary gland, whereas binasal hemianopia can be caused by calcified, expanding internal carotid arteries. Both are classified as heteronymous (crossed) hemianopias. Quadrantic hemianopia is due to a lesion of the optic radiation or, more rarely, the occipital lobe.

High dose thioridazine may cause

Pigmentary retinopathy (poor visual acuity, loss of peripheral vision, scotomata)

Chromatopsia (e.g. seeing yellow or red)

Pyrexia of 'unknown' origin²²⁶⁴ (PUO)

Psychiatrists are sometimes asked to evaluate a case of PUO. It is good practice to assume that something has been overlooked until proven otherwise, e.g. the present author has diagnosed tuberculosis in two cases presenting with respiratory symptoms and 'negative' work up by finding *M. tuberculosis* in gastric washings. A complete and chronological history is often revealing as is a review of those tests that have (and have not) been done.

²²⁶³ Compression of chiasma from underneath firstly affects lowest crossing fibres with resultant upper outer visual defects; bitemporal hemianopia follows with further field loss. A pituitary tumour can spread down into the sphenoid air space or, extremely rarely, the nose (CSF rhinorrhoea). Very rarely is there lateral spread to involve the cavernous sinuses (ophthalmoplegia from damage to oculomotor nerves).

²²⁶⁴ Historically there are childbed fever (the present author diagnosed infected retained placenta twenty years ago in a delirious patient transferred from a maternity to a psychiatric hospital) and the improvement of neurosyphilis with malaria treatment.

Fevers of particular psychiatric interest include those associated with pneumonia in a sedated patient, meningitis, fever in an antipsychotic drug-treated patient exposed to high ambient temperatures, delirium tremens, withdrawal from TCAs, cheese reactions (MAOI plus tyramine), MAOI plus pethidine reactions, eosinophilia-myalgia syndrome (contaminated L-tryptophan), benign low grade fever with clozapine or reaction to drugs like carbamazepine/oxcarbazepine/SSRIs/nefazodone, increased risk of lithium toxicity with pyrexia, fever from marrow suppression (clozapine, carbamazepine, etc), side effect of anticholinergic drugs, febrile convulsions (association with later epilepsy in some cases), precipitation of epileptic attacks by fever, improvement and worsening of restless legs syndrome and multiple sclerosis respectively with fever, depression following fevers such as brucellosis, lethal catatonia, neuroleptic malignant syndrome, NMDA, burst internal bag of cocaine, and factitious fever. (see also Ahuja & Cole, 2009) **Factitious fever** is suggested by normal appearance, absent diurnal rhythm, no change in pulse rate with temperature change, no sweating as temperature abates, very high temperature, normal ESR/CRP, self-harm/injection marks/paraphernalia, and tampering with thermometer.

People with eating disorders have an elevated state-dependent pain threshold. People with borderline personality disorder report lack of pain when cutting themselves.

Pain

Nociceptive pain – direct stimulation of peripheral nerve ending²²⁶⁶

*Neuropathic*²²⁶⁷ pain – abnormal pain perception in the peripheral or central nervous systems²²⁶⁸

Combined pain – nociceptive and neuropathic, e.g. bone secondaries

Asymbolia for pain - pain is recognised but does not upset the perceiver, follows damage to the anterior insular cortex

'Jurisigenic' pain - maintenance of the sick role with complaint of pain in order to maximise financial return

Depression and pain may have a reciprocal relationship. 5-HT and noradrenaline inhibit pain transmission from the dorsal horn of the spinal cord. A reduction in noradrenaline availability leads to pain and low mood. Antidepressants with relatively greater noradrenaline reuptake inhibition have better analgesic efficacy than are those that are more 5-HT selective. (Atkinson et al, 1999; Fishbain, 2003) Binding of substance P to neurokinin receptors, an increase in cytokine activity, or decreased opioid receptor activity lead to pain and depression.

Reduced activity for fear of pain leads to poor conditioning which leads in turn to more discomfort if activity is undertaken.

Gate theory of pain

This starts in the substantia gelatinosa of the dorsal horn of the spinal cord where enkephalin fibres synapse on the endings of pain fibres carrying pain impulses from the periphery. These synapses, when activated, inhibit substance P release. Enkephalin fibres in the reticular formation activate cells in the same system that then descend to the cord and release enkephalin. Enkephalins and endorphins are found in the amygdala, part of the limbic system, thus adding an emotional element to pain responses.

At a spinal cord level, cells in the dorsal horn 'decide' if pain information reaches the brain or not. T (transmission) cells in the dorsal horn are affected by myelinated (A fibres inhibit transmission) and unmyelinated (C fibres allow transmission) fibres. These fibres are influenced by G (gate or gelatinosa) cells also in the dorsal horn. G cells inhibit passage of pain impulses. G cells are activated by large myelinated fibres and inhibited by C fibres.

*Idiopathic pain disorder*²²⁶⁹

Pain is the main focus of clinical attention and is judged to be psychogenic in terms of onset, severity, exacerbation or maintenance. Value judgements are still alive and well in this area. There are problems of both construct and face validity with terms like 'psychogenic pain'. (Aigner & Bach, 1999) Almost anyone with chronic pain²²⁷⁰ will fulfil the criteria for this disorder. Pain arises from multiple interacting sources: organic²²⁷¹, emotional, cognitive, social, cultural, etc. Pure psychological pain is therefore rare. (Tyrer,

²²⁶⁵ All analgesics inhibit cyclooxygenase (COX), thereby blocking prostaglandin synthesis. COX-1 does 'housekeeping', protecting the stomach lining as well as platelet and kidney function. COX-2 is important in inflammation/pain. Selective COX-2 inhibitors have been implicated in myocardial infarction/CVA. The older agents are non-selective, e.g. ibuprofen.

Equivalent doses of narcotic analgesics (mg): hydromorphone 2.5; oxycodone 5-10; methadone 5; morphine, hydrocodone, and heroin 10; and pethidine 100.

²²⁶⁶ Angina pectoris, broken bone, or wound/burn.

²²⁶⁷ Neuropathic pain: burning/stabbing/pulsating quality; hyperalgesia (increased response to painful stimulus) and dysaesthesia (unpleasant sensation); spontaneous pain; occurring where there is loss of sensation; major deficit e.g. trauma to spinal cord; little response to opiate drugs given on their own.

²²⁶⁸ Injury, surgery (including amputation), or disease.

²²⁶⁹ Also called pain of psychological origin, psychogenic pain, or atypical pain disorder. DSM-IV 'pain disorder' is classified with the somatoform disorders. It was called 'somatoform pain disorder' in DSM-III-R and 'psychogenic pain' in DSM-III.

²²⁷⁰ Pain persisting beyond the expected period of healing.

²²⁷¹ Damage to thalamus, internal capsule or cortex may give rise to relatively incomplete anaesthesia, mainly involving distal parts of limbs. Exaggerated response to sensory stimulation and touch may elicit something akin to pain in cases with thalamic lesions. Spontaneous pain is not uncommon. This constellation may mislead the examiner into diagnosing 'hysteria'.

1992) Walsh (2002) advocates a biopsychosocial perspective on pain, a model that accepts multiple inputs²²⁷².

The patient is not pretending; the pain is real to the sufferer. It can affect any body part. The patient usually denies any problem other than pain. There may be secondary alcohol or drug abuse. The pain does not resemble closely known organic patterns such as renal colic or angina pectoris; does not follow known nerve distributions; it lasts for a protracted period of time; contrary to popular belief, it is described in similar terms to organic pain; poor response to analgesics; and a good response to psychotropics, as with antidepressants in 'atypical' facial pain.(Merski & Spear, 1967) However, we should look out for an improbable description of pain; using emotionally-laden words; pain that increases in severity and extent over time; a history of multiple treatments; exaggerated facial expressions; exaggerated abnormal posture; frequent grimacing and sighing; and rubbing of the affected parts. Patients with psychogenic causes for abdominal pain will close their eyes when the examiner palpates 'tender' areas, whereas those with organic causes will keep their eyes open.

Patients having a number of the elements on the '*MADISON Scale*' (Hackett & Bouckomb, 1987) have an increased likelihood of experiencing prolonged and incapacitating pain.²²⁷³

'Psychological pain'²²⁷⁴ is very common in psychiatric patients, especially in neurosis, depression and somatisation disorders. It does not wake the patient from sleep. Operant conditioning may be involved. Those closest to the patient should ideally also be seen by the therapist and the interactions between them and the patient should be observed (are they rewarding him for having pain?). Patients who have been brought up in a household with a chronically ill relative are at risk of 'developing' psychological pain. 'True' physical pain fluctuates in intensity and is highly sensitive to emotions, thoughts, actions, and situational context.

Rather than trying to categorise the patient it is better to identify the various problems each patient has and to deal with them.(Large & Aamir, 2005, p. 99) Treatment strategies advocated for psychogenic pain include antidepressants²²⁷⁵, biofeedback, hypnosis, transcutaneous nerve stimulation (TENS), dorsal column stimulation, surgery (may give temporary relief but is generally ineffective), and psychotherapy (getting a person to examine the emotional ramifications of the pain without saying that the pain is not 'real'). Benzodiazepine and analgesic (including opiate) dependence should be avoided or treated.

Walsh,(2002) a psychologist, lists the main psychological interventions thus: psycho-education, biofeedback, relaxation therapy, stress/anxiety/anger management, supportive psychotherapy, operant conditioning techniques, CBT²²⁷⁶, and outpatient multidisciplinary pain management programmes in specific pain services. Imagework is discussed under cancer.

Patients may sabotage treatment and decry psychological interventions as ineffective. Emphasis should be shifted from passive participation to the patient being active in their own management. Reinforcing of pain behaviour should be identified and discouraged, as should 'doctor shopping'. Non-pain behaviour is praised by therapists and family.

Hysterectomy

Hysterectomy is more likely to lead to depression if there is a prior history of alcoholism or psychiatric illness.(Ballinger, 1977) The risk of depression may have been exaggerated by the inclusion of women with normal uteri who sought hysterectomy for the relief of emotional problems.(Udwadia, 2000) In a prospective study (Ryan ea, 1989) hysterectomy for benign conditions was associated with a high prevalence of pre-operative psychological morbidity (55%), which declined to 31.7% later on. The main risk factors for a poor psychological outcome were the previous scores on mental health measures and personality inventory. Hysterectomy, vaginal or abdominal, for benign conditions led to significantly improved sexual pleasure in a Dutch study.(Roovers ea, 2003) Gutl ea (2002) found less body image

²²⁷² Biological, psychological, emotional, behavioural, social, etc.

²²⁷³ **M**ultiplicity (> 1 site/variety of pain and relief leads to new pain), **a**uthenticity (person spends at least as much effort convincing evaluator of reality of pain as seeking a remedy), **d**enial (denial of emotional difficulties and emotional influences on pain), **i**nterpersonal (presence of significant others worsens pain), **s**ingularity ('my pain is unique because...'), **o**nly the current doctor ('can cure me'...this may not last!), **n**othing helps (constant, non-varying pain – may even get worse).

²²⁷⁴ A.K.A. pain disorder, pain behaviour, or psychogenic/idiopathic/somatoform pain disorder.

²²⁷⁵ TCAs, SSRIs – dual action drugs like venlafaxine or duloxetine may be particularly effective.

²²⁷⁶ Distraction, relaxation, attention diversion, challenging negative pain-related thoughts, etc. Certain cognitions are unhelpful in pain patients, e.g. 'I will always be in pain' (catastrophising) and 'Pain is a message to tell me I am a useless human being' (personalisation).

dissatisfaction after vaginal hysterectomy than after abdominal hysterectomy, the problem with the latter being a visible scar.

Strategies to minimise psychosexual problems after gynaecological surgery²²⁷⁷ (de Marquiegui & Huish, 1999)

Involve partner
 Avoid radiotherapy if possible
 Minimise physical mutilation
 Preserve ovaries
 Reconstruct vagina if possible
 Check sexual activity at follow-up
 Refer for sexual counselling
 Attend to alternative positions, lubrication, intimacy issues, fears and myths, etc

Polycystic ovarian syndrome (PCOS)

Pregnancy or weight gain can precipitate the onset of PCOS. It has also been associated with the use of valproate (in people with epilepsy and/or obesity, so the association with the drug is controversial) and with TLE. Patients on valproate should be monitored for depression, weight gain, type 2 diabetes, metabolic syndrome, sleep apnoea, hirsutism, irregular menses, and acne vulgaris. (Norman et al, 2007)

Mastectomy

One study of survival after mastectomy for breast cancer found that those women who denied their predicament and those who tried to fight harder both did well in comparison to those who gave up trying. Another study found that 25% of women who had this operation had significant psychological symptoms, especially depression, anxiety, and sexual dysfunction. Increased risk for psychological dysfunction is associated with poor marital relationship, unsupportive social network, recent adverse life events, and prior psychiatric disorder. Numerous variables interact to determine psychological health or ill health, e.g. personality, coping styles, immune status, type and stage of cancer, metastatic or non-metastatic disease, marital harmony versus disharmony, surgical and other interventions, and so on. Marital (sexual) problems are sufficiently common after mastectomy to warrant involvement of the husband early on in treatment. The woman may be embarrassed by her disfigurement and feel bad about herself as a person (woman). Prostheses may help. Both partners should be helped to see and touch the scar. Open groups for mastectomy patients have been advocated in the prevention of long-term morbidity. Differences of opinion exist as to whether radiotherapy after mastectomy increases or decreases psychological morbidity. Less radical surgery is used more often today than heretofore. Some women respond worse to loss of their breast than to others. Counselling by a nurse should be given after diagnosis and before operative surgery. Psychiatric morbidity, such as depression, should be recognised and treated. The patient should be given the choice for mastectomy or a less radical procedure since this does seem to reduce the associated psychiatric sequelae.

Phantom²²⁷⁸ breast

Experience of still possessing the lost breast after mastectomy
 Very common (Jarvis, 1967)

Amenorrhoea:

Secondary amenorrhoea may be of organic or psychological origin.

²²⁷⁷ **Female genital mutilation (FGM)** is most common in Africa but is also found in parts of Asia and among immigrants to western countries. Type I involves clitoridectomy while type 2 also involves removal of the labia minora. Girls may be held down during the procedure. Pain, haemorrhage and infection are common and it is likely that PTSD and other psychiatric disorders are commonplace following FGM. (Burki, 2010) In Guinea, 97% of all females undergo FGM, although some progress is being made to eradicate this practice. Recent figures for Cameroon and Mali were 20% and 92% respectively. (Wakabi, 2007)

²²⁷⁸ Flor (2002) points out that phantom sensations or pain can affect many surgically removed parts, e.g. rectum, penis, teeth, tongue, eye, limb, or breast.

Aetiology

Pre-pubertal
 Pregnancy
 Emotional stress
 Severe organic (e.g. increased prolactin due to chronic kidney disease) or functional psychiatric disorder
 Drugs increasing prolactin levels
 Prolactinoma
 Chronic alcoholism
 Substance abuse
 Pseudocyesis²²⁷⁹
 Excessive physical exercise (e.g. jogging)
 Debilitating illness or malnutrition (including anorexia nervosa)

Hyperemesis gravidarum

This was once considered to be psychogenic and to arise from ambivalence toward the pregnancy. It is no longer viewed in this way. It is one cause of the amnestic syndrome.

Genitourinary medicine (GUM)

The psychological aspects of sexually transmitted infection (STI) have a long history. AIDS phobia finds its early roots in syphilophobia in particular and venereophobia in general. Syphilis accounted for about one in ten psychiatric admissions during the pre-antibiotic era. Non-specific urethritis and herpes were strongly feared in the time gap between the wane of syphilis and the rise of HIV. The shame attached to such conditions was reflected in medical euphemisms such as 'specific disease' (syphilis) and 'gram negative intracellular diplococci' (gonorrhoea). In 2008 the US Centers for Disease Control (CDC) stated that at least 25% of teenage American girls have an STI²²⁸⁰. (Anonymous, 2008a) Longterm effects of STI include infertility and cancer of the cervix. Numerous important issues are raised by such statistics, such as emotional versus physical readiness for intimacy, condom non-use and needle-sharing, various other risk-taking behaviours, alcohol and substance misuse, and sexual assault. A number of studies demonstrate the high rates of psychiatric morbidity in GUM clinics (Osborn, 2007), much of which goes undetected.

Dialysis

This prolonged procedure, in the case of end-stage renal disease, has been associated with such adverse psychiatric sequelae as depression²²⁸¹, dementia²²⁸², the dialysis disequilibrium syndrome (transient acute confusional state secondary to rapid changes in plasma osmolality²²⁸³), (possibly) encephalopathy due to cytokine activation (reaction to synthetic dialysis membranes), and abnormal marital relationships with much covert anger and lack of healthy communication. The stress of dialysis may lead to behavioural problems in offspring. Aluminium was used to reduce phosphate serum levels, but it was inferior in this regard to calcium carbonate. The pathology of dialysis dementia differed from that of Alzheimer's disease²²⁸⁴ and the dementia-Parkinsonism complex of Guam. The pathology of dialysis dementia²²⁸⁵ has been described as follows: increased brain aluminium levels; increased number of senile plaques; absence of neurofibrillary tangles; and abnormal tau protein processing with deposition of insoluble phosphorylated tau in grey matter as in Alzheimer's disease. Wernicke's encephalopathy has been noted in some cases on longterm haemodialysis who had not received vitamin supplementation. The incidence of suicide is raised among patients on chronic haemodialysis, although not all patients who withdraw from dialysis are suicidal ('rational suicide') even if some are also feeling depressed. (Levenson, 2008, p. 1016) It has been suggested

²²⁷⁹ Pseudocyesis is classified under somatoform disorder not otherwise specified in DSM-IV.

²²⁸⁰ The main infections are human papilloma virus, Chlamydia, herpes simples, and trichomonas.

²²⁸¹ This is often untreated. (Watnick et al, 2003)

²²⁸² And osteomalacia: aluminium poisoning – desferoxamine binds iron and aluminium.

²²⁸³ Patients often note progressive impairment as the next dialysis session approaches and may develop brief delirium (minutes-hours) after the session ('disequilibrium' because of rapid fluid/electrolyte changes). Such events are much less common with the slower acting continuous ambulatory peritoneal dialysis. However, the potential *full syndrome* consists of nausea, vomiting, headache, myoclonus, hypertension, and (if cerebral oedema occurs) coma and seizures.

²²⁸⁴ As the dialysis patient ages vascular and Alzheimer dementias are more often seen.

²²⁸⁵ Dialysis dementia may still occur where undialysed patients in chronic renal failure receive medication contain aluminium.

that early discussion of the option of dropping out of treatment may reduce later levels of morbidity and mortality. Ideally, a psychiatrist should assess all patients who are being considered for long-term dialysis.

Lithium and the dialysis patient

Lithium is readily dialysed

Patients maintained on dialysis do not excrete lithium

They do not require daily lithium therapy (it is only removed at dialysis)

They are usually maintained on 300-600 mg lithium *after* each dialysis treatment (some people need doses on non-dialysis days)

Serum lithium levels are checked 2-3 hours after a dose (monthly after a dosing schedule is established)

Testosterone levels may fall (often staying within the normal range) in patients with chronic renal disease and cause erectile dysfunction and reduce sperm production.

Restless legs syndrome²²⁸⁶ (RLS)

It has been suggested that RLS emanates from altered dopamine (DA) function in the CNS (reduced threshold in spinal flexor reflex) and/or reduced cerebral iron acquisition (low basal ganglia iron). RLS is equally common in both sexes at all ages (some say it is more common in females: Anonymous, 2003), and it is more common in the elderly. Most sufferers do not seek professional advice, many cases are not diagnosed, and the taking of inappropriate remedies is common.(O'Keeffe ea, 2007) Although most cases are idiopathic/sporadic, there is a positive family history in 92% of people with RLS.(Anonymous, 2003) Families with an autosomal dominant inheritance of RLS with complete penetrance have been reported. Susceptibility to RLS has been linked to specific foci on chromosomes 6p, 9p, 12q and 14q. A variant found on 6p predicted both periodic limb movements of sleep and iron deficiency in RLS patients and in their families.

A Canadian study of familial RLS (Xiong ea, 2010) found a high rate of familial aggregation of RLS (77%), sibling and offspring relative risks of 3.6 and 1.8 respectively, disease duration averaging 24 years, and an average age of onset of 28 years (SD 15); most family members had early-onset of RLS with mild/moderate symptoms.

RLS affects at least 2-5% of the population at some time, and almost 25% of people over 60 years of age. However, according to Medcalf and Bhatia (2006) many cases may start in childhood but are not diagnosed. RLS consists of a very annoying but usually non-painful deep creeping sensation in the calf, less often in the thighs, and rarely in the arms. It mainly comes on when the patient is sitting or lying down for a prolonged time. It causes insomnia but is not confined to bedtime. Social withdrawal and depression may follow. There is an irresistible urge to move the legs. Paraesthetic sensations are usually relieved by vigorous exercise, although relief may be transient in severe cases. It is made worse by sleep deprivation and improved by fever. The sleeping partner may be kicked. RLS may occur for the first time during pregnancy²²⁸⁷ and then remit²²⁸⁸. Myoclonic jerks may be observed during waking hours. Periodic leg movements are usually present during sleep (this combination has been linked in Iceland to chromosome 6p and with decreases in serum ferritin levels of 13% per allele of the at-risk variant: Stefansson ea, 2007).

RLS: other associations

Pregnancy (improves with delivery)

Gastrectomy

Diabetes mellitus

Vascular insufficiency

²²⁸⁶ Although Willis described this condition in 1685 and Wittmaack wrote of *anxietas tibiae* in 1861 it is more often associated with K. A. Ekbom who wrote about it in 1945.

²²⁸⁷ 19% of pregnant women have RLS, especially in the third trimester; perhaps related to iron deficiency.

²²⁸⁸ RLS usually resolves after delivery.

Excess caffeine
 Antidepressants
 Antihistamines
 Barbiturate or opiate withdrawal
 Uraemia (may herald neuropathy)
 Fibromyalgia
 Amyloidosis
 Acute anterior poliomyelitis
 Myelopathy
 Motor neurone disease
 Peripheral neuropathy (including subclinical sensory) or radiculopathy
 Chronic pulmonary disease
 Hypothyroidism
 Parkinson's disease
 Malignancy
 Malnutrition
 Sleep apnoea
 Iron deficiency²²⁸⁹
 Rheumatoid arthritis (perhaps one-third of cases²²⁹⁰)

Any iron, B12 or folate deficiency should be treated. Reassurance, relaxation exercises, and massaging of affected parts may be sufficient in mild cases. Reducing or stopping caffeine intake may help. Carbamazepine, gabapentin, carbidopa/levodopa (not recommended by Anonymous, 2003), carbergoline (dopamine agonists), pergolide²²⁹¹ (higher doses, as in Parkinson's disease, may be associated with valvular heart disease), pramipexole (Mirapexin)²²⁹², opioids (oxycodone, codeine), clonidine²²⁹³, clonazepam and CBT have been reported to be helpful, and sublingual nitrates may be worth a trial. (e.g. O'Keeffe & Lavan, 1994) However, the hard evidence for efficacy of these drugs varies from limited to poor. (Anonymous, 2003) Rotigotine (Neupro)²²⁹⁴ became available in 2009 for moderate-to-severe idiopathic RLS. 'Augmentation' refers to the phenomenon of earlier onset during the 24-hour day of RLS due to treatment (especially levodopa) and should prompt consideration of a change in medication. Restless legs in association with chronic kidney disease may respond to erythropoietin (for anaemia) or clonazepam and it should disappear after kidney transplantation.

Periodic limb movements of sleep (PLMS)

Every 20 to 40 seconds for periods of minutes or as long as an hour during sleep, perhaps associated with arousals, there are kicking movements, the covers land on the floor, and the patient is often oblivious to these events but may feel tired by day and complain of insomnia. The sleeping partner may be kicked! Most such movements occur during light stage 2 sleep. Background physical disorders are similar to the list for RLS. Age of onset varies enormously. Treatment strategies are as for RLS. Strategies that may be of help include leg stretching, relaxation tapes, and warm baths. PLMS often co-occurs with RLS, and antidepressant drugs may exacerbate both phenomena.

Rheumatoid arthritis (RA)

According to Molodofsky and Chester (1970) poor outcome is associated with low motivation, low IQ, depressed mood not linked to pain, poor impulse control, and poor ego strengths. The specificity of this

²²⁸⁹ Low CSF ferritin (protein storage form of iron) levels have been reported by Early & Connors. (1999) Low CSF ferritin may co-occur with normal serum iron levels. It is important to note that iron is involved in dopamine synthesis and in regulation of the dopamine receptor.

²²⁹⁰ But see Anonymous (2003) who has doubts about a rise in incidence of RLS in rheumatoid arthritis, peripheral neuropathy, and Parkinson's disease.

²²⁹¹ Pergolide (e.g. Periactin), a dopamine agonist, is derived from ergot.

²²⁹² Used for Parkinson's disease. The starting dose for RLS is 0.125 mg, increasing every 4-7 days if needed in steps (0.25 mg, 0.5 mg), the highest recommended dose being 0.75 mg.

²²⁹³ May aggravate depression, or cause insomnia, or lead to a rise in blood pressure if stopped suddenly.

²²⁹⁴ Rotigotine transdermal patches are available as 1mg, 2 mg or 3 mg per 24 hours. Adverse effects include nausea, fatigue, headache and application site reactions.

kind of finding is questionable. Cigarette smoking is a risk factor for RA, especially men who are positive for rheumatoid factor and heavy smokers (Sugiyama ea, 2010). An interaction occurs between cigarette smoking and HLA-DRB1 shared epitope genotype and RA risk. (Karlson ea, 2010)

Fatigue

Fatigue has numerous causes, e.g. excessive work and lack of sleep, worry/anxiety/neurasthenia, depression, lack of stimulation, dissatisfaction, chronic fatigue syndrome, alcohol, benzodiazepines (BZD), beta-blocking drugs, dapsone²²⁹⁵, corticosteroid/alcohol/opiate/opioid/antidepressant drug/BZD/withdrawal, anaemia, dietary deficiencies, myopathies, myasthenic syndromes, MS, motor neurone disease, cardiac/renal/hepatic failure, chronic diarrhoea, chronic pain or infection (including HIV), post-viral, malignancy, connective tissue disease, diabetes mellitus, hypoadrenalism, and hypothyroidism.

Fibromyalgia²²⁹⁶

This is characterised by chronic musculoskeletal (MSK) pain and multiple tender points. These 'points' are commonly found in distressed people are not as specific as was once believed. There is much overlap with anxiety, depression and other 'non-organic' disorders. Poor physical fitness is common.

Fibromyalgia/chronic widespread pain

'Fibrositis' coined by Gowers in 1904

Multiple regional MSK pain, disability

Overlap with symptoms of chronic fatigue syndrome²²⁹⁷ (Sharpe & O'Malley, 2007, p. 156)

Occurs at all ages

Risk factors: older age, female (10 F:1 M), marital problems, alcoholism in family, poverty, self-reported child sexual abuse, injury/assault

Decreased delta wave sleep²²⁹⁸

Abnormal processing of pain²²⁹⁹

Objective signs < subjective severity

Treatment: often unsatisfactory

- Face-saving explanation (sleep loss → pain → sleep loss)
- Graded aerobic exercise improves self-reported health status (Richards & Scott, 2002)
- CBT, coping strategies, relaxation exercises
- Exploration of unresolved problems
- Low dose amitriptyline²³⁰⁰, SSRIs, pregabalin
- Nefazodone (withdrawn) may have therapeutic effects in this disorder

Prognosis generally poor: worse in cases seen in hospitals than in general practice

Osteology, orthopaedics & traumatology

Poor mobility is common in care homes. Predictors of falling in such environments include prior falls, older age, poor balance or functional ability (including dementia), behaviour problems, and psychotropic medication (including TCAs, BZDs, and SSRIs²³⁰¹). (Denning & Milne, 2008, p.360) There is evidence that insomnia as such is a factor in falling. (Avidan ea, 2005)

About 61% of patients operated on for fractured femur develop delirium (Pitt, 1998) and depression, delirium, and dementia increase the chances of dying after hip fracture. (Nightingale ea, 2001) Mental distress in women over 50 years of age may be an independent risk factor for hip fracture, independent of medication effects. (Forsen ea, 1999) Similarly, major depression in women is associated with a reduction

²²⁹⁵ Resulting from methaemoglobinaemia.

²²⁹⁶ See also Henningsen ea.(2007)

²²⁹⁷ The same authors point out that if one doesn't believe that either diagnosis is a medical one they could be replaced by a label of somatoform disorder. In some cases there is hypochondriasis or somatoform pain disorder. (Sharpe & O'Malley, 2007, p. 158)

²²⁹⁸ Deprivation of delta waves in normal people causes fibromyalgic symptoms.

²²⁹⁹ At certain sites there (mainly neck and back) are decreased pain perception threshold (hyperalgesia) and poor pain tolerance; exaggerated skin flare in response to topical capsaicin; dermatographism; allodynia (pain is experienced from stimuli that would not normally be associated with pain; reduced thalamic and caudate blood flow; increase in substance P in CSF; and decreased CSF 5-HT.

²³⁰⁰ Hauser ea (2009) conducted a meta-analysis of antidepressants in fibromyalgia and found that they improve pain and a variety of other complaints. Effect sizes for pain reduction were large for TCAs, medium for MAOIs, and small for SSRIs and SNRIs.

²³⁰¹ Thapa ea (1998) found no difference in falls between TCAs and SSRIs in the elderly.

in trabecular bone, 14% in the femoral bone.(Michelson ea, 1996) Prolactin-raising medication may increase the chances of fracturing a hip.(Howard ea, 2007) Longterm psychiatric inpatients often have low bone mineral density that is related to prolactin levels and chlorpromazine equivalence; they are also often obese and have metabolic dysfunction.(Hallahan ea, 2008)

Avascular/aseptic/ischaemic necrosis (osteonecrosis) of the head of femur leads to severe hip pain. X-rays eventually (weeks) show an area of increased density but are normal initially. Scintigraphy and MRI will show early lesions. Bony collapse may occur. Risk factors include alcohol, corticosteroids, anabolic steroids, heparin, biphosphonates (jaw affected)²³⁰², irradiation, trauma, sickle cell disease, diabetes mellitus, Cushing's disease, HIV, and high barometric pressure (working far underground or deep sea diving [Caisson disease]).

'Athlete's neurosis'²³⁰³ refers to distress in someone who is unable to exercise because of injury or illness and who is heavily emotionally invested in such activity. Back problems have been found to relate to the employer's personality and to job dissatisfaction. Indeed, the best predictor of return to work after back injury is how one liked ones previous employment.(Kirmayer & Loooper, 2007, p. 437) CBT may have sustained positive effects on subacute/chronic low-back pain.(Lamb ea, 2010)

12% of patients with Down's syndrome have atlanto-axial instability.

Fractured bones are not diagnostic of child abuse but, in the absence of a confirmed cause should raise suspicion. The site and type of fracture and the child's developmental level may provide clues.(Kemp ea, 2008) Multiple fractures are more common in abuse cases. Rib fractures may also warrant suspicion.

Benign joint hypermobility (joint laxity) syndrome (Bulbena ea, 2004) is probably inherited and consists of multiple hypermobile and painful joints. This disorder of collagen appears to be associated with an excess of anxiety disorders (panic disorder, agoraphobia, and social phobia). These children are often said to have 'growing pains', especially following exertion, and may become unfit as a result of avoidance behaviour.

Marble bone disease (osteopetrosis) is a group of autosomal mild dominant or severe recessive²³⁰⁴ disorders with a very dense, fracture-prone skeleton. Acid phosphatase levels are elevated. Other features in severe cases are intellectual disability and anaemia with early demise. This is one disorder for which stem cell transplantation has been used.

Retroperitoneal fibrosis (chronic periaortitis)

This has many causes, although two-thirds are of unknown aetiology. Smoking, aortic aneurysm, and asbestos are associated with retroperitoneal fibrosis. It may occur with cancer, infection, surgery, or trauma. Drug causes include beta-blockers, methysergide, methyl dopa, ergot alkaloids such as ergotamine and lysergic acid, bromocriptine, cabergoline and other dopamine agonists, and hydralazine.

Toxicity of prescribed treatments

About 0.5% of inpatient deaths are iatrogenic.(Turner & Pearson, 1994) Beta-blockers, isoniazid, lithium, and penicillamine may cause a SLE-like syndrome. Some *anti-cancer drugs* cause encephalopathy and alkaloids are neurotoxic. *Tricyclic antidepressants* may reduce absorption of sublingual nitrates because dry mouth may prevent the tablet dissolving. Especially if given with antineoplastics, *radiotherapy of the CNS* can cause personality change/dementia that may be delayed in onset.

Anticholinergic drugs - side effects (severe in brackets)

Neurological:

- Peripheral: mydriasis, blurring of vision (narrow angle glaucoma), dry mouth (caries), reduced sweating (heat stroke), tachycardia (angina and MI in patients with coronary artery disease), constipation (obstipation/ileus), difficulty urinating (hypotonic bladder & infection)
- Central: difficulty encoding new memory (delirium), restlessness, visual hallucinations, and psychosis
- Physostigmine (**very slowly** 1-2 mg IV) response is diagnostic of atropine psychosis, but normally it is sufficient to stop the offending agent; excess physostigmine may cause a cholinergic crisis (nausea,

²³⁰² This appears to occur mainly in patients with cancer who receive high doses of nitrogenous biphosphonates (e.g. alendronate) given IV.

²³⁰³ Described by Little in 1969.

²³⁰⁴ There is a recessive form with renal tubular acidosis and deficiency of carbonic anhydrase II.

vomiting, bradycardia, and seizures) that responds in turn to an anticholinergic drug such as atropine; carbamazepine has anticholinergic activity.

Jimsonweed (*Datura stramonium*) and related plant species contain the alkaloids atropine and L-hyoscyamine that act as muscarinic antagonists

Drug causes of peripheral neuropathy (not exhaustive: see England & Asbury, 2004):

Sensorimotor neuropathy – vincristine

Sensory neuropathy - metronidazole, flecainide, cisplatin, and large doses of pyridoxine

Mixed neuropathy - nitrofurantoin, isoniazid, lithium, ethambutol, chloroquine, amiodarone, hydralazine, phenytoin²³⁰⁵, and disulfiram²³⁰⁶

Procaine (when given accidentally IV²³⁰⁷)

- May precipitate immediate and short-lived fear of impending demise, hallucinations, or seizures
- Management is by reassurance and prevention of self-harm (e.g. restraint)

Beta-blockers (especially propranolol) can cause lassitude, depression, vivid nightmares, & visual hallucinations. *Bromides* are associated with delirium, mania, depression, and psychosis Give sodium chloride IV or orally; if agitated, give antipsychotics (or paraldehyde). *Cardiac glycosides* – in toxic doses these can cause altered visual perception/hallucinations, mania, & delirium. The *clonidine withdrawal syndrome* consists of irritability, psychosis, violence, seizures (withdraw gradually). *Diuretics*, especially bendrofluazide, may cause impotence. *L-DOPA* can lead to mania, depression, schizophreniform, or rapid cycling in bipolars; reduce the dose or stop the drug. Found in OTC diet aids and nasal decongestants, *phenylpropanolamine* can cause psychosis, paranoia, restlessness, anxiety, and headache. In these cases the drug should be stopped.

H2-blockers

Cimetidine (not ranitidine) may cause impotence and reduced sexual drive

Cimetidine inhibits hepatic metabolism of other drugs by competing for pathways:

- Increased anticoagulant effect with warfarin
- Increased sedation with diazepam
- Increased beta-blockade with propranolol

Various *antidotes* may be used for poisons, e.g. ethanol or fomepizole (4-methylpyrazole) for methanol or diethylene or ethylene glycol, naloxone for opioids, flumazenil for BZDs, N-acetylcysteine for paracetamol, atropine for beta-blockers or nerve agents, oxygen for CO, Prussian/Berlin blue for thallium, and dicobalt edetate²³⁰⁸ for cyanide. Antidotes form inert complexes with poisons (e.g. dicobalt edetate with cyanide), speed up detoxification (e.g. N-acetylcysteine), bypass the poison (e.g. oxygen), compete for (e.g. naloxone) or block receptors (e.g. atropine), or decrease the rate of conversion of poisons into even more toxic compounds (e.g. ethanol).

Illicit substance abuse²³⁰⁹

Brian O'Shea

'Because of the strong countertransference reactions such patients evoke, inappropriate diagnostic and treatment decisions may ensue'. (Mack ea, 2003, p. 327)

Direct and indirect costs of substance use disorders to the USA are over \$300 bn annually²³¹⁰. (APA, 2002, p. 255) Annual economic cost of substance use in the UK was estimated as between £10.1 and £17.4 bn. (Godfrey ea, 2002)

The time lapse between the synthesis of a drug and its marketing varies.²³¹¹ Drug-induced psychoses are increasingly seen, especially in young males.

Not all drugs associated with a withdrawal state are dependence producing, e.g. antidepressants.

Dependence may occur with little or no withdrawal. Almost any drug can be abused, e.g. insulin abuse among body builders.

Psychological dependence (habituation) might be mediated by the interaction of a drug with the mesolimbic DA pathway subserving drive-oriented behaviour. Craving becomes strongly cued to environmental triggers.

In the case of physical dependence on opiates, withdrawal (abstinence) symptoms are partly caused by disinhibition of noradrenergic neurones of the locus coeruleus, and of other neurones in the periphery, including gut cholinergic neurones.

²³⁰⁹ Bacchus, deification of ethyl alcohol, cocoa-chewing runners of the Incas and Aztecs, psilocybin-induced states on ancient Easter Island, ache-dulling *Cannabis indica* of Far East sugar cane plantations, 'Purple Hearts' of the 1960s racecourse, amphetamine-induced combat vigilance of twentieth century troops (benzedrine included in US soldiers' kits in WW II), modafinil use by military personnel in Iraq, laudanum abuse by 19th century English poets or more modern use of cocaine powder intravaginally to prolong the 'high' of orgasm, attest to the very human and ancient nature of substance abuse/misuse. Methamphetamine, associated with risky sexual behaviour and more rapid symptomatic progression in AIDS patients, was given as an antidepressant to American women in the 1950-60s. Methamphetamine was first synthesised in Japan in 1919. Clive of India died of an overdose of laudanum at 45 Berkeley Square, London in 1774. (Porter, 1996, p. 107) Nutmeg intoxication (contains myristicine and causes delirium, dry mouth, dizziness, and nausea) has an old pedigree. (Faguet & Rowland, 1978) Synthetic chemicals can be more powerful than the diluted natural alkaloid. *Papaver somniferum* (Oriental Poppy) has been used for centuries for its sedative and analgesic properties. Cocaine was extracted from the cocoa shrub in 1859. *Psilocybe semilanceata* or Liberty Cap, *Amanita muscaria* (Fly Agaric), and the peyote cactus gave us psilocybin, muscinol, and mescaline respectively. The Assassins of India killed under the influence of *Cannabis sativa*. Substances resembling serotonin with a long history of abuse include psilocybin ('magic mushrooms' – sold openly in Amsterdam, on sale in Irish health shops to January 2006) and substances found in the cohoba bean (*Anadenanthera peregrina*: DMT and bufotenine). Bufotenine (5-OH-DMT or dimethylserotonin) was first isolated from a toad in 1934. In fact, bufotenine is found in a variety of toads, especially *Bufo alvarius*.

Bufo alvarius (Colorado river toad)

²³¹⁰ The National Institute on Drug Abuse (2007: 301-443-1124 or www.drugabuse.gov) put the US societal cost of drug abuse in 2002 at \$180.9 bn, \$107.9 bn of which relate to crime, justice and victim-borne costs. \$15.8 bn went on treatment, research and prevention.

²³¹¹ E.g. 1826 to 1838 for the bromides, 1912 to 1932 for the amphetamines, 1957 to 1960 for chlordiazepoxide, and 1960 to 1962 for diazepam. Time lapsed between first report of drug dependence and common reports of dependence also varies, e.g. 1877 and continuously thereafter for the bromides, 1936 to 1947 for the amphetamines, 1963 to 1966 for chlordiazepoxide, and 1965 to 1966 for diazepam.

The number of substance related deaths in the 27 EU countries and Norway during 2005 lay between 7 and 8 thousand. The greatest increases in such deaths were in Ireland, Greece, Portugal, Finland, and Norway²³¹². (Watson, 2007)

Timeline

1960s USA

Supreme Court held that it was unconstitutional to convict drugs addicts of the crime of having an addiction (*Robinson v California*, 370 US 660 1962) or using substances (*Powell v Texas*, 392 US 514 1968)

During 1960s two types of drug abuser formed the majority of users

Professional - someone e.g. doctor or pharmacist who had ready access to drugs and started taking drugs to relieve psychological or physical symptoms

Iatrogenic - a patient given drugs for pain and became unable to break the habit

Most European countries during early 1990s: about 30% of prison inmates had history of drug abuse; of those inmates who injected drugs 75% were sharing injection equipment

Home Office, England: 5,415 notifications of new narcotic addicts in 1984²³¹³, nearly 30% more than in 1983, and double the number of 1982

Roughly 90% of these new addicts claimed addiction to heroin

About 18% of addicts were seropositive for HIV in 1988, and, in certain areas, such as Edinburgh, the figure was nearer 50%

1984-1992, Ireland: number of heroin abusers stabilised, with rise in the injection of prescribed opiates, especially morphine sulphate (M.S.T.), buprenorphine (Temgesic), and dihydro-codeine tartrate (DF118) **1987, Ireland:** admission rate for 'drug dependence'²³¹⁴ to psychiatric facilities/100,000 population = 6.6

Preventable causes of death in the US in 1990 (% of total deaths)

Tobacco (19)

Diet/exercise (14)

Alcohol (5)

Illicit drug (<1)

National Comorbidity Survey (Kessler ea, 1994): one-year prevalence for (non-alcohol) drug abuse and dependence in the US was 3.6% (5.1% for males and 2.2% for females), while lifetime prevalence was 11.9%

Deaths in both Ireland and Britain, 2000: intramuscular heroin contaminated by *Clostridium novyi* (soil and dust anaerobe; prominent cause of gangrene during the Great War)

Opiate-related deaths in Dublin in 2000 and 2003: 83 and 46 respectively

Dublin: 332 opiate-related deaths (and 253 deaths on its roads) during 1998-2001 (Ryan, 2004)

1999-2001, Britain: number of 14-15 year old who tried cannabis increased from 19% to 29% and 18% to 25% in males and females respectively (Henry ea, 2003)

Face to face interviews of representative sample of people on the Island of Ireland aged 15-64 years

(MORI MRC, late 2002/early 2003 [National Advisory Committee on Drugs & Drug and Alcohol Information Research Unit, 2003]) 70% and 63% response rates in the Republic (ROI) and Northern Ireland (NI) respectively

19% of all Irish ever took an illegal drug (20% NI, 19% ROI)

Most commonly abused drug was cannabis (previous month use: 2.9% NI, 2.6% ROI)

Lifetime prevalence rates for all other illegal drugs were less than 5%²³¹⁵

For lifetime, last year, and last month use of drugs, men outnumbered women (for having ever used cannabis: 23% males, 12% females)

10%, 4%, 1% and 0.5% of persons aged 15-34, 35-44, 45-54, and 55-64 years took illegal drugs in the previous year

6% and 4% of NI and ROI interviewees respectively took ecstasy at sometime during their lives (for cocaine the percentages were 1.7% and 3% respectively)

Cocaine in London in 2004

Smoking freebase cocaine (crack: crystals without the hydrochloride moiety) was twice as common as use of powdered cocaine

Americans aged at least 12 years in 2004

About 19.1 million (7.9%) used illegal drugs during past month

North Eastern Health Board questionnaire study of post-primary schools (Flanagan ea, 2004)

Found the following changes from 1997 to 2002:

Decreased lifetime smoking prevalence - 57.1% to 50.8%

Decrease in regular smoking - 30.7% to 18.2%

No significant change in alcohol consumption - 57.3% drop to 53.7%

Increased weekend binge drinking and feeling drunk more than 10 times - 24% up to 27.2%

Increases in ever (41.2% from 34.9%) and regular (15.1% from 11.9%) illegal drug use

HRB: treated problem drug use in Ireland 2001-6 (Reynolds ea, 2008)

Based on data reported to National Drug Reporting System and to Central Treatment List

Rise in prevalence of treated 'cases' of 15% among 15-64 year-olds (74.8 'cases'/100,000)

168,754 'treatment episodes'

²³¹² The European Monitoring Centre for Drugs and Drug Addiction is based in Lisbon.

²³¹³ Notification ceased to be compulsory in 1997.

²³¹⁴ As distinct from alcohol abuse and alcohol-related psychoses.

²³¹⁵ Ecstasy and magic mushrooms, 4%, amphetamines, cocaine, LSD and poppers [amyl or butyl nitrite], each 3%, solvents, 2%, heroin, 0.4%, and crack, 0.3%.

Increase is mainly due to *same cases* being treated again, i.e. it is a chronic problem
 People on waiting list (longer outside Dublin) not counted, non-reporting occurs, and changes in methodology also reduce figures
 100% increase in new cases in western area
 72% of new cases reported polysubstance use

Need for unique case identifier in order to distinguish individuals from treatment 'episodes'

Ireland 1998-2005

According to HRB, among drug users there were 885 non-poisoning deaths (476 due to 'trauma' such as suicide, shooting, and RTAs; 270 due to medical causes such as hepatic or cardiac disease) plus 1,553 deaths directly related to drug use; there were 30 deaths, mostly among teenagers, from volatile substances

Ireland 1998-2007

National Drug-Related Deaths Index: 2,120 drug-related poisoning deaths (55.3% implicated opiates) plus 1,183 non-poisoning deaths (cardiac, respiratory infection, hepatic, etc)

England and Wales 2007 (O'Dowd, 2008)

Big increases in male deaths from opiates (particularly methadone) and cocaine

Ireland 2008-9

Numbers self-reporting ever using cocaine rose from 3% in 2002/3 to 5.3% in 2006/7²³¹⁶

Commonest source of cocaine is friends/family

Reports of 'crack houses' wherein cocaine is turned into free-base rocks

Irish prisons 2003-8: 'over 10,000 prisoners' (almost 4,000 in Clover Hill and over 3,000 in Mountjoy) received methadone treatment programmes²³¹⁷

There are between 13,405 and 15,819 problem opiate users in Ireland and the number of new opiate users entering treatment increased from 809 in 2002 to 1,350 in 2008

Opiate cases, chiefly heroin, presenting for treatment rose from 8,804 in 2002 to 11,538 in 2007 (reasons include service and reporting changes and drug use); fewer cases inject opiates than heretofore; cocaine cases jumping from 954 to 2,643 during the same period
 Irish Medical Council (medicalcouncil.ie) stated in 2009 that clinicians must use their registration number on anything that is practice related; they must bear in mind the dependence potential of any drug prescribed; and do not treat opiate dependence unless you are approved under the Methadone Treatment Protocol

World 2009-10

Authors argue that war on drugs is being lost and greatest problems occur where laws are strictest (Wood ea, 2009)

Poorer parts of the world have a greater disease burden per unit of alcohol consumption than do the better off parts of our planet (Rehm ea, 2009)

Driving under influence of illegal substances is now more common than drunk driving in USA, and abuse of prescription drugs is that nation's most rapidly growing drug problem (Anonymous, 2010)

Europe 2010

European Court of Justice rules that minimum cigarette prices imposed by Ireland, Austria and France were contrary to Directive 95/59 but stated that same goal could be achieved by raising tax on cigarettes!

Aetiology

The 'causes' of drug abuse²³¹⁸ and dependence²³¹⁹ are numerous and occur in different combinations and permutations in different individuals.

Genes: Children of alcohol-dependent parents who are reared by non-alcohol dependent adoptive parents have 3-4 times the risk of developing dependence on alcohol than do adopted children whose biological parents were non-alcoholic. In a meta-analysis, Young ea (2004) found the A1⁺ allele of the DRD2 gene to be a marker of substance use and severe substance misuse. A twin study (Agrawal ea, 2004) suggests that part of the association between early cannabis abuse and subsequent abuse of other drugs may be genetic. In particular, genes on chromosomes 1 (e.g. ELTD1), 4 (e.g. GABRA2), and 6 (e.g. CNR1²³²⁰) may increase the tendency to cannabis use disorders (Agrawal ea, 2008) and, in the case of CNR1 variants, of nicotine dependence. (Chen ea, 2008; see Bierut ea, 2008) GABRA2 may be associated with risk for externalising behaviours (including alcohol dependence) but its effect is diminished by parental monitoring of youngsters. (Dick ea, 2009) The C allele of CNR1 may experience greater subjective reward from alcohol. (Hutchison ea, 2008) Various loci may harbour associations with cocaine dependence and cocaine-induced paranoia, e.g. a SNP in the alpha-endomannosidase (MANEA) locus at 6q16.1. (e.g. Farrer ea, 2009) However, environmental influences also seem to be important. Also, using cannabis after discharge

²³¹⁶ See also Abel Thula (2009): during 12 weeks in 2007 9.1% of clients at the Drug Treatment Centre in Dublin had at least one urine positive for cocaine and the majority of these (84.2%) were dependent on cocaine.

²³¹⁷ Of 14 places of detention in the Republic of Ireland, 8 (accommodating 80% of prisoners) offered methadone maintenance in 2009.

²³¹⁸ Substance abuse is a residual category in the DSM system in that it only applies to someone who is not dependent on the drug in question.

²³¹⁹ The main symptom of dependence is the priority given to getting supplies of the drug despite the fact that abstinence syndromes and tolerance are often given great weight in definitions.

²³²⁰ Cholinergic nicotinic receptor 1.

from hospital increases the chances of using other substances.(Aharonovich ea, 2005) Indeed, environment may act to entice a person into substance use whilst genes may influence duration of use.(Kendler ea, 2008) Importantly, most alcohol-dependent individuals do not have an alcohol-dependent first-degree relative.(Kay & Tasman, 2006, p. 414) A genome-wide association study of alcohol dependence found an association with markers rs7590720 and rs1344694 on 2q35.(Treutlein ea, 2009)

Imprinting: It has been suggested that exposure of the mother in labour to drugs might increase the risk for later dependence on drugs in her offspring.

Availability: Dublin held a world record for dipipanone (Diconal, 'Dyke') abuse. Heroin became widely available here since early 1980. Dublin IV drug users have a very high prevalence of hepatitis C²³²¹, and while there was an overall increase in the numbers of heroin users during the period 1991-96 (including increase in female users) there was a relative shift from IV to smoking. Cocaine in socioeconomic (SE) groups 1 and 2 (the 'Celtic Tiger' effect). Proneness to deviancy and neighbourhood drug availability promote marijuana use.(Tarter ea, 2006)

Home: we learn to turn to chemicals at an early age. Excess pocket money, boredom, and lack of supervision.(Robertson ea, 2003) Australian adolescents living with a lone parent were, among other problems, more likely to use cannabis in a study conducted by Rey ea.(2002) Parental knowledge of their children's whereabouts and a confiding child-parent relationship are protective against drug abuse during adolescence (McArdle, 2008) whereas parental smoking increases the likelihood of adolescent substance use and other problem behaviours.(Keyes ea, 2008) Teenage pregnancy correlated with substance abuse in a Swedish study.(Ekéus ea, 2006)

Neighbourhood: Experienced psychiatrists and other health professionals are usually cognisant of potential implications of the patient's address, although it is essential to avoid generalisations. Stahler ea (2009) found that neighbourhood characteristics could have an important influence on treatment continuity and rehospitalisation in dually diagnosed patients, e.g. areas with many vacant houses and higher educational attainment had opposite effects on the follow-up parameters being studied.

Prison: the use of injected drugs and hepatitis C are endemic in Irish prisons; tattooing may be an independent risk factor for hepatitis C in non-injecting prisoners.(Long ea, 2001) Farrell ea,(2002) in a UK national survey of prisoners, found that cannabis, cocaine, and amphetamine use, but not heroin use, were associated with psychosis.

Changes in frontal cortical and subcortical monoaminergic systems during **adolescence** might promote social maturation or confer vulnerability to addictive actions of drugs.(Chambers ea, 2003)

Hero worship: the abuse of drugs by singers or sportsmen.

Peer pressure/need to belong, mood instability of adolescents, and pressure from peer groups²³²² and other pushers. Most young people are introduced to drugs by people known to them rather than by 'pushers'. Knowledge of drug names, but of little else, is common in secondary schools. Many of these children know of others who take illicit drugs and are offered drugs themselves.

Adolescents do not often believe the warnings of doctors and the authorities about the dangers of drug abuse.(Chatlos, 1996) Long-term heavy cannabis users persist with their habit despite acknowledgement of negative effects.(Gruber ea, 2003) Gau ea (2007) found that some factors predicted (male, ADHD, conduct disorder, sibling using tobacco) and others protected against (2 parents at home, good at school, objection to use of substances) substance use in adolescence.

Social status of drug abuse, such as the masculinity of alcohol consumption. Social class is not a protection against drug abuse as such, although certain drugs may be more freely available to different economic groups, such as glues in SE group 5. Macleod ea (2004) found fairly consistent associations between cannabis use and both lower educational attainment and increased reported use of other illegal drugs.

Association of drugs, including alcohol, with holidays, sex, anti-authoritarianism, etc.

Personality disorders, social phobias, and other psychiatric disorders leading to a search for relief in drug taking. Antisocial personality is common in cocaine-dependent persons and childhood conduct disorder is a risk factor for cocaine abuse.(Gamma & Liechti, 2002) Higher cortisol prior to onset of drug use disorder may be a vulnerability factor.(Rao ea, 2009) High impulsivity and low deliberation were found

²³²¹ There were 1,154 and 1,439 reported cases of hepatitis C in Ireland in 2004 and 2005 respectively.

²³²² The fact that the finding that occasional cannabis use predicted later substance use and educational difficulties was influenced by use of tobacco suggested (to Degenhardt ea, 2010) a role for the group to which subjects belonged.

by Love et al (2009) to be associated with increased regional mu-receptor concentrations²³²³ and greater stress-induced endogenous opioid system activation in healthy young male volunteers.

Life crises e.g. combat. Psychoactive substance use disorders significantly co-occurred with borderline and histrionic personality disorders in one study. (Oldham et al, 1995) There is some evidence that patients may use substances as self-medication for PTSD. (Hien et al, 2010)²³²⁴

Introduction to drugs of high abuse potential. Many different chemicals (alcohol, other drugs) and behaviours (e.g. gambling, overeating, and stealing) may have similar effects on so-called brain reward areas, e.g. the ventral tegmental area²³²⁵, locus ceruleus²³²⁶, and nucleus accumbens²³²⁷. Most drugs of abuse that elevate mood cause DA release, e.g. nicotine, (Brody et al, 2004) alcohol and cocaine. Opiates inhibit GABAergic neurones that tonically inhibit DA release. There is some evidence that genetic polymorphism of the D2 receptor is linked to drug abuse, e.g. the TaqI-A polymorphism of the ANKK1 gene (adjacent to the DRD2 gene) and the C957T variant of the DRD2 gene were associated with psychopathic traits in alcohol dependent patients. (Ponce et al, 2008) Substance abuse among patients with schizophrenia does not appear to be influenced by CYP2D6 or CYP2C19 polymorphisms. (Kobylecki et al, 2008) Symptoms of the DTs may be partially related to prefrontal DA hyperactivity. SPECT has revealed chronic dysregulation of the dopaminergic system in detoxified alcoholics. Goldstein and Volkow (2002) describe a I-RISA (impaired response inhibition and salience attribution) syndrome based on a review of neuroimaging studies in drug addicted persons: the orbitofrontal cortex and anterior cingulate gyrus²³²⁸ (regions connected to the limbic system and thought to be important in determining reinforcing stimulus salience) are the usual frontal areas involved in addiction and are activated when an addicted person craves for, binges on, or is intoxicated by substances, only to be deactivated during substance withdrawal. Dom et al (2005) conducted a systematic review of behavioural decision-making and neuroimaging in people with substance use disorders: acute withdrawal was associated with overactivity of orbitofrontal cortex, abstinence with underactivity of this region. Gamma-hydroxybutyrate (GHB, Georgia Home Boy, grievous bodily harm, liquid ecstasy), a GABA derivative, date rape drug (Renner & Ward, 2008, p. 359), and drug of abuse is discussed below.

TV and mass media, e.g. association of alcohol or cigarettes with car racing: media should not glamorise drugs

Classification of abused drugs

- Socially 'acceptable' - tea, coffee, tobacco, alcohol.
- Illicit - perception altering (hallucinogenic, psychedelic, psychomimetic), e.g. cannabis, LSD, mescaline, psilocybin - cause depersonalisation, hallucinations, or mood changes; opium and derived agents - heroin, morphine²³²⁹, codeine²³³⁰ (partially metabolised to morphine), dihydrocodeine, pethidine²³³¹ (meperidine [Demerol] in USA), methadone²³³² (Physeptone to October, 1998, Phymet DTF 1 mg/ml thereafter; Dolophine in US), and so on; sedative-hypnotics - barbiturates, benzodiazepines, etc; speed drugs (psychostimulants) - amphetamines, cocaine, anorectics, anti-diarrhoeals, benztropine (not available from 2003) and other anticholinergic agents, etc; glues, aerosols, volatile anaesthetics; and others, e.g. pseudo-cannabis.

Classification of drug-induced Psychoses

Serotonergic hallucinogens: LSD, dimethyltryptamine (DMT), mescaline, psilocybin

²³²³ PET study using labelled mu-receptor-selective radiotracer carfentanil.

²³²⁴ Reduction in PTSD severity ameliorated substance abuse but reduction in the latter had only minimal effect on the former.

²³²⁵ The VTA projects dopaminergic fibres to the nucleus accumbens.

²³²⁶ 'Sky-blue place'.

²³²⁷ Rats will readily self-stimulate by lever-pressing to electrically stimulate the medial forebrain bundle (dopaminergic neurotransmission), the latter connecting the ventral tegmental area and nucleus accumbens.

²³²⁸ Szeszko et al (2007), using MRI, found that first episode schizophrenic patients who had used cannabis, had less anterior cingulate grey matter compared with patients who had not used cannabis and healthy controls.

²³²⁹ (5 α ,6 α)-7,8-didehydro-4,5-epoxy-17-methylmorphinan-3,6-diol or morphine, after Morpheus (Greek god of dreams) the son of Hypnos (god of sleep).

²³³⁰ (5 α ,6 α)-7,8-didehydro-4,5-epoxy-3-methoxy-17-methylmorphinan-6-ol. Codeine was isolated in 1832 by Pierre-Jean Robiquet. Codeine addiction was a rising problem in Ireland in 2009-10 and is, worryingly, available OTC (without a prescription).

²³³¹ Ethyl-1-methyl-4-phenylpiperidine-4-carboxylate.

²³³² 6-(dimethylamino)-4,4-diphenylheptan-3-one.

Dopamine (DA) agonists: Amphetamine, cocaine, L-DOPA, bromocriptine

Alcohol & Hypnotics: Including withdrawal states

Cannabinoids

Glutamate antagonists: Phencyclidine, ketamine, dextrophan, amantadine

Muscarinic cholinergic antagonists (atropine psychosis): benztropine and related drugs²³³³, tricyclic antidepressants, low-potency antipsychotics, antihistamines

Others: ACTH, corticosteroids, disulfiram, indomethacin, methyldopa, digoxin, anti-tuberculosis agents, antimalarial drugs, etc.

Abusers themselves can be classified as experimenters, polyabusers²³³⁴, or dependent.

It should be remembered the terms 'habit' and 'addict' are not as popular in the official literature as heretofore, having been replaced by the wider concepts of dependence and abuse. Over 20 years ago, the WHO divided drug misuse into hazardous (harm may occur) and harmful (harm has occurred) use. ICD-10 defines the dependence syndrome as 'a cluster of physiological, behavioural, and cognitive phenomena in which the use of a substance or a class of substances takes on a much higher priority for a given individual than other behaviours that once had greater value'. There is a strong desire or compulsion²³³⁵ to take the drug, its use is difficult to control at every stage of its use, and there is a physiological withdrawal state on stopping the drug or reducing its use. There is use of the same or a similar drug to relieve abstinence symptoms and there is evidence of tolerance²³³⁶: the ability of one drug to relieve the withdrawal syndrome of another drug is called cross-dependence, whilst the extension of tolerance from one drug to another is termed cross-tolerance. There is progressive neglect of alternative pleasures and interests, and persistence of drug use despite evidence of harmful consequences.

Signs of drug abuse

The more signs the more likely is there to be a problem

Many signs also seen in non-abusing normal adolescents

Qualitative behaviour changes include spending much time alone, irritable if disturbed, excessively unstable mood swings, lying, secretiveness etc

Poor performance at school (e.g. scholastic failure) or work (e.g. absenteeism)

Stealing

Loss/change in interests and friends

Weight, poor hygiene/health

Use of drug slang

Possession of the appropriate gear

Not asking about substance abuse history during admission to psychiatric facilities was common in one London survey.(Barnaby et al, 2003)

*Cannabis*²³³⁷

Cannabis (Gk. hemp) (O'Shea & McCollam, 2001) can mean either a plant (*Cannabis sativa*) or the contained cannabinoids. It is chiefly young cigarette smokers who smoke²³³⁸ it with cigarette²³³⁹ tobacco or

²³³³ *Angel's trumpet* (species *Brugmansia*, family *Solanaceae*) is usually taken as a tea made from the trumpet-shaped flowers.(see Hall et al, 1977) It has hallucinogenic and anticholinergic properties and has been used by youth as an LSD substitute. The plant contains parasympatholytic alkaloids such as scopolamine.

²³³⁴ Polytoxicomania.

²³³⁵ Stimulant drug abusers may selectively attend to drug-related words and such bias correlates with increased activation of left prefrontal and right cerebellar cortex on fMRI.(Ersche et al, 2010)

²³³⁶ The need to increase the dose to maintain the original effect as well as the capacity to sustain such dosage increases without endangering life.

²³³⁷ Hashish is also called boom, chronic, gangster, or hemp. Marijuana is also called Marinol, blunt, dope, ganja, grass, herb, joints, Mary Jane, pot, reefer, sinsemilla, skunk (high-THC), or weed. Dagga is grown in South Africa and contains little CBD.

²³³⁸ At least half of cannabis users are also users of tobacco.

chew it (e.g. hashish brownies). Cannabis use in UK youths aged 16-24 years fell from 28% in 1998 to 21% in 2005.

Classification of cannabis based on content and appearance

(Tetrahydrocannabinol [THC] content increasing²³⁴⁰)

'False', e.g. peat, 'grass' (looks like it)

'Grass' (dried, leaves)

'Resin' (dried, compressed blocks)

'Oil'

Also: 'Laced' (mixed with other chemicals, e.g. with PCP in 'superweed')

Cannabis sativa may be grown for

Resin (secreted by flowering tops of female plant: *ganga/hashish*)

Dried leaves (*grass* or *marijuana*²³⁴¹)

Strong, seedless version (*sinsemilla*)

Hemp tea (*bhang*)

Cannabis sativa

'AMP' is marijuana soaked in formaldehyde and then dried. THC, one of many cannabinoids, is the chief active ingredient, with its own receptor in rat and human brain. This receptor is G-protein linked, inhibits neuronal adenylate cyclase, and is found mainly in basal ganglia, hippocampus and cerebellum, with lesser amounts in the cerebral cortex, and is sparsely represented in the brainstem. Anandamide²³⁴² is the endogenous ligand for THC receptors. It is much less potent and has a shorter duration of action than THC. Chronic use has damaged the animal and human hippocampus. (Yücel et al., 2008) Cannabis is home grown or smuggled. It was formerly used in corn plasters.

Possible legitimate uses of cannabis

Appetite stimulation ('munchies') in AIDS

Reduction of intraocular pressure (IOP) in glaucoma (high doses produce transient results - many adverse effects)

To counteract nausea, anorexia, wasting of cancer

MS-related spasticity

Relief from despair of dying

²³³⁹ Cannabis in pipe tobacco was popular in the past. The Netherlands in 2010 represents a paradox: it is legal to smoke cannabis in a cafe but not if it contains tobacco!

²³⁴⁰ The street name for high-THC-content cannabis is '*skunk*'. Cannabidiol or cannabidiol (CBD, C₂₁H₃₀O₂), another cannabinoid, may have antipsychotic properties. (Morgan & Curran, 2008) It has been suggested that the attraction of cannabis for people with severe mental illness relates to relief of dysphoria and anxiety. However, high-THC cannabis, as commonly used today, is low in CBD. (Atakan, 2008)

²³⁴¹ 'Skunk grass' is a hybrid breed with a relatively high THC content.

²³⁴² Sanskrit *ananda*, bliss.

The US Supreme Court found that medical use of cannabis was illegal in June 2005, despite laws in a number of states permitting its use. This does not mean that people in states allowing its use will not get it. (Hopkins, 2005) even though they are not shielded from federal prosecution. (Okie, 2005) A synthetic relative of cannabis, nabilone, can only be prescribed in Britain for nausea due to chemotherapy, and Δ^9 -THC (Dronabinol) is similarly licensed in America. Frank *et al* (2008) found that dihydrocodeine provided more pain relief than nabilone in patients with chronic neuropathic pain, neither drug being associated with significant adverse events. Dronabinol has modest analgesic effects in multiple sclerosis; side effects include dizziness. (Svendson *et al*, 2004) According to Cohen (2008), the evidence for effectiveness of cannabinoids²³⁴³ is strong for cancer, central pain, and pain due to spasticity, mixed for acute pain, and poor for peripheral neuropathic pain.

Cannabis causes dependence²³⁴⁴. Mild withdrawal symptoms²³⁴⁵ may follow chronic high-dose (that would be toxic to the novice) intake, indicating some degree of tolerance. These symptoms commence on day one to three after stopping cannabis intake, peak during day two to six, and last from four to 14 days. (Budney *et al*, 2003, 2004) Tolerance develops to cannabis-induced mood changes, tachycardia, hyperthermia, changes in IOP, and EEG changes.

DSM-IV cannabis abuse and dependence (US survey of > 40,000 adults: Stinson *et al*, 2006)

Abuse – 12-month and lifetime prevalence = 1.1% and 7.2% respectively

Dependence – 12-month and lifetime prevalence = 0.3% and 1.3% respectively

Associated with abuse/dependence – male, Native American, widowed/separated/divorced, living in West

Not associated with abuse/dependence – Black/Asian/Hispanic

Drug effects depend on the experiences and expectations of the user and co-users, the quality and quantity of the drug, and drug purity²³⁴⁶. Cannabis causes anxiety, panic, dry ('cotton') mouth, a sleepy look, red-eye, over eating, increased confidence, verbosity, and distortions of time, colour and shape. These effects are followed by sleep and, commonly, a hangover. Prolonged use leads to apathy and self-neglect. A study of monozygotic male twins from the Vietnam Era Twin Registry found that those who had abused cannabis in the past (almost 20 years after regular use) differed from co-twins only on the block design sub-test of the WAIS-R. (Lyons *et al*, 2004) Heavy users appear 'stoned'. Heavy use of cannabis is associated with poor recall of word lists but this tends to normalise with abstinence. Fear, apprehension, irritability, and a dejected state may also feature. Hallucinations are more likely with high doses of THC.²³⁴⁷ 2.5 mg of THC given IV causes positive psychotic symptoms, anxiety, and impaired neuropsychological performance in healthy adult males. (Morrison *et al*, 2009) Other problems include bronchitis (and bullous lung disease in young people) and lung, tongue and other cancers²³⁴⁸, aspergillosis, gynaecomastia,²³⁴⁹ priapism, or feminisation (suppression of testosterone). Reports of sudden death among cannabis users may relate to cardiac effects of THC. (Henry *et al*, 2003) Sidney (2003) argues that death rates from cannabis *per se* are low.

Intravenous crude cannabis extract

- Can cause: nausea, vomiting, abdominal pain, watery diarrhoea, hypotension, pyrexia, arthralgia, acute renal failure, pulmonary oedema, disseminated intravascular necrosis, death

²³⁴³ Side effects include tiredness, sedation, sickness, tingling, and feeling strange.

²³⁴⁴ Dependence is more likely with more frequent use. Withdrawal has been linked to the CB1 receptor and the THC component of cannabis. Prolonged dysphoria after stopping cannabis intake may be due to reduced dopamine activation.

²³⁴⁵ Various combinations of craving, irritability, anger, aggression, restlessness, sweating, tremor, depression, anxiety, insomnia, vivid dreams, tachycardia, nausea, abdominal pain, myalgia, diarrhoea, and anorexia beginning the day after last use, reach maximum intensity on the third day, and wane over the following week.

²³⁴⁶ E.g. lead has been added to marijuana to increase its weight leading to plumbism! (Busse *et al*, 2008)

²³⁴⁷ THC content in the average marijuana cigarette has increased substantially over the last several decades: from 0.5% in 1990 to about 5% in 2003 in Britain, and, in 'Nederweed', the variety smoked in the Netherlands, there is about 10-11%. (Aston, 2001; Henry *et al*, 2003)

²³⁴⁸ Cannabis smoke contains 70% more cancer-producing hydrocarbons, e.g. benzopyrene, than tobacco smoke.

²³⁴⁹ Gynaecomastia is also caused by alcohol, cyproterone acetate, digitalis, oestrogens, and spironolactone.

- Admit, manage fluid/electrolyte balance

AMP may cause psychomotor retardation, poor attention, thought disturbance, anxiety, and poverty of speech. Proposed chronic effects include the 'amotivational syndrome' and a schizophreniform psychosis (some experts have interpreted both as representing chronic intoxication).

Controversy exists as to whether early cannabis use leads to depression and schizophrenia. Does it cause or trigger schizophrenia? The evidence is against a simple self-medication hypothesis. (Arseneault ea, 2002; Rey & Tennant, 2002; Zammit ea, 2002)

Cannabis and psychiatric disorder

Cannabis makes schizophrenic delusions and hallucinations worse

Specific cannabis-induced psychosis in clear consciousness - controversial

Toxic confusional state may occur after high doses

New Zealand study (Fergusson ea, 2003) - heavy use in young people independently causes psychotic symptoms

Arendt ea (2007) - depression more likely while taking cannabis than when not using it, and cannabis is taken by depressives for the same reasons as others

Green ea (2005) - 58 studies of varying methodology, 5 of which were epidemiological - found that epidemiological studies consistently reported higher cannabis use and misuse prevalence in people with psychosis

Arseneault ea (2004) - about 8% of schizophrenia could be prevented by eliminating cannabis use

Munich study (Henquet ea, 2005; see also Hall, 2006) - highly suggestive of role for cannabis-related psychotic symptoms, especially in the predisposed

Danish study (Arendt ea, 2005) - cannabis-induced psychosis may be followed, after a gap which may be in excess of a year, by schizophrenia spectrum disorders (see also Arendt ea, 2008)

Carriers of COMT valine158 allele more likely to show psychotic symptoms and develop schizophreniform disorder with cannabis, but 2 copies of the methionine allele protect against this (Caspi ea, 2005)

EEG changes²³⁵⁰ and increased schizotypy have been described in cannabis users (Skosnik ea, 2006)

Panic attacks in panic disorder patients and hypomania/mania in bipolar disorder cases may be triggered by cannabis (Kay & Tasman, 2006, p. 443)

Systematic review suggests cannabis is psychotogenic (Moore ea, 2007)

Evidence for causal relationship with psychosis is not strong (Macleod, 2007) but anything that reduces the burden of schizophrenia is worthwhile; the risk of psychosis if one ever used cannabis is 1.4 that for a person who never used it (Kelly, 2007)

Dutch MRI study of first-episode schizophrenia suggests that brain volume loss is greater over five years if cannabis is used (Rais ea, 2008)

Systematic review (Zammit ea, 2008) suggests that cannabis is associated with increased relapse and non-adherence in psychotic disorders but few studies adjust for baseline illness severity or adjust for potential confounders such as alcohol – adjustments for only a few confounders may greatly reduce results

English fMRI study (Bhattacharyya ea, 2009) suggests that modulation of mediotemporal and ventrostriatal function by Δ^9 -THC may explain effects of cannabis on verbal learning (impaired) and psychotic symptoms (provoked) respectively

Di Forti ea (2009) in London found first episode psychosis patients had smoked stronger cannabis and had smoked for longer and more often than had healthy controls

A systematic review of neuroimaging in cannabis use (Martín-Santos ea, 2010) found that studies differed so much that meta-analysis was impossible; resting global and prefrontal blood flow are lower in cannabis users than in controls; methodological differences lead to different functional findings during cognitive tasks; acute use of cannabis/THC find increased resting activity and activation of frontal and anterior cingulate cortex during cognitive tasks; and the effects of cannabis on brain structure may be small.

Flashbacks, which may result from release of psychoactive components from body fat, are rarely attributable to cannabis as such, but cannabis may precipitate flashbacks due to earlier abuse of powerful

²³⁵⁰ Decreased power and signal-to-noise ratio at stimulation frequency of 20 Hz.

drugs like LSD. Cannabis, like alcohol and cocaine, is associated with reckless (and fatal – Anonymous, 2005) driving²³⁵¹ or flying with effects lasting for up to 48 hours. It increases uterine contractions that can lead to precipitate labour; heavy maternal use may lead to some increased separation of the eyes, tremor, excessive startle response, and decreased visual response to photic stimulation in the newborn. Co-morbid alcohol abuse complicates interpretation. There is a suggestion that exposure to cannabis during the first trimester may be associated with increased risk for childhood neuroblastoma²³⁵².

Cannabis and the law

Illegal in USA, 1937

Medical use legalised in Australia, 1994

Whilst still illegal in Britain, cannabis was downgraded as an offence but upgraded again in 2008 – maximum penalty for possession was increased from 2 to 5 years in prison

Schedule 1 controlled drug under the Irish *Misuse of Drugs Acts*

Irish licence can only be granted for research, forensic analysis, use as an essential ingredient in industrial manufacturing, or (in the case of low THC yield plants) for the growing of hemp

Cannabis use is associated with poor educational, occupational, and interpersonal outcomes, although direction of causality is unclear. (Hall & Degenhardt, 2009) In the author's opinion, there is no realistic hope that associated lawbreaking will disappear automatically if cannabis were legalised. The media should de-glamorise illicit drugs. Medical use of cannabis, preferably by inhaler rather than by smoking, requires more research. The evidence for such use is still weak. (Tobin, 2004)

Phencyclidine (PCP; angel dust, boat, hog, love boat, peace pill)

PCP (O'Shea, 2000a), an arylcyclohexylamine, relative of pethidine, and former dissociative anaesthetic agent²³⁵³, antagonises glutamate transmission by inhibiting calcium influx at the NMDA receptor. It also activates ventral tegmental DA neurones. It can be smoked (sprinkled on joints of parsley or marijuana), sniffed (snorted), eaten or injected. It can cause dizziness, ataxia, amnesia, excitement, dissociation and a paranoid-hallucinatory state. The pupils of users are small or normal, the skin red and dry. SGOT and CPK levels may be raised. PCP is detectable in urine for up to 8 days. Venlafaxine, O-desmethylenlafaxine, and dextromethorphan may give false-positive tests for PCP.

Complications

- Hyperpyrexia
- Muscle rigidity
- Dystonia
- Seizures
- Cardiac arrhythmias, tachycardia, hypertension
- Rhabdomyolysis-myoglobinuria-renal failure
- CVA
- Choking (hypersalivation)
- Symptom return after a lapse due to leakage from adipose tissue (flashbacks)
- Failure to form new memories (long term hippocampal potentiation)
- Suicide

Palm test

Hold your palm open and ask patient to name the colours he sees in your palm – LSD patient names various colours and/or images whereas PCP users try to attack your hand. (Abraham & Aldridge, 1993)

Consider PCP intoxication in anyone with nystagmus²³⁵⁴, high blood pressure and an altered mental state. Severe intoxication should be managed in hospital. Anticholinergic antipsychotics may exacerbate

²³⁵¹ An Irish study showed that 9.5% and 15.7% of tested drivers were positive for any drug and cannabinoids respectively. (Bergin, 2007)

²³⁵² *Cancer Causes and Control* 2006;7:663-9.

²³⁵³ Introduced during the 1950s, it was withdrawn because of rat neuronal toxicity and adverse human mental effects. (Johnstone et al, 1959)

²³⁵⁴ Nystagmus may also be found in sedative-hypnotic intoxication or withdrawal. PCP (although also causing rotator or horizontal nystagmus) is unique in causing vertical nystagmus.

symptoms of PCP intoxication. Haloperidol may exacerbate the behavioural and cognitive effects of PCP²³⁵⁵, whereas atypical agents reverse them.(Starter & Bruno, 2002) However, antipsychotic drugs are often ineffective and may lower the seizure threshold. Diazepam is often preferred.(Aronow ea, 1980) Avoid acidification of the urine (danger of myoglobinuric²³⁵⁶ renal failure and exacerbation of systemic acidosis) but nasogastric suction with multiple doses of activated charcoal can be employed.

Ketamine (Special K, Ketalar SV, cat Valiums, Kit Kat, vitamin K)

This is a similar drug to PCP (O'Shea, 2000a) and is mainly diverted from legitimate sources such as hospitals and veterinary clinics. It can cause excited behaviour, depersonalisation, hallucinations, delirium, and vivid dreams.

Khat

Catha edulis or the Qat shrub is an Afro-Asian tea plant.(O'Shea, 2000a) Ingestion of the Qat shrub can cause sleep problems, anxiety, depression, anorexia, various GIT symptoms, and, on rare occasions, psychosis.(Cox & Rampes, 2003) The most important ingredients are D-pseudonorepinephrine (cathine) and cathinone. These have central amphetamine-like properties.

Bundle of khat

Complications of khat

- Drug interactions – phenylpropanolamine (in cold cures, appetite suppressants, and prescription drugs – synergism), MAOIs (avoid – sympathetic hyper-stimulation), surgical anaesthetics (may experience bizarre reactions; post-operative agitation/over-arousal)
 - CNS – dizziness, headaches, migraine, ataxia, fine tremor, stereotypy
 - Psychiatric – insomnia; poor concentration; paranoid, schizophreniform, manic psychoses (pure khat-induced psychosis resolves rapidly but may require BZDs and antipsychotic drugs); depression (esp. on cessation of khat use); self-harm/suicide (rare); violence directed against others
 - Cardiovascular – tachycardia, arrhythmias, palpitations, hypertension, vasoconstriction/ischaemia/MI, pulmonary oedema, cerebral haemorrhage, worsening of pre-existing heart disorders
 - Respiratory – bronchitis, tachypnoea, TB
 - GIT/liver - xerostomia, polydipsia, dental caries/periodontal disease, chronic gastritis/gastric ulcer, constipation/paralytic ileus, anorexia, loss of weight, increased risk for upper GIT cancer, cirrhosis
 - GUT/obstetric – impotence, spermatorrhoea, altered libido, urinary retention, reduced birth weight, stillbirth, impaired lactation
 - Metabolic/endocrine – fever, sweating, hyperglycaemia
 - Ophthalmic – conjunctival congestion
- CNS – central nervous system; BZD – benzodiazepine; GIT – gastrointestinal tract; GUT – genitourinary tract; MAOI – monoamine oxidase inhibitor; TB – tuberculosis.

4-methylmethcathinone (2-methylamino-1-p-tolylpropan-1-one, mephedrone, Miaow, MMCAT, 4-MCC, Blue Light)

This stimulant, illegal in some countries²³⁵⁷ including Ireland, is bought over the internet and can cause poor concentration, anxiety, depression, euphoria, talkativeness, and paranoid thinking. Users may develop auditory and visual hallucinations and a mania-like state. Rash, tachycardia, arrhythmias, hyperhidrosis, bruxism, trismus, and seizures have been recorded. It may have vasoconstrictor effects. Deaths have been reported.

²³⁵⁵ However, some authors recommend haloperidol for PCP delirium. Chlorpromazine may potentiate anticholinergic effects of PCP and cause severe, prolonged hypotension.

²³⁵⁶ Myoglobin levels are raised in NMS and in patients in restraints or in those taking LSD, PCP, or cocaine.

²³⁵⁷ The UK decided to ban mephedrone and related cathinones in 2010.

This stimulant, a substituted cathinone with MDMA- and amphetamine-like effects, can cause mydriasis, sweating, and hyperthermia.

As well as mephedrone and methedrone, the beta keto cathinones sold in head shops (QV) include methylone (3,4-methylenedioxy-N-methylcathinone; Ease; Explosion; MDMC; MDMCAT), butylone (-keto-N-methyl-3,4-benzodioxolylbutanamine), ethylone (3,4-methylenedioxy-N-ethylcathinone; MDEC), dimethylcathinone, ethcathinone, 2- and 3- and 4-fluoro-methcathinones (the last of which is also known as flephedrone), and 4-methoxy-methylaminobutyron.

*Lysergic acid diethylamide*²³⁵⁸ (*LSD₂₅, acid, L, blotter, dots, paper mushrooms, boomers, cubes, trips, microdot, yellow sunshines*)

Lysergic acid²³⁵⁹ is a constituent of the ergot alkaloids, and LSD is its semisynthetic hydrolytic derivative. (O'Shea & Fagan, 2001) LSD is commonly used as part of the 'rave' scene. (Riley et al., 2001) It is used for its effects on perception and mood. Users may seek help after a 'bad trip', i.e. if frightened, or may be brought for treatment if psychotic. LSD comes in various guises, such as 'microdots' or impregnated blotting paper, stuck to the back of postage stamps, small coloured tablets, in biscuits, in various drinks²³⁶⁰, etc.

Ergot infestation

Psychedelic (Gk, 'to render the psyche visible') drugs as a group appear to act mainly by mimicking serotonin at the 5-HT₂ receptor subtype. As little as 50 micrograms can cause hallucinations. Tolerance to LSD varies widely. Tolerance to its psychosocial effects can occur after a few daily doses (but return after a few days of abstinence), possibly due to desensitisation of 5-HT receptors. The cardiovascular system is much slower to develop tolerance. Cross-tolerance occurs within the LSD-mescaline-psilocybin group, but not between that group and the hallucinogenic amphetamines. Dependence on LSD is psychosocial in origin, with no physical dependence or withdrawal (abstinence) syndrome.

LSD distorts sense of time, colour, sound, movement and distance, increases the amount of REM sleep, and causes synaesthesiae.²³⁶¹

There may be bizarre visual hallucinations of great vividness. Everything becomes very real and familiar. Problems include severe anxiety (bad trip), suicide²³⁶², accidents, homicide, and, probably, the unearthing

²³⁵⁸ In 1943, Albert Hoffman (1906-2008), a chemist working with Sandoz Laboratories, took LSD₂₅ to confirm its reported effects, felt pleasantly sleepy, and then experienced fantastic, vivid images. LSD, the most powerful hallucinogen (syn. psychedelic, psychodysleptic, or less specifically, psychotomimetic) known, was used extensively medically (e.g. abreactive 'psychotherapy' for homosexuality, neuroses, and alcoholism, and induction of 'model psychoses' [attempts to mimic 'functional' psychotic disorders]) and socially (e.g. attempts to find a new 'spiritual dimension' and to 'inspire' musicians) during the 'swinging' 1960s. Some LSD-treated patients are seeking legal compensation and the British NHS agreed to pay stg£195,000 in an out of court settlement to 43 former psychiatric patients who received the drug between 1950-70. (Dyer, 2002)

²³⁵⁹ LSD₂₅ was synthesised by the Swiss chemist Albert Hofmann in 1938.

²³⁶⁰ 'Spike with acid': to surreptitiously put LSD in another's drink.

²³⁶¹ **Synaesthesiae**: stimulation of one sensory modality leading to perception in a different modality, as when sounds are 'seen' or when a light induces voices heard; many people with synaesthetic experiences appear to have normal mental states, as with the man who could feel rounded or peaked shapes when eating different foods or the woman who experienced colours when tasting foods. (see Eagleman, 2010) Synaesthesiae may occur in Parkinson's disease treated with dopaminergic drugs. Cannabis intoxication may include visual hallucinations associated with listening to music.

²³⁶² Especially if psychotic experiences seem 'real'.

of schizophrenic or other psychotic tendencies in vulnerable individuals. Rarely, patients may deliberately damage their own tissues, causing, for example, blindness. Flashbacks of earlier LSD experiences, usually unpleasant and mostly lasting minutes or hours, may occur even years after drug use. They are possibly due to release of stored drug from fat stores, or may be brought on by cannabis use at a later time. There have been some tentative in vitro experiments that support a possible teratogenic effect: chromosomal damage has not been confirmed.

LSD in high dosage is suppresses cytokines as well as T, B and natural killer cells.(Spies et al, 2002)

The classical hierarchical approach to psychiatric diagnosis holds that we cannot record the presence of a 'functional' psychosis in the presence of drug abuse. However, the American DSM-IV classification system warns us not to exclude a functional psychosis unless the clinical evidence for a causative role for drugs is compelling. Most clinician will allow time to clarify the most likely culprit.

Treatment of a bad trip may include observation, 'talking the patient down' (reassurance and reality-orientation), and a benzodiazepine, e.g. diazepam 20 mgs orally. Phenothiazines may aggravate the problem if the patient has taken some of the more unusual hallucinogens. If a neuroleptic is required, the choice is between risperidone and haloperidol, the former having been found to block LSD behavioural recognition in rats. Selective serotonin reuptake inhibitors (SSRIs) should be avoided for depression following LSD use as they may lead to recurrent flashbacks²³⁶³.

Ergine (d-lysergic acid amide, LSA)

This LSD-like chemical, an ergoline alkaloid, comes from the seeds of the morning glory²³⁶⁴ plant. These were used by Aztec priests in Mexico for their hallucinogenic properties.

Other hallucinogens

These are less potent than LSD. 'Magic mushrooms' (banned in Ireland from 2006), especially *Psilocybe semilanceata* or Liberty Cap, which contains psilocybin (magic mushroom, purple passion, shrooms), and *Amanita muscaria* (or *muscaria*)²³⁶⁵ or Fly Agaric, containing muscinol, are abused in Ireland and Britain. Mescaline²³⁶⁶ is found in *Teonanacatl*, a Mexican cactus. Mescaline use can lead the user to perceive body parts to be severed or the colour of objects to be altered. MDMA²³⁶⁷ has both stimulant and hallucinogenic properties. Bufotenine, a MAOI, is derived from the skin of pet bufo (and other) toads in the US by licking.(Howard & Foerstl, 1990) It has only one-thousandth the hallucinogenic effect of LSD. Bufotenine can cause sweating, palpitations, vomiting, and faecal incontinence. There are many other examples²³⁶⁸ that can be lethal in overdose - orphenadrine was withdrawn from the market in 1999.

Liberty cap

Post-hallucinogenic perceptual disorder (PHPD)

PHPD is a chronic disorder that can last for years following LSD ingestion.(Smith & Seymour, 1994) The patient reports seeing trails of light or afterimages following hand movements. Patients may experience anxiety or depression. Closing the eyes or going indoors to a darker place may exacerbate PHPD and wearing dark glasses outdoors may help (reduces indoor-outdoor difference in brightness). Some cases have responded to SSRIs, BZDs, or naltrexone.

Gamma-hydroxybutyrate (GHB, liquid ecstasy, liquid X, easy lay, scoop, cherry meth)

This anaesthetic and drug of abuse is derived from GABA and is found in mammalian brain. It is available as a liquid, powder or capsule. . It is sold in sex shops or can be ordered in the post. It is associated with the

²³⁶³ But see post-hallucinogenic perceptual disorder.

²³⁶⁴ Morning glory (*Convolvulaceae*) includes over a thousand species. The best known is *Rivea* (or *Turbina*) *corymbosa*, a perennial climbing vine with white flowers found throughout Latin America.

²³⁶⁵ This and *Amanita pantherina* contain isoxazole agonists of GABA and may induce a drunken state, hallucinosis, disturbed vision, muscular excitability, seizures, and coma.

²³⁶⁶ Buttons, cactus, mesc, peyote.

²³⁶⁷ New Ecstasy, Adam, clarity, ecstasy, Eve, lover's speed, etc.

²³⁶⁸ Such as the behavioural toxicity of anticholinergic drugs.

rave and club scene, date rape, and has putative anabolic effects²³⁶⁹. (Ricaurte & McCann, 2005) Despite its abuse potential, (Caputo & Zoli, 2007) it found a medical use in the treatment of narcolepsy. (Littner ea, 2001) Its euphoriant and disinhibiting effects resemble those of alcohol ('*G-ber daze*'). GHB increases cerebral DA. It is synergistic with alcohol and may depress respiration. Some effects of GHB are reversed by naloxone in animals. (Jones & Volans, 1999. GHB is found naturally in the body, there is a specific receptor for it but it affects many neurotransmitter system (incl. GABA, 5-HT, DA, opioid).

Effects

- Euphoria, sedation, amnesia
- Paradoxical agitation
- Nausea, vomiting
- Muscle stiffness
- Disturbed vision
- Dizziness, confusion, ataxia, abnormal movements
- Respiratory depression/arrest²³⁷⁰, bradycardia, coma and seizures

Body builders may develop physical dependence and withdrawal phenomena, the latter resembling withdrawal from alcohol. BZDs may be needed for severe withdrawal, as may antipsychotic drugs.

Gamma-butyrolactone

This precursor of GHB is converted peripherally to GHB by a lactonase. It is present in some health supplements. It is said to burn off fat, increase sexual potency, and enlarge muscles. Prolonged use may lead to physical dependence and an abstinence syndrome.

1,4-butanediol

An aliphatic alcohol that resembles GHB, 1,4-butanediol is found naturally in trace quantities in the body. It is dehydrogenated to GHB in the body. It is used as a solvent in industry and is found in some health supplements. Toxicity resembles that of GHB but there may be urinary and faecal incontinence. Overdose may lead to abnormal mental state, movement disorder, respiratory depression/arrest, coma, and death.

Opiates and opioids

Some of the research in this area is summarised in the table. Repeated use of opioids suppresses activity of the endogenous opioid system. Opiates and opioids are often 'cut' (adulterated²³⁷¹) with other substances such as cocaine (snowball), strychnine, quinine, lead, N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or sodium bicarbonate. Mixtures of mild opiates with anticholinergic drugs (scopolamine, atropine, antihistamines) that increase the sense of euphoria are known as 'T's and Blues' or 'Juice and Beans'. The potential uses of heroin ('scag'²³⁷²) in medicine are detoxification from opiates and opiate maintenance programmes²³⁷³ (van den Brink ea, 2003; Luty, 2005; Rehm ea, 2008; Oviedo-Joekes ea, 2009; Berridge, 2009) and very painful conditions such as bone metastases and laryngeal tuberculosis. In the UK, only doctors with a special licence are allowed to prescribe heroin and cocaine as maintenance treatment for dependent patients. Oviedo-Joekes ea (2009) warn that, because of a risk of overdose or seizures, heroin (injectable diacetylmorphine) should be administered in centres capable of dealing promptly with emergencies. Heroin can be swallowed, injected under the skin or injected straight into a vein²³⁷⁴. It can also be smoked or sniffed²³⁷⁵. Inhalation of heroin can provoke acute severe asthma. 'Chased' heroin involving heating it on tin foil and inhaling the sublimate. Opiates can be detected in urine for 2-3 days.

²³⁶⁹ Used illegally for weight loss, muscle building, and L-tryptophan replacement.

²³⁷⁰ Especially if taken in overdose or with alcohol.

²³⁷¹ Substances added to illicit opioids may cause a variety of complications, e.g. amblyopia, peripheral neuropathy, and melopathy.

²³⁷² Derived from morphine by acetylation of the phenolic and the alcoholic groups on carbon atoms 3 and 6 respectively. Morphine itself was isolated from laudanum in 1805 by Frederick Setürner.

²³⁷³ Not used in Ireland but is available in the UK. A random sample of Irish GPs in July 2009 (Anonymous, 2009) found that 50% opposed the legal availability of diamorphine to heroin addicts while 41% said yes with conditions and only 7% would welcome it. In the same survey, 74% opposed the legalisation of cannabis, 10% had no opinion, and 14% were in favour.

²³⁷⁴ Often dissolved in water with lemon juice to improve solubility. This practice may be associated with Candida blood infection with cutaneous, eye and osteoarthritic consequences.

²³⁷⁵ Intranasal use, according to the Drug Enforcement Administration (DEA) in the US (US Department of Justice, Drug Enforcement Administration, 2003), increased since more pure forms of heroin became available and because users were concerned about the association of HIV and IV drug use.

Capsule of *Papaver somniferum*

The heroin user takes his first 'fix'. An injection leads to intense pleasure, flushing, itching (histamine release), slowed breathing, lowered body temperature, hypotension, and bradycardia, followed by drowsiness giving way to sleep. Anorexia and reduced libido also occur. If he continues to take the drug, he enters the 'honeymoon period' when the drug continues to have pleasurable effects: some users rate it much higher than sexual orgasm. This effect wears away quite soon however, and any attempt to stop the drug is met with withdrawal symptoms.

Opiates & opioids: research findings (abbreviated)

Year	Results	Comments
1974	95% of Vietnam vets gave up opiates on return home	As many as 20% claimed to be addicted ('strung out'); 11% of soldiers tested positive for opiates on being 'demobbed'
1978	36% off drugs, 46% using, 12% RIP	British heroin addict attendees after 7 years
1990	In-patient detox necessary	Too much methadone on Dublin streets
1990	Of notified addicts, 84% addicted to heroin, 6% to cocaine	England
1990	70% of methadone maintenance cases HIV+	Dublin's Pearse St. Mostly young, poorly educated, U/E, * had legal history, injectors, especially heroin
1991	Injecting drug use fastest growing AIDS group	Europe (in Britain, HIV+ injectors still low at < 10%)
1991	Methadone withdrawal more severe than heroin withdrawal!	No difference in onset or duration of symptoms
1992	86% of IV heroin users HIV+	Central Dublin & Dunlaoghaire; 83% were hepatitis B antigen positive
1994	8% of Norwegian population obtained controlled analgesics	Especially older females – dispensed prescription study
1995	Risk of HIV from 1 percutaneous needlestick injury = 1/500	USA
1997	> 40% of Irish AIDS due to IV drug use	69 of 209 cases newly confirmed in 1999 were drug misusers
1998	Male drug users with HIV have more psychiatric problems than other HIV cases	
2000	50-90% of injectors in EU are hepatitis C positive	Females often fund habit via sex industry
2001	130,000 people in US current heroin users in 2000	Aged 12 and over; 0.1% of population
2003	Irish GP's methadone maintenance patients	Many are hepatitis C-positive but a large number were not tested
2005	Irish GP's methadone maintenance patients	22 of 23 hepatitis C positive – knowledge of harm reduction and health implications not associated with reduced high-risk activity
	Pharmacists suspicious of analgesic prescriptions	Welsh study – frequent requests by same person, their demeanour, refusal to consider alternative medications
2004	0.5% of 12th graders used heroin in last month (0.9% in last year)	US Monitoring the Future Study
	Big increase in use of opioid analgesics for non-medical reasons	In US
2005	Outcome 2-3 years after discharge from hospital	5 died; 109 (76%) of remaining 144 interviewed; 54 cases reported recent abuse; 57% on methadone maintenance; 23% abstinent; completion of inpatient course and attendance associated with abstinence; family history of substance abuse negatively associated with abstinence
2007	Methadone maintenance patients (outpatients) – 3	Urine screens used to detect opiates. Less than 24 months in treatment, lower methadone dose, cocaine abuse and intermittent BZD abuse associated with lower

2008	months in 2004 Dopamine may not be important in opioid addiction	rates of opiate abstinence; dual diagnosis associated with more opiate abstinence No change in [¹¹ C]-raclopride binding after diamorphine or hydromorphone
2009	Methadone-treated drug users with hepatitis C failed to modify alcohol use Deaths related to overuse of methadone, past psychiatric admission, and increasing comorbidity Adherence may be measured by doses picked up from pharmacy	Dublin study Scottish study of dispensed liquid methadone. Non-adherence associated with supervised consumption, more frequent pick-up, shorter length of treatment, younger age, lower methadone dose, and recent urine positive for opiates
2010	91% relapse to daily opiate use, 59% within 1 week Opiate substitution associated with better survival + reduced chance of cessation in injectors	Dublin study: early relapse associated with younger age, stronger habit, history of injecting, and not entering aftercare; completion of full 6-week inpatient programme associated with significant delay before relapse 82% follow-up of 794 Edinburgh primary care attendees who injected drugs

Some clinical effects of opiate abuse

Meiosis (mydriasis in the cases of anoxia due to severe overdose)

Euphoria

Sleepiness²³⁷⁶

Constipation

Amenorrhoea

Self-neglect

Sexually transmitted disease

Infective endocarditis – usually attacks damaged tissue but can attack normal tissue in IV users, e.g. tricuspid valve staphylococcal infection

Hepatitis²³⁷⁷

Abscesses²³⁷⁸

AIDS

Wound botulism in IV users

Anthrax in contaminated heroin

Other infections, e.g. HIV-visceral leishmaniasis co-infection (*L. infantum*) with needle sharing

Necrotising fasciitis

Bruised veins and puncture marks

Thrombophlebitis, venous thrombosis, thromboembolism (pulmonary and systemic)²³⁷⁹

Long sleeves (to cover needle tracks)

Respiratory arrest (large doses - esp. after a period of abstinence is followed by the use of previously tolerated high doses)

As tissue levels fall: agitation, anxiety, and an obsession with the procurement of further supplies

‘Heroin pulmonary oedema’ - may follow opioid use (can be present despite preserved consciousness; a non-cardiogenic state resulting from increased pulmonary vascular permeability)

Angioedema²³⁸⁰

Oxygen administration can worsen respiratory suppression in those who have taken an overdose of opiates because the latter reduces the sensitivity of the respiratory centre to CO₂. Morphine inhibits the function of

²³⁷⁶ The origin of 'Opium Dreams'.

²³⁷⁷ Hepatitis B virus can cause acute hepatitis or an asymptomatic carrier state in which the hepatitis B surface antigen, HbsAg, can be detected. 954 cases of hepatitis B were reported in Ireland in 2008 (there may be some duplication), 91 more than in 2007.

²³⁷⁸ Flexion at hip + back pain suggests ilio-psoas abscess in injection drug-users.

²³⁷⁹ May be caused by insoluble additives: starch, talc, etc.

²³⁸⁰ Angioedema = episodes of localised, non-pitting swelling of submucosal or subcutaneous tissues. Drug-induced cases may be due to aspirin, NSAIDs, ACE inhibitors, antibiotics, radio-contrast media, or opiates.

natural killer, B, T, and phagocytic cells. Opiates probably have widespread effects on the immune system.(Spies et al, 2002)

Continued use of heroin may possibly lead to an increase in heroin receptors and to tolerance.

Three types of opiate receptor²³⁸¹

μ (mu)
 κ (kappa)
 Δ (delta)

Short-term use reduces noradrenergic neuronal activity in the locus coeruleus - mu (μ) opioid receptors activate the same potassium ion conductance as the alpha-2-adrenoceptors. If heroin is withdrawn there is an 'overcompensation' of normal physiological activity (e.g. small to large pupils and constipation to diarrhoea). This includes excess noradrenaline release. Clonidine reduces noradrenaline release and ameliorates some aspects of the abstinence syndrome. It has little effect on craving.

Opiate abstinence syndrome

Starts 4 - 6 hours after last dose of heroin

May last for over a week

Anxiety, fear, restlessness

Sleep disturbance for days (heroin) to weeks (methadone)

Mydriasis

Rhinorrhoea, lacrimation, sneezing

Aches and pains

'Cold turkey' or 'clucking': excess perspiration with goosefleshing of the skin

Abdominal cramps, diarrhoea, anorexia, loss of weight, dehydration and insomnia

Sudden leg spasms explain the term to 'kick' a habit, i.e. to give up opiate use

Orgasms may occur in either sex during opiate withdrawal (Wise & Gardner, 2002)

Myoclonus resulting from excess production of the metabolite 6-mercaptopurine rarely occurs in very ill patients taking opiates, often with renal impairment. Management includes dose reduction or wider spacing of doses, fluids, and BZDs. Opiate withdrawal is dangerous if the patient has an accompanying significant somatic disorder such as cardiac disease.

Nevirapine, ritonavir, and efavirenz²³⁸² (non-nucleoside reverse transcriptase inhibitors), by inducing P450 enzymes involved in methadone metabolism, can precipitate opiate withdrawal symptoms in subjects taking maintenance methadone.(APA, 2002, p. 201) The oral solution of the protease inhibitor amprenavir contains propylene glycol which is metabolised by aldehyde dehydrogenase; if the latter enzyme is inhibited by disulfiram the patient may develop propylene glycol poisoning. Rifampicin increases methadone elimination and can likewise induce opiate abstinence symptoms.

Pregnant opiate addicts

Often have socially deprived backgrounds, poor antenatal attendance, and frequent hospital admissions

May have hepatitis and HIV infection

Withdrawals (irritability, jitteriness, and, in the absence of infection, hyperthermia) can occur in both the neonate and in breast fed infants (heroin crosses the placenta and is excreted in breast milk)

²³⁸¹ The *mu receptor* is important for analgesia and euphoria. Whilst found widely in the nervous system it is concentrated in dorsal root ganglia of the spinal cord and in ventral striatum.

²³⁸² Efavirenz can give a false-positive cannabinoid test.

Newborn infants of mothers who inhaled heroin²³⁸³ during pregnancy may experience withdrawal convulsions
 Switch mother to oral methadone because it exposes fetus to a regular dose of an opiate that is protein-bound and longer acting
 Women on methadone maintenance who are in receipt of regular prenatal care have superior obstetric outcomes than women whose opiate use remains untreated (Burt & Hendrick, 2003, p. 1519)

Prognostic studies of opiate addicts are summarised in the table.

Opiate/opioid use: prognosis

Year	Results	Comments
1978	¼ to 1/3 abstinent; 10-20% RIP drug-related deaths	7-year follow-up of heroin addicts
1987	Many early relapses; ½ opiate-free after 6 months	50 opiate addicts post-detox in London
1988	71% used opiates within 6 months; 45% abstinent by that stage	British post-detox study
1990	Stopping IV drug abuse may reduce progression from asymptomatic to symptomatic HIV infection	Switzerland
1990	Best outcome if treated in a therapeutic community	12-year follow-up; but only 15-25% voluntarily completed programme
1993	7 of 45 pregnant opiate addicts RIP inside 6 years (AIDS, OD)	Ireland
1994	Deaths in 1980s due to ODs, those in 1990s due to AIDS	UK 10 year follow up of IV users; big change from IV to PO; 78% had been in prison & 41% of these injected in prison
1998	42% of HIV cases were drug abusers	Ireland
2000	16% still using heroin (31% of these injecting)	Cross-sectional survey of methadone maintenance in GP in Dublin; people using & injecting earlier (trend)
2007	HIV commonest cause of death; often unemployed; most misusing substances and in public accommodation	20-year outcome of pregnant opiate users in Dublin

Needle exchange programmes have been initiated in an attempt to reduce the transmission of infectious diseases, particularly AIDS²³⁸⁴. They have been available for less than a decade in Ireland²³⁸⁵. Needle sharing is a highly dangerous and common habit (even in those collecting sterile needles from official outlets) and some injectors may attend only once. Unfortunately, needle exchange has been used by police to target drug users for arrest in some countries.(Csete & Wolfe, 2008) The antidote for an opiate overdose is IV naloxone (Narcan). Other opiate antagonists may induce withdrawal states in established opiate users (e.g. nalorphine). The use of a narcotic antagonist during pregnancy carries the risks of spontaneous abortion, early labour, or stillbirth.(APA, 2002, p. 321)
 Topical naloxone (Ghodse, 1986) may dilate the pupil of an opiate user (reversed on methadone withdrawal) but not that of healthy unmedicated subjects. It does not dilate the opposite eye. Naloxone is too short acting and ineffective when given orally. Methohexitone can block naloxone-induced opiate withdrawal symptoms.

Naltrexone²³⁸⁶ (Nalorex)

²³⁸³ Unpredictably absorbed from nasal mucosa.

²³⁸⁴ 60% of American children got AIDS from a drug-using parent.(Editorial, 1995)

²³⁸⁵ The Minister for Justice stated in 2009 that he was not in favour of introducing needle exchange in Irish prisons lest it be viewed as assisting prisoners in criminal activity.

²³⁸⁶ Naltrexone 6-month implant reduces opioid use in dependent, motivated patients.(Kunøe et al., 2009) Similar findings were reported in Hulse et al.(2009)

Orally administered long-acting pure opiate antagonist
 No euphoria or physical dependence, and consistently blocks effects of customary amounts of heroin and other addictive opiates for up to 4 days, depending on the dose of naltrexone used
 May reduce amphetamine use in amphetamine dependent patients (Jayaram-Lindström *et al.*, 2008)
 Side effects: dysphoria, fatigue, headache, anxiety and nausea, vomiting, abdominal pain/discomfort
 Hepatotoxicity – especially in obese patients on high doses (100-300 mg/day); raised liver enzymes (5 or more times normal) mostly normalise when medication is stopped (Anton, 2008)
 Can cause severe withdrawal symptoms if given in full dosage to patient still using or withdrawing from opiates²³⁸⁷
 Naltrexone compresses the withdrawal syndrome into 2-3 days
 If small doses (1-5 mgs. at first) are given every 3-4 hours with clonidine it reduces the duration and severity of withdrawal symptoms compared to clonidine alone
 After a few days, full doses of naltrexone can be given 3 times/week
 Main problem in practice is compliance (APA, 2002, p. 314)
 Main application may lie with opioid-dependent physicians and other health care workers

Ultrarapid heroin detoxification (general anaesthesia for 6-8 hours plus naltrexone) with alleged clearance of the opiate from the body within 2 days (with most abstinence symptoms occurring under anaesthesia) has been carried out but can be dangerous, even fatal. (Strang *et al.*, 1997)

Nalmefene

Novel opioid antagonist that may reduce relapse in alcoholics
 Longer duration of action than naltrexone
 Appears to be safe from a liver standpoint

Clonidine (Catapres), an alpha-2 adrenergic agonist, reduces the autonomic signs of withdrawal from opioids (sweating, chills, gooseflesh, diarrhoea, rhinorrhoea, and eye watering) but not the subjective discomfort. It can also cause systemic hypotension. TCAs inhibit the hypotensive effects of clonidine. Overdose of clonidine can mimic opiate overdose (coma and small pupils). Clonidine exacerbates the central depressant effects of other sedatives, including alcohol. It should never be stopped suddenly.

Clonidine adverse effects

Dry mouth and dry eyes
 Fatigue, sedation, dizziness
 Nausea, constipation
 Hypotension
 Uncommon - insomnia, anxiety and depression
 Rare - vivid dreams, nightmares, and hallucinations
 Fluid retention may occur, necessitating diuretic therapy

Ghodse *et al.* (1994) found clonidine to be of no value as an adjunct to gradual opioid detoxification. Another α -2 adrenergic agonist, lofexidine, a failed anti-hypertensive and structural analogue of clonidine, has been used to ameliorate the withdrawal symptoms from opioids. It does not share clonidine's effects on blood pressure but the blood pressure should be monitored. According to Lingford-Hughes, (2002) lofexidine can be employed in outpatients but clonidine should be used in hospital.

Acetorphan

Inhibits peptidases responsible for enkephalin breakdown

²³⁸⁷ Many practitioners administer a naloxone challenge prior to prescribing naltrexone, e.g. 0.8 mg IM or 0.2 mg IV. Naltrexone-induced withdrawal can usually be ameliorated with alpha-2 adrenergic agonists (clonidine or lofexidine) and, if required, other medications such as benzodiazepines.

Reported to be superior to clonidine for opiate withdrawals
Has to be given (50 mgs) IV twice daily

LAAM (1-alpha acetyl methadol or levomethadyl acetate²³⁸⁸) can be given as infrequently as three times a week instead of daily methadone as an opiate substitute²³⁸⁹. Take-home drugs can then be avoided. It has a relatively low 'narcotic' effect. Higher doses, just as with methadone, may be more effective in reducing craving and blocking euphoria from additional opiate intake. It should be avoided in pregnancy or during breast-feeding. Lingford-Hughes (2002) has expressed concern that LAAM may prolong the QT interval and cause arrhythmias²³⁹⁰. Monitoring of the ECG would therefore appear essential. It has been withdrawn in Europe and received a FDA 'black box' (caution) in the US.

Sublingual buprenorphine (*vide infra*) is also been used as an opiate substitute²³⁹¹ and can potentially be given every second day. Buprenorphine, a partial opioid agonist, slowly dissociates from opioid receptors, which may be used to antagonise the effects of other opioids and to offer a more gradual withdrawal from this class of drugs.(Williams ea, 2002) There are advocates for maintaining opiate addicts on IV heroin (Perneger ea, 1998) but this is controversial (see Farrell & Hall, 1998) and has been viewed as a 'last resort' approach.(van den Brink, 2009) However, Strang ea (2010) in the UK found that supervised injectable heroin led to much less use of illegal heroin than did supervised injectable methadone or optimised oral methadone.

Conflicting results have been reported concerning the value of electro-acupuncture in the management of withdrawal from opioids.(APA, 2002, p. 318)

Methadone²³⁹² maintenance programmes: This practice has been received with a variety of reactions.(Hafford, 2000) For examples, pharmacists may view it as saving lives, substituting one form of addiction for another, or as placing themselves at risk of antisocial behaviour. There is evidence that these reduce illicit opiate abuse (although diversion does occur), reduce criminality and improve social rehabilitation, reduce risky behaviours such as IV drug administration, and help to prevent HIV infection. There is some evidence that methadone may lessen the euphoria induced by illicit opiate use (so-called 'agonist blockade') for as long as 72 hours.(Kreek, 2000) Methadone has a half-life of 15 hours. Whether or not a patient should be kept on daily or twice-daily methadone is a complex issue and is best decided after a thorough knowledge of the individual has been gained. Most patients need 20-60 mgs/day initially. It is safer to underdose at the start, although higher doses (say 60-80 mgs) in the long run may ensure better retention in treatment.(Kamal ea, 2007) Withdrawal symptoms from methadone come on more slowly and last for longer than with heroin. Methadone maintenance in Dublin during the mid-1990s was more likely in people with a long history of drug abuse, with multiple custodial sentences, previous unsuccessful rehabilitation, and positive HIV status. Two-fifths of methadone deaths in Manchester during the period 1985-94 were in people prescribed the drug, and the death rate from methadone increased eight times over those years. Also, while methadone prescribing may reduce other opiate use, it has no effect on cocaine use.(Gottheil ea, 1993) Methadone combined with MAOIs has led to hypertensive crises.

It is important to avoid mixed agonist-antagonist drugs such as pentazocine and butorphanol in this population because they can precipitate abstinence symptoms in opiate-dependent individuals. If a painkiller is required, the patient should be prescribed a short-to-medium-acting opioid, like oxycodone²³⁹³ (Oxycontin) or morphine, and continued on the usual methadone dosage. (If the patient is on buprenorphine rather than methadone one should administer the supplemental opiate *after* the buprenorphine to avoid withdrawal symptoms, switch to methadone, or use other approaches such as NSAIDs, local anaesthesia, or sedation.)

Cocaine lowers the blood concentrations of both buprenorphine and methadone which may have implications for clinical stability.(McCance-Katz ea, 2010)

²³⁸⁸ Derived from methadone in Germany in 1948.

²³⁸⁹ LAAM's very long duration of action makes it unsuitable for an inpatient taper.

²³⁹⁰ Prolonged QTc and *torsade de pointes* led to withdrawal of LAAM in the USA.

²³⁹¹ There is considerable experience of using buprenorphine during pregnancy – neonatal signs are less marked than those associated with methadone. Its effectiveness in pregnancy has been shown by Fischer ea.(2006)

²³⁹² Whilst methadone binds to mu receptors it also acts as an NMDA receptor antagonist. It can be given once daily for managing opioid addiction but needs to be given every 6 to 8 hours for pain relief.

²³⁹³ Oxycodone is abused by people looking for a high or buzz (Carise ea, 2007) and is replacing heroin in the US as a starting point for opiate abuse.(Renner & Ward, 2008, p. 359)

Patients on stable methadone maintenance should not be automatically excluded from being considered for organ transplantation.²³⁹⁴ Neither should they be pushed into coming off methadone before transplantation. (DiMartini et al, 2007, p. 296)

Methadone poisoning: Methadone²³⁹⁵ contributes to half of opioid overdose-related deaths in England and Wales and to 20% in Australia - heroin is the biggest killer in this regard in developed countries, commonly in combination with alcohol and BZDs. A non-tolerant individual may die after taking 40-60 mgs of methadone.

Indicators of methadone toxicity

Stupor, coma
Small pupils
Shallow breathing
Bradycardia, hypotension
Hypothermia, cold and clammy skin
Apnoea, cardiac arrest, terminal (hypoxic) mydriasis

Treatment includes airway maintenance, gastric lavage, IV fluids, and IV naloxone (0.4-2 mgs every 2-3 minutes) if required. If there is no response after a total of 10 mgs naloxone the diagnosis should be reconsidered. Respiratory depression may return after the action of naloxone wanes, so continued monitoring is mandatory. Methadone is a rare cause of choreiform movements. (Wasserman & Yahr, 1980)

Methadone and QTc prolongation

May occur with higher doses or if there is structural heart disease e.g. as left ventricular dysfunction or other risk factors (low potassium level, cytochrome P450 inhibitors²³⁹⁶, TCAs, etc)

ECG monitoring indicated in such higher risk cases (Krantz & Mehler, 2006; Hussey et al, 2009)

Methadone should be avoided if a patient has a prolonged QT interval

Changing to buprenorphine²³⁹⁷ may be an option in serious cases

Opiates and sex

Sexual behaviour tends to decline in people on long-term regular opiates

This probably has more to do with reduced sexual arousal than with erectile problems

Some people develop erections with naltrexone (due to reduced tonic opioid-mediated inhibition of spinal reflexes?)

Reduced sexual desire, reduced penile erectile ability, and anorgasmia are common in chronic opiate users

Opiates and constipation (see Becker & Blum, 2009)

Methylnaltrexone bromide (Relistor), a peripherally-acting mu-opioid receptor antagonist relieves opioid-induced constipation with interfering with (central) pain relief; it is indicated for use in patients with advanced disease where laxatives have failed; it may cause abdominal pain and flatulence

Alvimopan, another peripherally-acting mu-opioid receptor antagonist, should only be used with inpatients because of an increased risk of myocardial infarction

The laxative danthron (Codalax, Allax) causes liver and intestinal tumours in rodents; human use should be confined to terminal cases

Alpha-Methylfentanyl (China White)

This synthetic analogue of the dissociation analgesic fentanyl dates to 1980. It has been responsible for many deaths from respiratory depression²³⁹⁸. The features of its abuse are those of opiates in general.

Buprenorphine (GGs)

²³⁹⁴ Lifestyle *per se* should not be a block to beneficial medical interventions because then could not only remove smokers and other substance users from consideration but also rugby players and mine workers.

²³⁹⁵ Often taken with other drugs in overdose.

²³⁹⁶ Methadone clearance is decreased by CYP3A4 inhibitors, e.g. cimetidine, azole antifungals, macrolide antibiotics, and some anti-HIV drugs.

²³⁹⁷ Various ways of doing this have been described but the methadone needs to be tapered first and mild withdrawal symptoms should be evident before giving buprenorphine.

²³⁹⁸ Fentanyl-laced heroin and cocaine (Flatline, Drop Dead, Lethal Injection) can be lethal. (Boddiger, 2006)

Buprenorphine (Temgesic), a synthetic opioid, is a *partial* agonist of μ opioid receptors that has been used as a heroin substitute²³⁹⁹, although controversy exists as to whether it is as effective as methadone for maintenance²⁴⁰⁰. (Krantz & Mehler, 2006; Anonymous, 2007; Schottenfeld et al, 2008) It is taken sublingually or by IM or slow IV injection for pain. It is often used postoperatively (epidural), when it has been reported to cause a psychotic state with hallucinosis. Addicts may break down the tablets and inject then IV. Side effects include drowsiness, nausea, vomiting, dizziness and sweating. It may rarely cause respiratory depression. Naloxone only partially reverses its effects. Buprenorphine has also been used as an opiate substitute because it is associated with less physical dependence and toxicity than methadone. A buprenorphine-naloxone combination tablet (Suboxone), developed in the US, became available in Ireland in 2007: when the tablet is placed under the tongue only the buprenorphine is absorbed, but both compounds are absorbed if the combination is injected. It is used in willing addicts aged 15 years and older. Buprenorphine abuse is no stranger to Ireland. (O'Connor, 1988) Ho et al (2009) warn that prescribed buprenorphine may be diverted for recreational use, may cause medical complications, and may rarely cause death if taken in overdose with other sedatives. They state that its low misuse potential is based on animal studies and that its partial agonist role may be exaggerated, that IV use of buprenorphine can cause euphoria and opioid-like effects, and that its potential for illegal use is similar to that for morphine. Sublingual preparations are 'often injected' and use of the drug can give rise to abstinence effects because of its 'higher affinity than methadone for opiate receptors'. IV buprenorphine can lead to skin infection, infective endocarditis, and risk of contracting HIV or infectious hepatitis. (Ho et al, 2009)

Sedative-hypnotics other than benzodiazepines

Examples of sedatives are ethyl alcohol, methylated spirits, methaqualone hydrochloride²⁴⁰¹, diphenhydramine hydrochloride (and other antihistamines), chlormethiazole edisylate (clomethiazole: Heminevrin), paraldehyde (remember that the major site of metabolism is the liver, only a small amount being excreted via the lungs), chloral betaine (Tricloral syrup²⁴⁰²), and the barbiturates. While all of these are associated with occasional abuse, only meprobamate and the barbiturates will be considered further.

Meprobamate: Marketed first in the 1950s, meprobamate is a derivative of the muscle relaxant mephatesin. It acts by potentiating adenosine²⁴⁰³. Restrictions on benzodiazepine prescribing in New York State led to an increase in prescriptions for the more toxic meprobamate! In overdose it formed a lump or bezoar in the stomach, which, if not extracted by gastroscopy, could break up and cause a second relapse into a comatose state.

Barbiturates (Barbs, Goof Balls): Barbiturates are metabolised by the hepatic microsomal enzyme (P450) system and metabolites are mainly excreted through the kidneys. Barbiturates increase GABA activity on the GABA-A (GABA_A) receptor complex. The medical uses of these drugs are dwindling: prophylaxis in convulsive states, general anaesthesia, and, possibly, abreaction. Their use as a hypnotic in narcosis or a sedative in very disruptive patients is now very rare. They cause both psychological and physical addiction. The actress Marilyn Monroe died from barbiturate overdose.

- **Clinical effects**
 - Disinhibition, psychomotor slowing, confusion
 - Incoordination, slurred speech
 - Nystagmus, mydriasis
 - Coma
- **Stages**
 - Few hours after last dose – dependent user tense, anxious and tremulous
 - Later - muscle twitches, weakness, dizziness, dyspepsia, vomiting, insomnia, alertness, and even convulsions
 - (Aggression released in some users)
 - Long term - may alter vitamin D metabolism causing osteomalacia with hypocalcaemia

²³⁹⁹ Buprenorphine displaces most opiates from receptors and, in dependent cases, can precipitate a withdrawal state if opiates are currently in the body. It is therefore important to withhold this drug until at least mild abstinence symptoms occur.

²⁴⁰⁰ Buprenorphine is as effective as methadone in detoxification from opioids but it may not cover high doses of opioids because its effects plateau as the dose increases. (Anonymous, 2007)

²⁴⁰¹ Combined with an antihistamine in the now defunct preparation Mandrax; also called Quaalude, Sopor, Parest, ludes, quad, and quay.

²⁴⁰² 500 mgs./5 mls., 1G. nocte max. or 500 mls. b.i.d. to t.i.d. for daytime sedation.

²⁴⁰³ Adenosine is sedative and caffeine antagonises adenosine.

Tolerance is due to a number of factors, such as liver enzyme induction and neuronal adaptation. Cross-tolerance to other sedatives, such as alcohol and BZDs, may occur. Withdrawal from barbiturates should be conducted in hospital whenever possible. It takes about 10-14 days to carry it out safely. Various drugs have been used for this purpose, including barbiturates (e.g. short-acting such as pentobarbital for inpatients and longer-acting such as phenobarbitone for outpatients: 30 mgs of phenobarbitone per 100 mgs of short-acting agent), long acting BZDs, and chlormethiazole. Phenytoin, an anticonvulsant, is ineffective in preventing seizures secondary to barbiturate withdrawal. If a patient has become dependent on opiates²⁴⁰⁴ and barbiturates or other sedative-hypnotic agents should be kept on the opiate until withdrawn from the sedative-hypnotic. Older people on barbiturates for many years (a rarity today) should not be forced to undergo heroic detoxification if their dependence is not causing problems.

Drugs associated with a delirium tremens-like withdrawal state

Alcohol
Barbiturates
BZDs
Glues
Methaqualone

Barbiturates, but not BZDs, increase the metabolism of TCAs. Short-acting and long-acting barbiturates can be detected in urine for 1 day and 3 weeks respectively.

Cocaine (Coke, snow, blow, bump, C, candy, Charlie, coke, etc)

1.2 million Americans were current cocaine users in 2002 (0.5% of population), and 265,000 were crack users. Estimated cocaine use over the previous 12 months in Europe and 15-64-year-olds rose from 3.5 million in 2004 to 4.5 million in 2005. According to Farren (2008) 1% of the Irish population used cocaine during the last month and lifetime use increased from 2.9% to 5% in the period 2003-7.

Erythroxylon coca

Cocaine blocks DA uptake. Cocaine (O'Shea & Stokes, 2000) is derived from the shrub *Erythroxylon coca*. It has been used as a local anaesthetic. It can be smoked, sniffed, or injected.

Crack²⁴⁰⁵ is a pure form of cocaine that is smoked for rapid effect. Crack users may develop tolerance to large doses. Crack causes a sudden rise in blood pressure. Cocaethylene is a toxic metabolite of cocaine that is produced in the presence of alcohol; simultaneous users of alcohol and cocaine²⁴⁰⁶ report enhanced euphoria; as well as cardiotoxicity, there may also be a propensity to violence.

Cocaine inhibits the dopamine transporter²⁴⁰⁷. There is a rise in DA levels in the nucleus accumbens. There is evidence for loss of vesicular monoamine transporter protein (VMAT2 – distinct from synaptic DA transporter) in human cocaine users, a possible indicator of damage to striatal DA fibres.(Little ea, 2003) Chronic haloperidol use leads to upregulation of postsynaptic DA receptors which can reduce the amount of cocaine needed to cause euphoria.(Marder & Wirshing, 2003, p. 484) Clozapine may increase cocaine levels in plasma.(Farren, 2008) Apart from inhibition of the DA transporter, conditioned cueing²⁴⁰⁸, cocaine-induced priming (reintroduction of a drug in formerly dependent user with subsequent increased

²⁴⁰⁴ These include buprenorphine and methadone.

²⁴⁰⁵ Cocaine separated from HCl base (therefore 'free-base'), melted, then smoked (pipe, cigarette). Sold as 'rocks' or as a 'line'.

²⁴⁰⁶ The combination appears to be increasingly employed in Ireland.(Lyne ea, 2010)

²⁴⁰⁷ Transporters for noradrenaline and 5-HT are inhibited to a lesser degree.

²⁴⁰⁸ This activates various brain areas and involves various neurotransmitters.

drug intake – can be blocked by micro-injection of DA antagonists into medial prefrontal cortex), stress (modulated by noradrenaline and extra-hypothalamic CRF – lofexidine and CRF antagonists modulate noradrenergic and CRF responses to stress²⁴⁰⁹), and frontal cortical inhibition (an effect of drugs on the frontal lobe – blamed for compulsive behaviour associated with drug-taking and ameliorated by modafinil) are among neurobiological mechanisms proposed for cocaine addiction.

Cocaine

- Strong psychological dependence – typically the patient binges for 2-3 days, followed by a slightly longer break during which he/she ‘crashes’ – financial resources and drug availability determine level of cocaine use
- Peak effects of smoked or IV cocaine reached in 3-5 minutes
- Peak effects of snorted cocaine reached within 15-20 minutes
- User feels very well, is in great spirits, feels powerful, is socially gregarious
- May have ideas or delusions of persecution²⁴¹⁰
- May hallucinate – may experience subcutaneous sensation called ‘formication’²⁴¹¹ or ‘cocaine bug’ (amphetamines can also induce this)
- Sparkling peripheral ‘snow lights’
- Insomnia, impaired thinking, and panic
- Dental neglect (local anaesthesia masks pain)
- Pneumothorax²⁴¹², gastric ulcers, weight loss
- Cerebrovascular accident
- Myocardial (or other organ, e.g. spleen: Devitt ea, 2005; McLaughlin ea, 2009) infarction²⁴¹³
- Nasal septum perforation, chronic sinusitis, subperiosteal abscess, pneumomediastinum, pneumothorax, pulmonary oedema – in snorters
- Ulceration of the vagina (local use)
- HIV (needle sharing²⁴¹⁴)
- Road traffic accidents
- Seizures
- Hyperthermia
- Feminisation in chronic users
- Smoking cocaine can exacerbate asthma or COPD and lead to a form of pulmonary fibrosis called ‘crack lung’ (Tashkin, 2001)
- Chorea, choreoathetosis, dystonia, akathisia, eye blinking, and lip smacking (‘crack dancing’)
- Cocaine overdose – mostly metabolised in < 1 hour – intubate and give O₂ if needed; monitor ECG; if agitated or delirious or convulsing give BZDs (antipsychotics may cause potentially fatal hyperpyrexia); urine acidification is not recommended for cocaine intoxication; do not give beta-blockers for hypertension (**danger of paradoxical hypotension and worsening of cocaine-induced coronary spasm**) – phentolamine (2-5 mg IV) may be used; chest pain responds to aspirin, nitrates or BZDs

These effects may be transient or persistent. Similar effects have been attributed to amphetamines and nor-pseudoephedrine. Low doses of cocaine may cause toxicity in the presence of congenital pseudocholinesterase deficiency.

Body packers (‘mules’)

Ingest drugs like cocaine or heroin packed in condoms or wrapped in cling film

Enquire as to what is in the packs

X-ray abdomen to show location and number of packs

Carefully remove *gastric packs* with gastroscope or use a laxative (e.g. lactulose) to help passage (**avoid** paraffin-based preparations as they may corrode packs)

For *intestinal packs* employ laxatives or whole bowel irrigation

For *rectal/vaginal packs* employ manual removal

Observe in hospital until all packs removed

²⁴⁰⁹ Cocaine-dependent individuals exhibited higher stress and craving for CRH compared with controls in one study. (Brady ea, 2009)

²⁴¹⁰ E.g. drug dealers or police looking for him or people want to steal his cocaine.

²⁴¹¹ *L. formica*, a bug.

²⁴¹² Due to employing a Valsalva manoeuvre to aid drug absorption.

²⁴¹³ Increased creatine kinase levels in the absence of MI may occur in cocaine users; measurement of serum troponin I (cardiac marker unaffected by cocaine) may be a useful indicator of MI. (Weber ea, 2000)

²⁴¹⁴ The first case of HIV from needlestick injury in Ireland was in 1995.

Rupture of packs can cause psychosis, fever, or rapid death

Body stuffers

Ingest drugs to evade detection/arrest

Swallowed substance may be free or packaging may be poor

While physical dependence on cocaine occurs, abstinence symptoms are often mild. In treatment, the drug should be stopped abruptly and the patient should not be able to procure supplies of cocaine. The worst of the withdrawal symptoms are over within a week. The patient should be monitored for depression and suicidal tendencies. Propranolol (avoid if taking cocaine – *vide supra*) and amantadine may have some ameliorative effects on cocaine abstinence symptoms.

Cessation of intake in chronic, heavy cocaine users may lead to

Fatigue

Nightmares

Insomnia/hypersomnia

Excessive appetite

Psychomotor retardation or agitation

Suicidal ideation²⁴¹⁵

Symptoms peak in a few days

Cocaine use during pregnancy²⁴¹⁶

Prematurity

Poor fetal growth

Microcephaly

Vasospastic fetal CVA

Neonatal cocaine withdrawals

Poor sleep/feeding

Irritability

Seizures

Abnormal EEG and brainstem auditory evoked responses with slow return to normal

Managing cocaine craving²⁴¹⁷

TCAs – poor/transient reduction in craving

Fluoxetine - 40 mgs – some reduction (Lingford-Hughes, 2002)

Disulfiram²⁴¹⁸ - may improve abstinence rates (Carroll ea, 2000)²⁴¹⁹

Baclofen (GABA-B receptor agonist), tiagabine (GABAergic), and modafinil - reported to reduce cocaine craving

N-acetylcysteine²⁴²⁰ (LaRowe ea, 2007)

Vigabatrin may have efficacy (Brodie ea, 2009)

CBT - may reduce cocaine use (Carroll ea, 2004)

Cocaine vaccine undergoing trials²⁴²¹

²⁴¹⁵ Acute brief depression and a lower intensity persistent dysphoria (lasting a few months) have been described and may be due to depletion of dopamine.

²⁴¹⁶ The specificity of such findings to cocaine has been challenged by Frank ea (2001).

²⁴¹⁷ Nearly all cocaine addicts experience intense craving for the drug, especially for the crack form. Farren (2008) believes that pharmacological approaches add little but is more positive about the benefits of CBT, interpersonal psychotherapy, regular group therapy, telephone-based continuing care, and contingency management (basically, rewards for staying off the drug).

²⁴¹⁸ Blocks aldehyde dehydrogenase and dopamine β -hydroxylase. This leads to a rise in plasma dopamine (DA). If cocaine is ingested the rise in DA is much greater, with resultant dysphoria.

²⁴¹⁹ Although it may (Lingford-Hughes, 2002) or may not (Carroll ea, 2004) work by reducing alcohol intake.

²⁴²⁰ A cysteine prodrug which increases glutamate exchange activity.

PET shows areas of poor cerebral perfusion in chronic users. PET also found a decrease in D2 and D3 receptor binding in cocaine-dependent individuals and such cases may also have lower levels of endogenous dopamine than is found in normals. (Martinez et al, 2009) Urine and serum toxicology may be negative for cocaine because of its very short half-life (detectable in urine for 6-8 hours), but metabolites, especially benzoylecgonine, can be detected for over one week. Homicide may occur as a result of cocaine abuse.

*Amphetamines*²⁴²² (*Amphetamine, Speed, Dixies, Bennies, truck drivers, LA turnaround, etc*)

Amphetamines abuse is very common, (DrugScope, 2000) especially among young people. It directly releases DA (reversed transport) and blocks noradrenaline uptake, effects potentiated by TCAs. Amphetamine sulphate (can cause coagulation problems, hyperthermia, and renal failure) can be snorted. Amphetamines are used to treat ADHD, narcolepsy, and, in America, unresponsive depression. A questionnaire study of amphetamine prescribing in the English Midlands (Moselhy et al, 2002) revealed that they are being prescribed by a few drug services as a substitute for illicit use. Those with relatives who have Tourette disorder are at risk of developing tic disorder if given stimulants. The FDA declared a total ban on sales of dietary supplements containing ephedra in 2004. This herb (*Ephedra sinica*²⁴²³) contains amphetamine, was popular as an aid to weight loss, and was associated with 155 deaths and many adverse effects, including psychosis and mania²⁴²⁴. The classic members of the group are dextroamphetamine and methamphetamine²⁴²⁵ (*crystal, tea, ice, Tina, crank*, etc). Methylphenidate²⁴²⁶, ephedrine and propanolamine are related drugs²⁴²⁷. Propanolamine and ephedrine can cause hypertension, psychosis and death. Seizures may follow amphetamine use. Amphetamine psychosis²⁴²⁸ usually, but not always, ceases on stopping intake of the drug: the patient is over-responsive, and is less thought disordered or hallucinated than is the patient with schizophrenia. Phenothiazines may increase dysphoria and agitation in amphetamine users; 'talking down' and, if needed, benzodiazepines may be used. Hypertension is treated with benzodiazepines or, if severe, phentolamine. Beta- and combined alpha- and beta- blockers should be avoided²⁴²⁹. Secondary mania has been attributed to amphetamine. Longterm high-dose amphetamine use may lead to stereotyped behaviour e.g. inability to stop tidying. Amphetamines decrease resistance to bacteria, viruses and tumours. Cell-mediated immunity in particular is decreased. (Spies et al, 2002) Combining amphetamine or other sympathomimetic drug with an SSRI, especially if the dose of SSRI is increased, could potentially cause a transient psychosis. Urinary acidification may increase amphetamine clearance. 'Ice' (pure amphetamine) can be smoked in a pipe or on aluminium foil or taken IV.

'Designer drugs'

Cheap and synthetic

Can resemble the usual drugs of abuse

²⁴²¹ The carrier is cholera toxin B subunit. This is linked to a nor-cocaine derivative at methyl ester group as immunogen. The hope is to reduce the effects of cocaine and to prevent relapse. Patients may only respond if they achieve at least 43 mcg/ml IgG anti-cocaine antibody levels. (Martell et al, 2009)

²⁴²² Amphetamine was developed by Alles in 1927. (O'Shea, 2000b)

²⁴²³ It was called *Mormon's tea* when used as a drink.

²⁴²⁴ Hypertension and cardiac arrhythmias were reported. When combined with another stimulant (e.g. caffeine) it may be lethal. It does cause weight loss. It can still be acquired via the internet!

²⁴²⁵ **Methamphetamine** (methylamphetamine, N-methylamphetamine, desoxyephedrine, originally synthesised from ephedrine by the chemist Nagayoshi Naga in 1894, has a long duration of action and its euphoric effects can last up to a day. It can be taken PO, PR, snorted, smoked (*crystal*), or injected. It was called *Fliegerschokolade* when given to German pilots. Prolonged use causes mental dulling. Intracerebral haemorrhage and, when inhaled, non-cardiac pulmonary oedema has been reported.

²⁴²⁶ Ritalin, JIF, MPH, R-ball, Skippy, the smart drug, spit tobacco, vitamin R. Stimulants, including methylphenidate, may have an association with sudden unexplained death in youths. (Gould et al, 2009)

²⁴²⁷ The UK Medicines and Healthcare Products Regulatory Agency announced in 2007 that methamphetamine precursors pseudoephedrine and ephedrine (used in flu remedies) may become prescription only drugs. (Gunter, 2007)

²⁴²⁸ This was described by Connell in 1958. The psychosis tends to subside over about a week, but cases persisting for months are not unknown.

²⁴²⁹ Potential exacerbation of stimulant-induced cardiovascular toxicity.

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP - contaminant in heroin), causes Parkinsonian syndrome.

New drugs appearing all the time, e.g. PCP derivatives, alpha-pyrrolidinophenones, and phenethylamines. Piperazines include 1-benzylpiperazine or BZP²⁴³⁰ (herbal ecstasy²⁴³¹), 1-(3,4-methylenedioxybenzyl) piperazine or MDBP, 1-(3-chlorophenyl) piperazine or mCPP (already employed as a probe in research), 1-(4-methoxyphenyl) piperazine or MeOPP, and 1-(3-trifluoromethylphenyl) piperazine or TFMPP; amphetamine-like 'party pill' drugs sold in various mixtures; can be toxic, including serotonin syndrome

Crystal: This form of methamphetamine is used as a replacement for cocaine or mixed with heroin. The euphoric effects are reported to last longer than those of cocaine do. A number of laboratories have been discovered in Indiana. Use is associated with increased libido and unsafe sex. Concerns have been raised about its role in the spread of HIV among homosexual men in the US. (Boddiger, 2005) Exposure to high doses of methamphetamine causes longterm changes in neurotransmitter systems. (Nordahl ea, 2005) It is sold as a powder for injection, inhaling²⁴³², or oral consumption.

Dopamine sensitisation (reverse tolerance) with psychostimulant exposure

Repeated use of methamphetamine may lead to schizophrenia-like psychosis. Previously non-psychotogenic adverse events may precipitate psychosis if methamphetamine was taken in the past.

With repeated use of methamphetamine there is increasing dopamine release.

Philip Seeman²⁴³³ suggested multiple pathways to dopamine supersensitivity: social, physical, and environmental.

Dimethoxybromoamphetamine (DOB, snowballs): A warning was disseminated about this synthetic agent in 2003 by the National Advisory Committee on Drugs²⁴³⁴ and the Gardai. This powerful hallucinogen is often mistaken for ecstasy and, because of a delayed effect (3 hours), impatient users may take more than one of these white tablets. Big doses can result in amnesia. Vascular spasm may lead to gangrene. Agitation is common. Depending on dose, effects last for 8-24 hours. Benzodiazepines such as diazepam or lorazepam may be used for hallucinations. Vascular spasm may require heparin and/or intravenous or intra-arterial nitroprusside.

Naltrexone may reduce amphetamine use in dependent subjects (Jayaram-Lindström ea, 2008) and methylphenidate may decrease the tendency to inject amphetamines IV. (Tiihonen ea, 2007)

3,4-methylenedioxymetamphetamine²⁴³⁵ (MDMA, ecstasy, X, XTC, E, Adam, Clarity, Lover's Speed, Red & Black, White Dove, White Burger)

This phenylisopropylamine is a synthetic oral amphetamine. (O'Shea, 2000b) E blocks 5-HT uptake by the neurone, inhibits serotonin breakdown, and induces its release by the neurone. Regular use leads to

²⁴³⁰ BZP was sold in so-called 'head shops' as a 'natural high' and can have many toxic effects: itch, vomiting, insomnia, hyperventilation, anxiety, agitation, psychosis, chest pain, tachycardia, palpitations, hypertension, hyperthermia, tremor, dystonia, dizziness, headache, confusion, collapse, seizures, urinary retention, and renal toxicity. (see McNamara, 2009) 'Head shops' (McNamara ea, 2010) and the Internet became part of a new drug market. Head shops tend to describe/disguise products as bath salts or plant foods and to mark them as 'Not for human consumption'! Illegal laboratories change the chemistry of illicit drugs in order to pass them off as legal substances. A little ammonium will convert coke to crack! Gamma-butyrolactone (GBL), a euphoriant, was banned in the UK in late 2009. *Salvia divinorum*, a hallucinogenic plant containing salvinorin A, was available through head shops. (Pillay & Kelly, 2010) As of May 2010, a majority of head shops closed down precipitously in the Republic of Ireland following the passage of an Order placing 'legal highs' under the *Misuse of Drugs Act 1977*, e.g. selling certain of these drugs could now attract a life sentence! Further legislation appears necessary to stem this menace.

²⁴³¹ Also A2, Frenzy, and Nemesis: the reader should not assume too much from these names, e.g. herbal ecstasy may also refer to ephedrine.

²⁴³² Crystals are heated and the vapour is then inhaled.

²⁴³³ Professor of pharmacology at University of Toronto, born Canada 1934, discovered dopamine D2 receptor in 1974.

²⁴³⁴ Est. July 2000 to improve knowledge and understanding of drugs of abuse.

²⁴³⁵ It was synthesised in the 1960s but never marketed. According to Lacy and Sworowski (2002) it was considered as a potential chemical warfare agent by the US Army during the 1950s and it was employed as a self-awareness/empathy-enhancing agent by psychotherapists during the 1970s. It was neurotoxic in animals. (Renner & Ward, 2008, p. 359)

tolerance (and increased intake). MDMA street samples are often impure²⁴³⁶ and may contain no MDMA at all!

Effects

- Intense empathy (5-HT flooding) that decreases with chronic use
- Paranoid psychosis, flashbacks, anxiety, restlessness, agitation, irritability, panic, depression, confusion
- Fatigue with insomnia
- Anorexia, nausea
- Mydriasis
- Sweating, fast pulse rate
- Lockjaw, teeth-gnashing, myalgia, stiffness
- Asthma
- Seizures, collapse, hypotension, pyrexia
- Thrombosis, stroke
- Disseminated intravascular coagulation, rhabdomyolysis, acute renal failure
- Ventricular arrhythmias
- Accidents
- Serotonergic neuronal damage²⁴³⁷

Immediate verbal memory is affected rather than visual memory – effects may last a few weeks or for much longer periods with lifetime abuse, (Bhattachary & Powell, 2001; Schilt et al, 2008) although it has proved difficult to exclude the effects of premorbid functioning, IQ, personality variables and the effects of ethanol. (Lacy & Sworowski, 2002) Excess fluid intake may lead to increased ADH levels in the presence of E, and reduced renal competence: the patient may collapse, develop metabolic acidosis, and become water intoxicated and hyponatraemic. There are several related compounds. (O'Shea, 2000b) Withdrawal from E can be associated with anxiety, tremor, dysphoria, fatigue, lethargy, nightmares, headache, sweating, myalgia, stomach cramps, and increased appetite, all lasting for up to a week and peaking after a few days. Sildenafil may be added to E (*sextasy*). Severe E intoxication is managed with IV fluids plus dantrolene. E users should drink small amounts of fruit or isotonic drinks rather than water. Other causes of hyperthermia must be considered, such as infection, heat stroke, NMS, serotonin syndrome, malignant hyperthermia, anticholinergic drugs, salicylate poisoning, amphetamines, cocaine, etc. SSRIs inhibit E uptake and block the euphoriant effects. Deaths associated with E in England were typically associated with taking other drugs as well, especially opiates, although 7% of one series of E-associated fatalities were due to E alone. (Schifano et al, 2003)

3,4-methylenedioxymphetamine (MDA, *old Ecstasy*) is a close analogue of MDMA. It destroys 5-HT terminals in experimental animals. A related agent is 3,4-methylenedioxyethylamphetamine (MDE, *Eve*).

*Ephedrine*²⁴³⁸

Ephedrine-containing products are sold at some parties as herbal ephedrine.

Effects

- Persecutory ideas, delusions, auditory and visual hallucinations, insomnia, anxiety, agitation
- Tremor
- Palpitations,
- CVA, seizures
- Hepatitis
- Death
- Positive drug screen for amphetamine

²⁴³⁶ Methamphetamine, theophylline, and caffeine among others may be present.

²⁴³⁷ SPECT and PET data suggested that lower 5-HT transporter density/binding in recent users might return to normal over time. (Buchert et al, 2004; Selvaraj et al, 2009) However, ecstasy might have a specific toxic effect on thalamic 5-HT neurones. (de Win et al, 2008)

²⁴³⁸ Amphetamines (analogues of ephedrine) were produced as a replacement for naturally occurring ephedrine in asthma treatment. (O'Shea, 2000b) The ancient Chinese knew ephedrine.

*Glues, aerosols, volatile anaesthetics*²⁴³⁹ (*laughing gas*²⁴⁴⁰, *poppers, snappers, whippets, etc*)

The usual user is a young boy or teenager. Most cases are occasional experimenters and a small minority is involved in solitary abuse. Regular abuse leads to psychological dependence. Young people in care and from social class V are over represented among deaths from inhalants. Over 4% of all deaths among boys aged 10-14 years in the UK during the early 1990s were due to solvent abuse. Of 75 deaths in the UK in 1996 one-fifth were female. There is little difference between the sexes in rates of abuse but males are more likely to die from it. The commonest agents involved in glue sniffing are solvents and adhesives and range from petrol to deodorant sprays. These often contain very toxic compounds (e.g. benzene, naphtha, nitrites, toluene, acetone, carbon tetrachloride, and aliphatic acetates). Petroleum distillates may lead to aspiration. Corrosion may complicate sodium hypochlorite (bleaches), denture cleaning tablets, etc. Nail polish and nail polish remover contain acetone and have caused coma in overdose! Inhalation of petrol is a problem in some developing countries because of its lead content. Computer cleaning materials may be applied to mucosal surfaces using a nozzle, so-called 'dusting'. Abusers inhale (jag) in order to become intoxicated (smashed or stoned). The glue may be warmed before it is inhaled from a plastic bag or milk bottle held over the face.

Physical withdrawals are rare. Following intoxication there may be headache, abdominal aching, cough and red eyes that may persist for a few days. However, abrupt cessation can sometimes be associated with an alcohol-like abstinence syndrome. Tolerance may develop with prolonged use. Early effects are similar to those of alcohol.

Mechanisms of sudden death in solvent abusers

Anoxia - inhaled vomit

Suffocation - plastic bag over head

Vagal inhibition - reflex from laryngeal stimulation because of direct spraying of aerosols – can also cause cold burns and laryngospasm

Respiratory depression - direct result of general depression of CNS

Cardiac arrhythmias – possibly sensitisation of myocardium to adrenaline and sympathetic stimulation – 'sudden sniffing death syndrome'

Trauma - accidents

Explosions/fires – unsafe storage of large amounts of inflammable solvents

Suicide

Delusion that one is able to fly - nearly one-quarter of solvent inhalers in one study (Evans & Raistrick, 1987)

Fluorinated hydrocarbons in aerosol propellants can cause spasm of the larynx. Cardiac arrhythmias are more likely to occur in glue sniffers if they exercise, become hypoxic or hypokalaemia, or possibly if halothane is given. Peripheral neuropathy is associated with the hexacarbons. 'Glue sniffer's rash' is a facial rash caused by repeated inhalation from a bag. Amyl and butyl nitrites are sometimes inhaled for their vasodilator properties in homosexual encounters.

Evidence for permanent structural brain damage with associated psychiatric manifestations is controversial.

Amyl nitrite ('poppers')

Smooth muscle relaxant used for angina pectoris

Glass ampoule crushed in a handkerchief and vapour is inhaled

Rumoured to increase sexual performance and orgasm – nitrites cause penile engorgement and relaxation of the sphincter ani

Can cause transient headache, tachycardia, hypotension, and dizziness

High doses can lead to nausea, vomiting, syncope, cardiac arrhythmias, glaucoma, coughing, wheezing, and dyspnoea

²⁴³⁹ If we omit drunk driving, inhalants are potentially the most lethal form of substance abuse.

²⁴⁴⁰ *Laughing gas* (nitrous oxide, 'shoot the breeze') is obtained from medical sources or from whipped cream dispensing machines ('whippets').

Chronic use may lead to tolerance, dermatitis/burns (perioral/nasal) and methaemoglobinaemia (treated with oxygen and, if needed, 1% methylene blue)
Activated charcoal reduces absorption from the gut²⁴⁴¹.

The clinical picture may be divided into acute and chronic.

Solvents

Acute effects

Excitement, euphoria, giddiness, disorientation, ataxia, strange behaviour, visual hallucinations, photophobia, powder about the face, and blurred vision

Chronic effects

Mental - fatigue, depression, agitation, poor concentration

Neurological - tremor, cerebral oedema, and cerebellar degeneration

Haematological - bone marrow depression, anaemia, leucocytosis, haematuria, and hypotension

Respiratory - stomatitis, rhinitis, bronchitis, pulmonary congestion, halitosis and anorexia

Cardiac - dilated cardiomyopathy

The abuse of 'over the counter' drugs, such as cough bottles, has been a major problem in some areas.

Toluene

Present in commonly used adhesives

Causes acute dizziness, euphoria, and perhaps hallucinations, convulsions and impaired consciousness (toluene encephalopathy), and longterm paranoid psychosis, intellectual dysfunction and temporal lobe epilepsy

Diffuse atrophy in cerebrum and cerebellum with white matter hyperintensities

Fetal solvent syndrome (Costa ea, 2002) – due to exposure to high dose toluene in utero – resembles fetal alcohol syndrome

Interventions that have been employed, with some good effect, include family and individual psychotherapy. The efficacy of publicity campaigns remains controversial. Solvent abuse is not illegal. Most abusers give up the habit eventually; some continue through to adulthood, and a few go on to abuse alcohol and other drugs. Inhalant-induced psychosis has been treated with carbamazepine (low EPS potential and does not lower seizure threshold).(Mack ea, 2003, p. 351)

Management of substance abuse

Motivation to come off drugs, including alcohol, is often a fleeting and changeable phenomenon. The patient should not be alienated, but should be encouraged to discuss his reasons for taking drugs.

Discussion and advice may be all that is required in the case of those experimenters who occasionally dabble in drugs for reasons of group hedonism. Deeper levels of dependence may require detoxification and assessment and treatment of psychiatric and physical (e.g. hepatitis) problems. Supervised urine sampling²⁴⁴² may be done for a few days, on a daily basis, to test for drug use and motivation before entering treatment. Alternatively, it is used on a regular or random basis to test for compliance. Recently passed urine should be warm. Direct supervision is essential.

Examples of detoxification regimens include reducing doses of lorazepam, chlordiazepoxide, alprazolam, or diazepam for alcohol dependence, and methadone syrup in reducing doses over about 7 days or more for opioid dependence.

²⁴⁴¹ The use of multiple-dose activated charcoal in the treatment of poisoning is being debated.(Eyer & Eyer, 2008; Eddleston ea, 2008)

²⁴⁴² E.g. amphetamines and cannabis are detectable for up to 2 days and (in chronic users) 4 weeks in urine respectively.

At present the main treatment agency for Ireland is based at the Drug Treatment Centre, Trinity Court, 30-31 Pearse Street, Dublin 1. Psychiatric hospitals may also treat these patients but it is advisable to treat them away from other patients. Strict security is required. Health Boards²⁴⁴³, especially the Eastern Region, expanded the number of clinics for drug abusing patients so that there were 4,556 people receiving methadone and 417 on a waiting list in the latter region in 2000 (8,029 people received methadone in Ireland in 2008). Coolemine Therapeutic Community (in north Dublin near Blanchardstown) offers a drug-free rehabilitation programme. The Garda Drug Squad is available for advice and guidance at Harcourt Square, Harcourt Street, Dublin 2.

Services for so-called dual diagnosis²⁴⁴⁴ patients require systematic co-ordination. There are at least three models of service provision in Ireland: parallel, integrated, and serial. (MacGabhann *et al.*, 2004)

Prognosis

Drug abusers in general do better if they come from a higher socioeconomic group, if they do not have an antisocial personality disorder or a family history of alcoholism, and if they have little in the way of physical or psychiatric problems.

Prognostic factors (Dunne, 1993)

Good

Non-opiate abuse, older age when starting, single drug use, more time in therapy, and fewer treatment arrests

Poor

Opioid abuse, low educational level, poor school attendance, and antisocial behaviour

Abuse of drugs by psychiatric patients is common and may exacerbate psychosis, increase non-compliance and hospitalisation rates, increase treatment resistance, and lead to violence, suicide, homelessness, criminality, family discord, and rejection by mental health services.

Prevention

Correct attitudes towards drugs at home are essential. Education plays some role on an individual level but whether it has a broader effect is more controversial. The HSE spent over six hundred thousand euro on an anti-recreational cocaine campaign in 2008 and found that 73% of under-35s stated that poster ads changed their thinking about cocaine and 93% said that radio ads offered novel information on the toxicity of alcohol-cocaine mixing. (Gantly, 2009) Prevention of smuggling, illegal manufacture and international trading by customs and police officials, including Interpol, is an on-going process. Three times as much is spent in the UK on enforcement and supply reduction as on prevention and treatment. Adequate police powers under drug misuse legislation are necessary. A 'Drug Tsar' was appointed in the UK in the late 1990s to co-ordinate anti-drug activities. Self-monitoring by the professions is crucial. General social measures such as employment and housing programmes are very important.

A drug abuser *per se* cannot be admitted as an involuntary patient under the Mental Health Act 1983 in England but the Irish 1945 Mental Health Act allowed for such admission. The (Irish) Mental Health Act 2001 is the same as the 1983 legislation in this regard. Both acts allow for involuntary admission of the same patient if his mental state warrants it. New mental health legislation in the Republic of Ireland brings Irish law into line with British legislation in this regard. The Dutch have taken a relatively liberal approach to drug dependence. This has received a mixed international reception. More than half of US federal prison inmates in 1994 were there for drug offences, many of which were non-violent. Arguments continue that drugs are only a problem because they are illegal. However, this approach ignores the damage done by alcohol and tobacco that are legal.

20

Abuse of 'legal' drugs

Brian O'Shea

'Thou hast the keys of Paradise, oh just, subtle, and mighty opium!' Thomas De Quincey (1785-1859), 1822.

Steroids

It can be difficult to distinguish between steroid-induced psychiatric disorder²⁴⁴⁵ and psychiatric disorder secondary to the disorder being treated. Steroids are more often causative when used in high dosage. Depression is more common than mania, which in turn is more common than mixed affective states. Other associated disorders include schizophrenia-like and delirious states. Reduction in steroid dosage, neuroleptics, lithium, or ECT may be required.²⁴⁴⁶ Anecdotally, TCAs may exacerbate the problem. (Hall et al, 1978) Patients with affective disorders take longer to recover than do those with delirium. Over 90% of patients with steroid-induced psychiatric disorder are recovered within 6 weeks of onset. There is a case for baseline psychiatric evaluation before starting high dose steroid therapy. Some patients develop psychological dependence on corticosteroids and they may strongly resist their discontinuance. They cause increased body weight (increased appetite, fluid retention, and redistribution of fatty tissues). Reversal of these changes, together with corticosteroid-induced skin atrophy, may make the patient look old and wrinkled. Many users of anabolic steroids 'stack' i.e. use various combinations of such drugs in order to achieve maximum effect.

Benign intracranial hypertension (BIH)

Reported with withdrawal from high steroid dosage

Especially in children

Irritability, headache, vomiting, papilloedema, poor sight and sixth cranial nerve palsy

CSF under increased pressure but otherwise normal

May cause permanent CNS damage

Management: increase dose, then withdraw very slowly

Cerebral vasculitis

Confusional state without localising signs

Occurs during withdrawal from prolonged steroid treatment

Management: as for BIH

²⁴⁴⁵ Testosterone levels may be reduced in anabolic steroid abusers. Prolonged depression of HPA axis contributes to sterility and depression.

²⁴⁴⁶ If the patient is steroid dependent it may be necessary to increase steroid dosage before each ECT treatment.

In the early 1990s 6.5% and 1.9% of American adolescent boys and girls reported non-prescription use of anabolic steroids (roids, juice). 1-5% of high-school European and American students admitted to using anabolic steroids in a study conducted by Thiblin and Petersson.(2005) Both physical and psychological dependence have been described in weight lifters using anabolic androgenic steroids (oral or IM) to increase athleticism or enhance physical appearance. Anabolic steroid abuse (see Rashid ea, 2007; Sjöqvist ea, 2008) is, however, not confined to athletes. A narcissistic body image is common among users of anabolic steroids, as is personality disorder (antisocial, paranoid, histrionic, and borderline). Needle sharing carries a risk of contracting HIV. Psychiatric, mainly depressive, symptoms are common in dependent users. ‘Roid rage’ is the slang term for anabolic steroid-induced violent behaviour. ‘Muscle dysmorphia’ is a term applied to a type of dysmorphophobia where the person is unreasonably dissatisfied with their musculature. Withdrawal symptoms include reduced sex drive, fatigue, depression, dissatisfaction with body image, headaches, physical violence, angry and hostile feelings, manic or psychotic episodes, and a desire for more steroids.

Possible complications of anabolic steroids (e.g. Perry & Littlepage, 1992, Arvary & Pope, 2000)
 Acne, gynaecomastia, testicular atrophy, oligospermia, infertility in men
 Menstrual irregularity/amenorrhoea, clitoral hypertrophy, deep voice, hirsutism, facial hair, male-pattern baldness in women
 Premature closure of growth plates (short stature) in adolescents
 Hypertension, atherosclerosis, increased low-density lipoproteins, decreased high-density lipoproteins, myocardial infarction, CVA
 Cholestatic hepatitis, oesophageal varices
 Renal, hepatic, and prostate neoplasia
 Anaesthetic problems
 Avascular necrosis of the femoral head
 Gateway to other drugs, e.g. opioids

Interestingly, men appear to want more muscle and believe that women want them to have more muscle, whereas women do not find big muscles so attractive in their men!(Pope ea, 2000)

Examples of commonly used anabolic steroids (**after Rashid ea, 2007**)

Oral – methenolone acetate, methandrostenolone, oxandrolone, oxymetholone, stanozolol
Intramuscular – boldenone undecenoate, methenolone acetate, Sustanon 250 (4 esters of testosterone), testosterone enanthate or cypionate

Opiates suppress activity of the hypothalamic-pituitary-adrenal (HPA) axis, with decreased secretion of ACTH and cortisol. They also induce a blunting of the response to CRF, ACTH and stress, and a decreased response to metyrapone. Sudden opiate withdrawal leads to activation of the HPA axis a number of days after the last intake of drug. Glucocorticoid levels normalise with abstinence, although a blunted stress response and increased glucocorticoid feedback may persist for long periods. Acute cocaine intake increases glucocorticoid secretion, this effect decreasing with chronic exposure. Abrupt cessation of heavy cocaine intake also increases glucocorticoid secretion, but this promptly normalises with abstinence. Suppressed cortisol response to stress occurs in abstinent cocaine addicts unless when craving for cocaine is induced.(Piazza & Aouizerate, 2002)

Acute and chronic ingestion of alcohol increases glucocorticoid secretion²⁴⁴⁷ and secretion increases further during withdrawal but normalises quickly during abstinence. Glucocorticoid secretion is increased by intense cigarette smoking, tolerance to this effect often appearing with chronic nicotine intake; cortisol levels rise when a heavy smoker ceases his habit; abstinence leads normalisation (and even an eventual drop in) of cortisol levels.

²⁴⁴⁷ Leading in some cases to a pseudo-Cushing’s syndrome.

744 Erythropoietin

Erythropoietin, a doping agent, may cause polycythaemia, hypertension, myocardial infarction, cerebral sinus thrombosis and other cerebrovascular disease.(Lippi et al, 2006)

Caffeine²⁴⁴⁸

The central pharmacological effects of the methylxanthines (cardiac stimulation, diuresis, bronchodilation, and central nervous system activation), such as caffeine, involve competitive antagonism at adenosine (an inhibitory amino acid) P₁ receptors (meprobamate blocks reuptake of adenosine and acts as an adenosine agonist, causing sedation). This results in an increase in intraneuronal cAMP phosphodiesterase (a second messenger that augments the actions of many hormones and neurotransmitters, such as noradrenaline).

Coffee and tea, though not caffeine itself, substantially reduce phenothiazine absorption. Caffeine antagonises BZDs. Caffeine- (or halothane-) induced contraction of muscle tissue *in vivo* is employed in the standardised test for malignant hyperthermia.

Caffeine (125-2000 mgs.) given intravenously five minutes before each application of bilateral electroconvulsive therapy (ECT) decreases the seizure threshold with no loss of clinical efficacy and with a reduction in the stimulus intensity required.²⁴⁴⁹

Suddenly stopping even a relatively low caffeine intake may give rise to headache, fatigue, reduced vigour, dysphoria (increased scores on Beck Depression Inventory), and drowsiness that begin within 12-24 hours, peak at 20-48 hours, and last for about 7 days. Symptoms may be mild to severe, and use of unauthorised medications, such as BZDs, may increase. An intake of two or more servings of caffeinated beverages per day may place one at risk for withdrawal symptoms.

Symptoms of caffeine poisoning (affects up to 10% of population)

- Restlessness
- Anxiety
- Irritability
- Agitation
- Muscle tremor
- Insomnia
- Headache
- Sensory phenomena - tinnitus, lightheadedness, light flashes
- Diuresis
- Cardiovascular symptoms - tachycardia and abnormal rhythms
- Gastrointestinal problems - nausea, vomiting and diarrhoea

Overdose of caffeine (> 10 cups of strong coffee)

- Insomnia
- Restless excitement

²⁴⁴⁸ A stimulant,(O'Shea & Yek, 2002; Winston et al, 2005) caffeine is found in tea, coffee, soft drinks such as cola, and various prescription and non-prescription medicines. It is the most widely used psychoactive drug worldwide and in excess is unhealthy. The status of 'functional' or 'stimulant' soft drinks, containing taurine (2-aminoethane sulphonic acid), glucuronolactone, such as 'Red Bull', remains worrying, including a risk for stroke. Caffeine has a half-life of about 5 hours. Purine receptors, e.g. adenosine receptors, are divided into P₁ and P₂ subtypes (A₁ and A₂). If a patient is drinking lots of coffee to counter sedation from medications such as anticonvulsants it may be possible to replace caffeine with modafinil.

²⁴⁴⁹ However, using caffeine and right unilateral ECT, no change has been found in convulsive threshold. Problems include anxiety, agitation, nausea, retching, and prolonged seizures. There is a risk of cardiac dysrhythmia, mainly in the elderly and those with pre-existing cardiac disease. However, moderate use probably has no adverse cardiac effects. The present advice is not to give caffeine pre-treatment before ECT.(Scott, 2005, p. 113) The xanthine theophylline, which also lowers seizure threshold (and blocks P₁ receptors), can lead to status epilepticus which given with ECT. Therefore, theophylline should be stopped or given in as low a dose as is clinically feasible during ECT. Anyway, a small dose of phenothiazine given several hours before ECT may be effective in reducing seizure threshold.

- Tachycardia
- Muscle tension
- Vomiting, delirium and seizures (severe cases)

There may be a role for caffeine in producing cardiovascular disease, but methodological problems disallow firm deductions. Ground coffee brewed by mixing it with hot or boiling water may increase the serum cholesterol level, an effect that is substantially reduced by filtering, but caffeine may not be the culprit. Cancer links (e.g. pancreatic) remain unproven since many subjects smoke tobacco. There is a possible link with fibrocystic disease of the female breast, but some research suggests reduced breast cancer risk in women with BRCA1 or 2 mutations who consume at least 6 cups of coffee a day. Caffeine increases gastric acidity and is best avoided in people with peptic ulcer disease. A 30-year follow-up of 8,000 Japanese–American males (Honolulu Heart Program) singled out caffeine itself (independent of tobacco smoking status) as being associated with a reduced incidence of Parkinson’s disease. (Ross ea, 2000) Animal studies have linked caffeine with birth defects. Wisborg ea, (2003) in a prospective Danish study, found that heavy coffee intake during pregnancy was associated with having a stillbirth (8 or more cups of coffee per day increases the risk to twice that where no coffee is consumed) but not with death of the baby during the first year of postnatal life. Earlier, Cnattingius ea (2000) had reported that caffeine use may increase the risk of spontaneous abortions in early pregnancy. Whilst maternal caffeine intake negatively correlates with the baby’s birth weight, it has been argued that this applies only to mothers who also smoke cigarettes. Whilst the CARE Study Group (2008) found that caffeine restricts fetal growth, not all studies show that reducing caffeine intake has an effect on birth weight or length of gestation. (Bech ea, 2007)

Caffeine causes insomnia, especially in the older person.

Some causes of early morning wakening

Depression
Alcoholism
Anorexia nervosa
Caffeine

Caffeine can worsen many psychiatric symptoms, especially panic. Caffeine given under double-blind conditions made psychotic symptoms worse in schizophrenia. (Lucas & Pickar, 1990) There are connections between adenosine A2A receptors and the brain dopaminergic system: adenosine inhibits dopaminergic transmission and therefore blockade of adenosine A2A receptors by caffeine may increase activity of DA, leading to worsening of psychosis. (Ferre ea, 1992) Sudden cessation of caffeine intake can increase serum lithium levels by about 24%. Caffeine exaggerates the tremor of lithium.

The management of excessive coffee consumption is based on education, a stepwise reduction in intake over 1-2 weeks, and a final goal of a more acceptable intake. Caffeine is contraindicated in panic disorder. Caffeine pre-treatment for patients undergoing ECT remains an unsettled issue: side effects may necessitate lowering the dose of caffeine, and prolonged seizures require medical intervention.

Nicotine & tobacco

‘Every year 5 million people die from tobacco-related diseases, the world’s major preventable cause of death and disease’. (Arnott ea, 2008)

Nicotine is a highly addictive alkaloid from the leaves of the tobacco plant, *Nicotiana tabacum*. Of course, tobacco contains more chemicals than nicotine²⁴⁵⁰. Cigarette smoking induces the metabolism of many drugs so that cessation or curtailment of smoking (e.g. during hospital stays) may cause raised serum concentrations and side effects of such drugs (e.g. clozapine).

²⁴⁵⁰ Nicotine is not a recognised carcinogen or a cause of COPD but addiction to nicotine is the main reason for continued smoking.

Nicotiana tobacum

Fifty years after the Doll and Hill (1954) study of mortality among male British doctors who smoked, Doll et al (2004) reported that such men who were born during 1900-30 and who smoked died an average of 10 years earlier than non-smokers; over half of young doctors who continued to smoke during the 1950s would die as a result of smoking; among those born in 1920, prolonged smoking increased the age specific mortality three times; stopping smoking aged 50 years halved the risk; and stopping at 30 years of age almost returned the risk to that of non-smokers.

Tobacco use is the single most important preventable cause of death and disease in the western world, accounting for 19% of all deaths in the USA in 1990 and claiming more lives worldwide than war.

1991

European Community: 44% of men and 28% of women smoked

Britain: Over half a million British children aged 11-15 years partook of tobacco

USA: one-third of men and one-quarter of women smoked²⁴⁵¹

British GPs: 10% of were smokers

UK: 300 people died daily in the because of tobacco

Over 430,000 and 4.2 million died annually in EC and worldwide respectively

According to Edwards (2004) the decline in smoking in the UK may have ended – since 1994 the prevalence among adults remained at about 28%. This negative prognostication does not seem to be true since only 23% of men and 21% of women were smokers in 2006, with a decline in British smokers over 16 years of age from 24% in 2005 to 22% in 2006.(Creagh, 2008)

Nicotine is not the main component of cigarette smoke that accounts for the bulk of premature morbidity and mortality, but rather the 40-plus carcinogens and other toxic materials that are inhaled with it (Kawachi, 2003)

About a quarter of all persistent smokers in India are killed by their habit before age 70 years, losing about 20 years of life expectancy (Gajalakshmi et al, 2003)

Despite overall decline of the habit in countries such as the USA, many people continue to smoke

2001: Lifetime prevalence of nicotine dependence was estimated at 24%, and more women around the globe were taking up the habit About 100,000 people die each year in UK due to of tobacco-related illnesses, the figures for the Irish Republic being 17,038, 16,790 and 15,329 for the years 1990, 1995, and 1999 respectively

Percentages of males and females who smoked in Britain in 1972, 1982 and 1984 were 52, 38, 36 and 42, 33, 32 respectively, although more girls than boys were smoking in 1996

31% of adults in the UK smoked in 1991 – the same percentage of adults as now smoke in Ireland

35% of Irish people aged 15-17 years smoke, and one in five of those aged 9-17

Presently, about 13 million people in the UK are regular smokers

2008: US Congress debates legislation to have tobacco regulated by FDA

2008: The prevalence of smoking among Cork bar workers was very high before smoke-free workplace legislation (Mullally et al, 2008)

2009: According to the British Household Survey for 2007 the prevalence of smoking had fallen to 21% (highest rate of smokers = 20-24 year-old age group) (Mashta, 2009)

2009: US Senate passage of legislation allowing FDA to strongly regulate cigarettes and other tobacco products; ban on smoking within 1,000 feet of schools/playgrounds and tobacco-brand sponsorship of sports/entertainment; President Barack Obama signed *Family Smoking Prevention and Tobacco Control Act of 2009* in June giving FDA broad authority to regulate tobacco products

2009: Tobacco hidden from view in retail outlets

2009: EU survey finds 33% of people in Ireland smoke (was 33%, 27%, and 29% in 1998, 2002, and 2007 respectively)

2010: Eurobarometer study of European Commission: 29% of Europeans smoke and 49% never smoked; 38% and 16% allow smoking at home and in the family care respectively; circa one in 4 are exposed to tobacco smoke in the workplace

²⁴⁵¹ In 1991, 73% of Americans ever smoked; 27% currently smoked – contrasting with 85% and 51% respectively for alcohol use. In 2007 and 2008 19.7% and 20.9% of US adults were current smokers, the increase being due perhaps to stresses of economic recession but in the face of massive increases in federal tax on cigarettes.(Barclay, 2009)

A German study of 18-65-year-olds found a 36.2% prevalence of current smokers and a one-year prevalence of nicotine dependence of 9.4%. (Schmitz *et al*, 2003) Adolescent females were the only group who showed an increase in smoking incidence in the UK in 1991. Smoking is very common in psychiatric patients in all settings, but recording of smoking habits and intervention by medical personnel are uncommon. The High Court in England and Wales, when deciding on an appeal by patients at Rampton in 2008, decided that there is no absolute right to smoke in one's place of abode and that staff are not obliged to arrange for smoking areas²⁴⁵². (Ratschen *et al*, 2008) Some staff in psychiatric units fear that patients' might become more ill if not allowed to smoke. (Praveen *et al*, 2009) Poorer countries are targeted for sales when home markets contract and major cigarette producing nations are unlikely to wholeheartedly support international tobacco control agreements. Poorer countries have more smokers, e.g. 73% of males in Vietnam smoke. (Edwards, 2004) Poorer people in general are more likely to smoke than are richer people. **Cost:** Lost productivity in the US due to smoking-related mortality averages \$92 billion annually. Health care costs of smoking in the US amount to \$75 billion per year. (Anonymous, 2007)

Aetiology: Availability is crucial to aetiology, especially among the young. (Hanrahan, 2002; Dobson, 2005) Most starters are in their early teens and commence smoking for psychosocial reasons²⁴⁵³. The aversive hurdle of the first cigarettes has to be overcome. The great majority will later regret having started to smoke. Factors associated with adopting the habit of smoking include extraversion, a wish to emulate 'adult' behaviour, risk-taking²⁴⁵⁴, using larger quantities of other drugs²⁴⁵⁵ than non-smokers, lower socio-economic status, smoking by peers, relatives or idols, advertising²⁴⁵⁶, and, perhaps, a modest hereditary element. (Lessov *et al*, 2004) Adolescents are at high risk of smoking if their parents started to smoke when young and reached high intake quickly and were persistent smokers. (Chassin *et al*, 2008) Nicotine withdrawal leads to anxiety, restlessness, insomnia, irritability, sweating, poor concentration, listlessness and depression. (Jarvis, 2004) The body may take a long time to adjust to cessation of nicotine intake. One theory behind the need to continue smoking considers this physical addiction model. (Jarvis, 2004) Another theory centers on the ability of the smoker to control his level of arousal, such as decreasing it and so reducing the effects of stress or increasing it and so maintaining vigilance. The latter overcomes the effects of monotony and increases the selectivity of attention. Displacement of aggression may be important. There is some tentative evidence that female non-smokers may be calmed by acute nicotine inhalation, with anxiety and aggressiveness being evoked in male comparators. The exact relationship between nicotine and anxiety has been the subject of conflicting findings, some workers suggesting that smoking may be an aetiological factor. A positive relationship between family and personal smoking habits may be explained in terms of nature and/or nurture. The relationship with education varies between cultures, being associated with lower education in Britain but higher education in southern Europe. Tobacco revenue²⁴⁵⁷ is considerable²⁴⁵⁸. Reduced consumption following a shift to jobs outside the tobacco industry is unlikely to increase unemployment rates as much as the tobacco industry suggests. The difference between financial solvency and destitution for many pensioners relates to smoking status.

Patients with histories of major depression or anxiety disorders may experience particularly severe abstinence symptoms when withdrawing from tobacco.²⁴⁵⁹ Schizophrenic patients have very high rates of cigarette smoking, and may be at greater risk for tardive dyskinesia because of it. It has been suggested that patients with schizophrenia smoke to decrease their negative symptomatology, perhaps because of a primary central nicotinic defect that leads to abnormal sensory gating, or to transiently normalise the P50 so as to better enable them to filter incoming stimuli. Male adolescents have been found to smoke more than comparison subjects before they develop schizophrenia. (Weiser *et al*, 2004) Alcoholics smoke excessively as a group; in fact, more alcoholics die because they smoke than because they drink.

²⁴⁵² Nurse escorts would be required for outdoor smoking.

²⁴⁵³ Peer pressure, media, and esteem.

²⁴⁵⁴ E.g. not using seat belts.

²⁴⁵⁵ Such as coffee and alcohol.

²⁴⁵⁶ Including smoking in movies. (Sargent *et al*, 2001; Dalton *et al*, 2003)

²⁴⁵⁷ Prized by Napoleon III who challenged others to come up with an equally lucrative "vice".

²⁴⁵⁸ Yielding, e.g., IR£440 million (IR£330 m excise duty plus IR£110 m VAT) for the Irish exchequer in 1990. Cigarettes involve a \$47 billion market in the USA, \$3 billion less than it costs to treat their medical consequences. The Japanese government owned two-thirds of the nation's tobacco in 2003, a fact which may explain its tardiness in tackling the problem. (Watts, 2003)

²⁴⁵⁹ Neuroticism may be a factor in the predisposition to both of these psychiatric disorders and to smoking. Fergusson *et al* (2003) and Benjet *et al* (2004) argue for a link between smoking and depression, but admit that the direction of causality remains unknown.

Addiction potential: The modified Fagerström test for nicotine dependence (Heatherton et al, 1991) is commonly used. A maximum score of 10 indicates greater dependence. Relapse is best predicted by number of cigarettes smoked and how long before smoking the first cigarette of the day.

Modified Fagerström test for nicotine dependence

- How soon after waking do you smoke first cigarette? – score 3, 2, 1, and 0 for < 5 minutes, 6-30 minutes, 31-60 minutes, and > 60 minutes
- Do you find it hard to refrain from smoking in no-smoking areas? – 1 for yes, 0 for no
- Which cigarette would you hate most to give up? – 1 for first in the morning, 0 for the rest
- Number of cigarettes smoked daily? – 0 for 10 or less, 1 for 11-20, 2 for 21-30, 3 for higher
- Do you smoke more frequently during the first hours after waking than during the remainder of the day? – 1 for yes, 0 for no
- Do you smoke if so ill that you are in bed most of the day? – 1 for yes, 0 for no

Possible sources of reward in smoking can be divided into three main areas: sensory²⁴⁶⁰, social²⁴⁶¹, and pharmacological. A variation in the nicotine receptor may be associated with excessive smoking and reduced likelihood of quitting. Cannabis use is more common among young cigarette smokers. The tobacco industry appears to be not beyond utilising the popular image of drug abuse among its customers: as when, for example, they give out free key rings with a concealed vial attached. It has also attempted to neutralise anti-smoking legislation and has hired scientists to misrepresent the facts.(e.g. Hong & Bero, 2002; Ramsay, 2002; Hammond et al, 2006) Smokers exposed to smoking cues cause similar changes on PET-scanning to those found with other addictive substances: there is a significant positive association between craving and metabolism in the orbitofrontal cortex, the dorsolateral prefrontal cortex, and the anterior insula.(Brody et al, 2002)

Pharmacology: One definition of a smoker is that the carboxyhaemoglobin concentration in the blood is equal to or greater than 2% (normally < 1.5% in a non-smoker), or the nicotine breakdown product cotinine²⁴⁶² concentration is equal to or greater than 50 nmol/L. Yudkin et al (2003) confirmed abstinence on the basis of a salivary cotinine concentration of at the most 20 ng/ml or an expired carbon monoxide of 10 ppm or less. Use of store second trimester maternal blood in Scotland to measure cotinine revealed that self-reported smoking by pregnant women underestimated smoking status by 17%.(Shipton et al, 2009) Nicotine in cigarette smoke reaches the brain in ten seconds (or less), faster than when given intravenously.(Kawachi, 2003) Rats will press levers to obtain water containing minute concentrations of nicotine at a faster rate than for water devoid of the chemical.

Nicotine releases noradrenaline and dopamine in the animal brain, and increases dopaminergic activity in human basal ganglia. It is possible that one or both of these transmitters may activate limbic pathways. It is thought that activation of nicotinic acetylcholine receptors in the ventral tegmental area triggers DA release in the nucleus accumbens. Results of various studies suggest that heritable predisposition to smoking may be partly mediated by genetic variation in DA receptors and its transporter.(e.g. Audrain-McGovern et al, 2004) Tyrosine hydroxylase and alpha-2-adrenoceptors are reduced in the locus coeruleus of chronic smokers. Nicotine reacts with some acetylcholine (ACh) receptors but it sticks to the receptor for a long time. Hence the initial effect is ACh-like, but thereafter it blocks the action of ACh. By changing certain aspects of smoking behaviour, such as depth and duration of inhalation, smokers exert some control over the stimulation/inhibition ratio.

It appears that higher availability of the beta-2 subunit (beta-2*-nAChR) of the nicotinic acetylcholine receptor persists for up to a month after stopping smoking and returns to non-smoking levels by 6-12 weeks of abstinence.(Cosgrove et al, 2009)

Smoking significantly inhibits brain MAO-A and -B. Smoking one cigarette does not have this effect. It is therefore surmised that this action is not due to nicotine.

Rats who receive nicotine by continuous infusion will develop withdrawal signs when given naloxone. Morphine will attenuate withdrawal signs in rats when nicotine infusion is terminated. Therefore, opioid systems may be involved in dependence on nicotine, at least in the rat.(Malin et al, 1993)

²⁴⁶⁰ Olfactory, gustatory, and visual effects; ritual handling; orality.

²⁴⁶¹ Social image; displacement of affect onto ritualised activity; associated interpersonal activities.

²⁴⁶² CYP2A6 is involved in metabolism of nicotine and cotinine.

Intravenous nicotine acts on the nucleus accumbens (dopamine release), amygdala, cingulate and frontal lobes, as do cocaine, amphetamine and opiates, areas that are important for the reinforcing, mood-elevating and cognitive properties of such chemicals. PET data suggest that nicotine increases normalised rCBF in the left frontal region and decreases rCBF in the left amygdala; and that the rCBF in the right hemisphere reticular system is related to nicotine dose in an inverted U-shaped pattern and is strongly related to craving/addiction.(Rose ea, 2003) An fMRI study (Hong ea, 2009) suggested that severity of nicotine addiction is associated with the strength of dorsal anterior cingulate cortex-striatal circuits (not modified by nicotine patch) whereas short-term administration of nicotine increased cingulate-neocortical functional connectivity patterns (suggesting a role in cognitive enhancement).

Nicotine withdrawal is the most common abstinence syndrome in intensive care units. Wider swings in alpha wave activity on the EEG are seen in cigarette smokers (decreased when relaxed, increased when stressed) than in controls. Heavy smokers may need bigger doses of psychotropic drugs because cigarette smoke induces hepatic enzymes²⁴⁶³ so that, e.g., plasma tricyclic antidepressant levels are lowered and schizophrenic patients may need higher doses of clozapine, olanzapine and many typical neuroleptics. Similarly, psychotropic toxicity may follow smoking cessation. So-called 'low yield' cigarettes can probably deliver as much tar and nicotine as 'higher yield' versions.(White, 2002) The shift to low tar cigarettes may account for an increase in adenocarcinoma, i.e. low tar smokers may inhale more deeply, the smoke now reaching peripheral pulmonary areas where that tumour arises. Harris ea (2004) found that the increase in lung cancer risk is similar in people smoking medium (15-21 mg), low (8-14 mg) and very low (7 mg or less) tar cigarettes, and people who smoke non-filtered cigarettes with tar ratings of at least 22 mg have an even higher risk of lung cancer.²⁴⁶⁴

Some adverse effects of smoking

Cancer - lung²⁴⁶⁵, oro-pharynx²⁴⁶⁶, larynx, oesophagus, pancreas, breast²⁴⁶⁷, bladder

Risk factor for macular degeneration (Mitchell ea, 2002; Kelly ea, 2004), ophthalmopathy in Grave's disease, vascular dementia, stroke, and other cardiovascular diseases, including acute myocardial infarction²⁴⁶⁸ (Teo ea, 2006) and acute recurrent and chronic pancreatitis (Yadav ea, 2009)

May be an independent risk factor for non-insulin dependent diabetes mellitus²⁴⁶⁹ and age-related cataract

Increased susceptibility - acute coryza, chronic bronchitis/emphysema (COPD), TB, other respiratory diseases²⁴⁷⁰, and peptic ulcer

²⁴⁶³ CyP450-1A2.

²⁴⁶⁴ The EU stated that it would ban all statements like 'light', 'low tar' and 'mild', and from January 2004 the tar content of cigarettes would be reduced from 12 to 10 mgs and a ceiling of 1 mg would apply for nicotine. Gray and Boyle (2004) state that figures for tar, nicotine, and carbon monoxide are misleading and call for their removal. A US federal judge ruled in 2007 that tobacco companies cannot use words like 'light' or 'low tar' to sell outside the US.(Harding, 2007)

²⁴⁶⁵ This is now the chief cause of cancer-related death in American females. British lung cancer deaths overtook deaths from TB in 1952: 14,000 v 9,000. Age-standardised death rates per 100,000 population from lung cancer in Ireland in 1996 were 62, 25 and 42 for men, women and in total respectively, compared to EU average of 70, 15 and 38 and UK figures of 70, 31 and 47 [Croatia, Hungary and Poland had very high figures for males whilst the Iberian countries had particularly low figures for women.].(Brennan & O'Connor, 2003, p. 27) A study of lung cancer mortality in the EU (Didkowska ea, 2005) found it to be higher in central and eastern areas than in western parts and, for each sex, to be particularly higher in Hungary; the rate was declining in middle aged men in all new EU states but was still increasing among women in most countries in the EU.

²⁴⁶⁶ Increasing in American women because of increase in snuff use and chewing of tobacco. Bangladeshis living in the UK often chew tobacco. Young people of south Asian origin in UK are using more (cheap) smokeless tobacco products. Smokeless tobacco may cause a small increase in risk of fatal MI and CVA.(Boffetta & Straif, 2009) Important causes of oropharyngeal cancer include the alkaloids in *Areca catechu* (betel nut, *supari*) and tobacco (in cigarette, the chocolate cigarette known as bidis, through a hookah, or chewed as *gutka* [tobacco, betel nut, and other spices in colourful sachets] or *paan* [so-called because wrapped in green betel nut plant leaf – a paste may be added which may contain lime]).(Panesar ea, 2008)

²⁴⁶⁷ Timing in relation to parity and menarche may be crucial.(Band ea, 2002)

²⁴⁶⁸ Admissions for smokers and non-smokers with acute coronary syndrome declined in Scotland since the ban on smoking in enclosed public places in March 2006.(Pell ea, 2008)

²⁴⁶⁹ Both active and passive smoking may have a role in the development of glucose intolerance in young adulthood.(Houston ea, 2006)

²⁴⁷⁰ Whilst sarcoidosis may be less common in smokers, certain interstitial disorders are more common, e.g. idiopathic pulmonary fibrosis (cryptogenic fibrosing alveolitis), respiratory bronchiolitis-interstitial lung disease, and desquamative interstitial pneumonia.(Innes & Reid, 2006, pp. 715 & 717) Smokers are less prone to hypersensitivity pneumonitis (extrinsic allergic alveolitis – smokers have a decreased antibody reaction to the antigen) but more prone to byssinosis and primary spontaneous pneumothorax than are non-smokers.(Innes & Reid, 2006, pp. 719, 720 & 733)

Rheumatoid arthritis (e.g. Sugiyama *et al.*, 2010)

Aphthous ulcers²⁴⁷¹

Hypertrophic pyloric stenosis²⁴⁷² in infants

Impotence²⁴⁷³, infertility²⁴⁷⁴, miscarriages, stillbirth, neonatal birth, reduced quality of breast milk, cleft lip/palate, and cervical cancer²⁴⁷⁵; in infants and children, passive smoking (among other factors) is blamed for SIDS (Kinney & Thach, 2009), respiratory infection (including TB), cognitive impairment (Llewellyn *et al.*, 2009), and asthma²⁴⁷⁶

Unclear cause-effect relationship with panic attacks

Decreased response to treatment of mania.(Berk *et al.*, 2008)

Premature greying of hair may be an effect of smoking²⁴⁷⁷

Smoking is associated with reduced bone mass, increased risk of osteoporotic fracture, diminished serum levels of 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D and parathormone, which may be independent of lifestyle

Decease in financial resources, despite wide disparity of retail prices between countries

Deaths may be increased from cirrhosis, suicide and poisoning, although associated alcohol abuse and personality factors contribute

Smoking does not protect against Alzheimer's disease (Mehta & Yaffe, 2002) but smokers are less likely to develop aphthous ulcers or to die from Parkinson's disease.(Doll *et al.*, 1994a; Ben-Shlomo, 1996) Whatever the cause, smokers usually die younger than their peers do. The P3 component of visual event-related potential (ERP) is prolonged in current but not ex-smokers, whereas the P3 component of the auditory ERP has been reported as normal in smokers.(see Gamma & Liechti, 2002, for a review) Two thirds of women who stop smoking during pregnancy start smoking again after parturition.(Coleman, 2004a)

Passive smoking: The tobacco industry has engaged experts to state that passive smoking is either harmless or neutralised by ventilation²⁴⁷⁸.(Dobson, 2006) Large amounts of money are now being awarded for the victims of passive smoking, i.e. exposure to other people's smoke. The home is the main source of passive smoking for children and less than one in five parents in smoking households banned smoking in the home in a cross-sectional survey carried out in Coventry and Birmingham.(Blackburn *et al.*, 2003) The family car provides an even more enclosed space for passively inhaling smoke. Non-smokers married to smokers are said to have three times as much cotinine in their blood as do those married to non-smokers. However, raised cotinine levels in non-smokers also reflects passive exposure at work, in pubs, and restaurants.(Jarvis *et al.*, 1992)

Mortality rate is increased among adults living with smokers by 15%.(Hill *et al.*, 2004; Wen *et al.*, 2006)

Jamrozik (2005) estimated that passive smoking in the UK was responsible for 617 deaths of employed persons per year²⁴⁷⁹ and 2700 and 8000 deaths per year from domestic exposure in people aged 20-64 years and those over 65 years respectively.

Smoking during pregnancy is given greater coverage elsewhere.

Adverse effects of passive smoking

²⁴⁷¹ Basically the aetiology is not known and autoimmunity may play a part. Some cases have haematinic deficiencies, bowel disease, or AIDS and some cases are related to the menstrual cycle. Smoking cessation and other stressors are also thought to be related.

²⁴⁷² There may be a connection between maternal smoking and this condition but there are methodological problems with such research: not all confounding variables are controlled for and it is not known whether it is smoking during or after pregnancy that is important.(Sørensen *et al.*, 2002)

²⁴⁷³ Smoking is associated with erectile dysfunction in males, since smoking increases atherosclerosis of the penile arteries.(Kandeel *et al.*, 2001) It might reduce arousal in females.

²⁴⁷⁴ Women smokers reduce their chances of conceiving by up to 40% each month. Smoking couples are less responsive to infertility treatment. Smoking has a mild but negative effect on spermatogenesis, and may contribute to infertility, e.g. if a man has a varicocele, and impotence.

²⁴⁷⁵ Smoking damages epithelial DNA in the cervix uteri.

²⁴⁷⁶ A BMA report (*Smoking and Reproductive Life: The Impact of Smoking on Sexual, Reproductive and Child Health* – www.bma.org.uk)

²⁴⁷⁷ We know that smoking shortens the telomere.(Valdes *et al.*, 2005)

²⁴⁷⁸ In Germany, the tobacco industry stopped Lufthansa from banning smoking on domestic flights in the early 1990s.(Tuffs, 2008)

²⁴⁷⁹ Including 54 in the hospitality industry.

Lung cancer and other respiratory disease²⁴⁸⁰

Coronary heart disease (Whincup ea, 2004; McGhee ea, 2005)

Death from acute myocardial infarction (Teo ea, 2006) and stroke (Bonita ea, 1999; McGhee ea, 2005)

Stroke risk increased in non-smoking spouse (Glymour ea, 2008)²⁴⁸¹

Children of parents who smoke have high urinary cotinine levels as well as upper respiratory and hearing problems, exacerbations of asthma, sudden death in infancy (SIDS)²⁴⁸², and, possibly, brain tumours

Stopping smoking: Currie ea (2010) found that intensive smoking cessation services in Ireland in 2006 used evidence-based interventions but lacked uniformity and consistency. Smokers have become increasingly socially marginalised (Christakis & Fowler, 2008) but the marginalised cannot be forgotten. (Schroeder, 2008) Motivation to quit the habit is crucial, (West, 2004) and unplanned quit attempts may be successful. (West & Sohal, 2006) However, there is evidence that 'quit-success' genes exist. (Uhl ea, 2008) Although often unaware of their patients' smoking habits and not as interventionist as they might be, medical practitioners can influence a few smokers to quit, with large public health benefits. Smoking among doctors is common in China, Bosnia-Herzegovina, Chile and Russia but is rare in India, Australia, Iceland, Sweden and the UK. (Jamrozik, 2004a) Approaches aimed at quitting are many in number.²⁴⁸³ According to Rigotti (2002), bupropion and nicotine replacement may be equally efficacious.

Strategies for individual cases include

Contingency contracting²⁴⁸⁴ - monetary consequences of relapse

Set target date

Change to weaker brands

Keep record of number of cigarettes smoked

Nicotine fading - slowly cutting down

Avoid/change cues for smoking

Coping skills training

Take more exercise

Nicotine replacement therapy (NRT) is subject to much greater regulation than cigarettes (Kawachi, 2003), a position that needs to be reversed. (Mayor, 2007) Whilst the RCT evidence is that NRT is effective in helping people to quit smoking (Moore ea, 2009) it has been difficult to tease out the contribution of NRT from the support derived from regular contact with a professional. However, Piper ea (2009) conducted a double-blind RCT of nicotine lozenge, nicotine patch, nicotine patch plus lozenge, sustained-release bupropion, bupropion plus nicotine lozenge, or placebo, all participants receiving 6 individual counselling sessions; only the nicotine patch plus nicotine lozenge produced significantly higher abstinence rates at 6 months after quitting than did placebo.

²⁴⁸⁰ Methodological problems may make it difficult to attribute lung cancer to passive smoking and negative findings are controversial. (Smith, 2003; Enstrom & Kabat, 2003; Wise, 2008) but lung cancer risk is most likely greater if a spouse smokes. (Anonymous, 2002) Vineis ea (2005) conducted a prospective study using cotinine measurements and concluded that environmental tobacco smoke is a risk factor for lung cancer and other respiratory diseases, especially in ex-smokers. This is supported by evidence from Hong Kong. (McGhee ea, 2005) Blackburn ea (2003) found that banning smoking in the home led to a small but significant reduction in urinary cotinine to creatinine ratio in infants. Women with glutathione-S-transferase M1 deficiency due to gene deletion may not be able to detoxify certain carcinogens and so become more at risk from passive smoking. Work done in China suggested a connection between passive smoking at home and at work and COPD and respiratory symptoms, although a causal relationship could not be proven. (Yin ea, 2007)

²⁴⁸¹ Whincup ea (2004) failed to find any consistent association between cotinine concentration and stroke.

²⁴⁸² Smoking father doubles risk; smoking mother quadruples risk; both parents smoking increases risk 5 times.

²⁴⁸³ These can be summarised thus: behavioural (electric shock aversion or getting someone to smoke very quickly until nauseated; relaxation exercises, systematic desensitisation; programmed smoking and contract management with the exercise of self control), which are relatively disappointing; drugs (see table); acupuncture, hypnosis, sensory deprivation, and various forms of counselling and psychotherapy, including telephone helplines such as "Smokeline" in Scotland.

²⁴⁸⁴ Contingency management is particularly effective for substance misuse according to a meta-analysis. (Dutra ea, 2008)

In real life, few smokers receive combined pharmacotherapy and psychosocial therapy.(Kay & Tasman, 2006, p. 473) Women with the variant T allele of the D2 receptor DRD2 32806 may be more likely to benefit from nicotine patches than those with the more common CC genotype.(Yudkin ea, 2004)

Drugs used to aid smoking cessation

(a) Nicotine preparations to aid smoking cessation

*Chewing gum**: contains nicotine (N) in buffered resin - released N absorbed through buccal mucosa.

Vigorous chewing causes gastrointestinal upset. Try smaller 2 mgs size initially. Long-term dependence on the gum can occur; 5-10% using it after one year. Side effects include transient oro-pharyngeal irritation, nausea, flatulence, hiccups, and aggravation of dyspepsia.

Transdermal patch e.g. Nicorette (Invisipatch), Nicotil, NiQuitin. Place on side of chest. Skin reactions include erythema, oedema, and pruritus. The strength of patch varies from 5 to 30 mg depending on the preparation.

*Nasal spray**. Quick absorption: useful for heavy smokers. Can cause short-lived nasal and throat irritation, sneezing, cough and watery eyes. Dose: 2 sprays/nostril/hour for 16 hours/day, decreasing dose over about 3 months.

*Inhaler**. Holder and cartridge set. Can cause throat irritation and cough. Effective.

*Microtabs**. Placed under tongue, dissolving over 20-30 minutes. If you smoke at least 20 cigarettes/day use 1-2 tablets/hour to relieve cravings.

Lozenges. Nicopass, 1.5 mg in fresh mint and liquorice mint flavours. Niquitin lozenges have been advertised for those wishing to decrease cigarette consumption one at a time.

NicoShot: The German company Nautilus announced in 2005 that it was developing a beer containing 3 mg nicotine and 6.3% alcohol!

*e.g. Nicorette

(b) Mecamylamine, a nicotine antagonist, may have a role in blocking the rewarding effect of nicotine and thereby reducing craving.(Lancaster ea, 2000)

(c) Cytisine, a high affinity agonist for the $\alpha 4\beta 2$ nicotinic receptor and alkaloid found throughout *C. laburnum*, has been used for decades for smoking cessation in Eastern Europe. Although trials have been of poor quality, it may be effective.(Elter, 2006)

According to Nides ea (2006) the $\alpha 4\beta 2$ nicotinic partial agonist varenicline tartrate (Champix) appeared to be effective in the long and short term²⁴⁸⁵. The aim is to reduce craving, withdrawals and, if one smokes, pleasure from that act. However,

Varenicline²⁴⁸⁶ (Champix)

Use in adults (> 18) only; avoid in pregnancy; only give during breastfeeding on risk-benefit analysis basis

Dose: start 1-2 weeks before quitting smoking; first 3 days 0.5 mg once daily; days 4-7 0.5 mgs twice daily; then 1 mg twice daily for 12 weeks (prolonged use does not appear beneficial: Anonymous, 2008e); consider tapering dose

Side effects: abnormal dreams/insomnia/somnolence/fatigue/dizziness, headache, nausea²⁴⁸⁷/abdominal discomfort or distension/flatulence/dry mouth/ vomiting/constipation/diarrhoea/increased appetite, dysgeusia (distorted taste function)

Exercise caution: driving, machinery

Reports of depression that may include suicidal thoughts and behaviour in patients attempting to stop smoking with varenicline²⁴⁸⁸ (Anonymous, 2008e; Irish Medicines Board, 2008); also reports of psychosis in patients with mood disorder history and withdrawal-related psychosis.(Laine ea, 2009)

(d) Bupropion²⁴⁸⁹ (Zyban, 150 mg tabs)

This is structurally related to the appetite suppressant diethylpropion. It is recommended that the dose starts at 150 mg/day for 6 days, increasing to 150 mg twice daily with at least 8 hours between doses, the smoker giving up smoking during the second week of treatment. Sustained-release form effective in placebo-

²⁴⁸⁵ It performed better than placebo and bupropion but it is unclear how it compares with nicotine replacement.(Anonymous, 2008e)

²⁴⁸⁶ Pronunciation: va-re-nik-leen.

²⁴⁸⁷ Nausea is common.

²⁴⁸⁸ Smoking cessation *per se* may account for much of this. Gunnell ea (2009), although aware of methodological issues, found no clear evidence for a connection between varenicline and self-harm, fatal or non-fatal, compared with other smoking cessation products. However, prescribers of varenicline (or bupropion) should remain cautious.(Lavigne, 2009)

²⁴⁸⁹ British approved name is amfebutamone.

controlled, double-blind study; carbon monoxide in breath analysed for compliance check; usually minimal side-effects (dry mouth, insomnia, dreams, and seizures in 1 in 1,000 cases on 300 mgs/day; rarely causes serum sickness-like illness or psychosis – Michels & Marzuk, 1993); no weight gain; effect independent of depression; may be usefully combined with nicotine patch.

Bupropion studies have included intensive behavioural support, which raises efficacy questions about it or any other agent used alone. Absolute cessation rates are small. Bupropion may work by increasing dopamine concentration in nucleus accumbens. It may attenuate weight gain following cessation of smoking. It should be avoided if there is a risk of seizures (e.g. alcohol abuse or withdrawal, brain tumour, head trauma, eating disorder [electrolyte imbalance from starvation/purgation], antipsychotic medication [but Tsoi *et al.* {2010} found in a meta-analysis that bupropion reduced smoking rates in schizophrenia without harming the mental state], antidepressants, theophylline, and benzodiazepine withdrawal), during pregnancy, if there is anorexia or bulimia nervosa, if there is a history of bipolar disorder, or within 2 weeks of taking a MAOI. Concerns have been raised about both bupropion and varenicline and possible self-harm/suicide. (see Lavigne, 2009) Metabolised by CYP 2B6 – can prolong action of certain antidepressants (e.g. desipramine, paroxetine), 1c antiarrhythmics like propafenone and flecainide, and antipsychotics such as risperidone and thioridazine.

(e) Other antidepressants, especially nortriptyline, seem to be effective in helping people stop smoking. (Roddy, 2004; Aveyard & West, 2007) However, there appears to be no extra benefit from adding nortriptyline to nicotine replacement. (Aveyard *et al.*, 2008) SSRIs do not seem to be effective. (Hughes *et al.*, 2007)

Published studies of hypnosis show success rates ranging from 13% to 64% for smoking cessation; self-hypnosis training is stressed by practitioners, and a form of 'cognitive restructuring' is used by the client tempted to smoke: thoughts of harming body, quality of life, life span. Hypnosis appears to help some individuals, even if no more effectively than other effective measures or even no intervention. (Weinberger *et al.*, 2008, p. 433) but few trained practitioners are available.

A rare possibility is the occurrence of myocardial infarction if one smokes while wearing a patch, although most people have no increase in cardiac symptoms when wearing patches. The general advice is not to start smoking. Patches and gums probably deliver nicotine too slowly, often to a sub-optimal level, and nicotine sprays are often unpleasant. Nicotine delivery systems are often used not for smoking cessation but to ward off withdrawal symptoms during periods of enforced abstinence, such as air travel. The APA does not advise acupuncture, the benefits from controlled studies being inconsistent, e.g. Jain (2003) describes it as being no better than sham (not penetrating the skin) acupuncture²⁴⁹⁰.

Advice and continued-rather-than-brief-support given by the GP or practice nurse are effective when combined with nicotine replacement. According to Coleman, (2004b) intensive behavioural support from a trained counsellor is the most effective non-drug intervention, whilst a combination of such counselling and drug treatment is best of all. Twenty percent of those given nicotine replacement therapy with a specialist counsellor's support will remain non-smokers for one year. Measuring carbon monoxide levels in the breath can test for compliance. The actions of nicotine replacement cannot be explained on the basis of a placebo effect; the effect is dose-related, e.g. 4 mgs is better than 2 mgs. Authorities agree that the higher dose is more effective. Prescribing of smoking cessation products (free in Ireland since April 2001 for medical cardholders - just under 30% of the population) by GPs prior to 2002 was analysed by Tilson *et al.* (2004) Nicotine replacement therapy (NRT) was prescribed for the great majority (47,147 patients, 94.6% - 82.8% patches). 5.4% (2,679) received bupropion. Follow-up during 6 months of a free (2-week) nicotine patch programme in New York City (NYC) found that the highest quit rates were among the foreign born, older people, lighter smokers, and those who received counselling. (Miller *et al.*, 2005) 8.5% of a sample of NYC public high school students admitted to smoking in 2007, down from 17.6% in 2001²⁴⁹¹. NYC uses teenagers to expose retailers who sell tobacco to underage customers. (Anonymous, 2008a)

²⁴⁹⁰ A systematic review (Madsen *et al.*, 2009) questions the analgesic effects of acupuncture.

²⁴⁹¹ 23% and 20% of US and UK adolescents smoked in 2005.

Swedish moist oral snus²⁴⁹² (snuff) might be a healthier option than continuing to smoke tobacco.(Gartner ea, 2007; Britton & Macara, 2008) However, there is a tentative link between snus and pancreatic cancer.(Luo ea, 2007) Also, it is a controversial step to suggest one addictive product to replace another.(Furberg ea, 2008)

Mecamylamine non-competitively blocks ion channels at both central and peripheral nicotinic receptors and reduces the subjective effects of smoking. It can cause constipation, cramps, headache, and dry mouth. There is some evidence that it might be useful in helping people quit smoking if combined with nicotine patches.(Weinberger ea, 2008, p. 430)

Simple intervention by untrained nurses has significantly reduced smoking levels in patients admitted to hospital for coronary artery disease.(Quist-Paulsen & Gallefoss, 2003) Telling patients their spirometric lung age may improve the likelihood of smoking cessation.(Parkes ea, 2008)

Problems in getting people to quit smoking include failure to feel better for a long time and a tendency to weight gain. An abridged version of the motivational approach to interviewing recommended by the Tobacco Use and Dependence Clinical Practice Guideline Panel, Staff, and Consortium Representatives (2000) is shown in the box. However, this kind of approach does not always work, even in pregnant smokers.(Tappin ea, 2005)

Young smokers are difficult to help as the evidence base chest is near empty. Youngsters may see no urgency in quitting and services may be viewed as being more geared for their elders; also, cannabis smoking using tobacco as a vehicle is a major obstacle to successful intervention. Therapists are advised to take a supportive, non-confrontational stance.(Grimshaw & Stanton, 2008)

Five 'R's for use with currently unmotivated smokers

Relevance: be specific, e.g. medical risks to self/others

Risks: patient identifies acute (e.g. dyspnoea), long-term (e.g. lung cancer) and environmental (e.g. others take up habit, SIDS) consequences

Rewards: patient identifies positive effects of cessation, e.g. taste of food, improved health

Roadblocks: withdrawal syndrome, weight gain, etc

Repetition: repeat earlier steps at each visit & advise that failure is part of the road to success

One large US company paid employees to stop smoking and to stay off cigarettes with greater success than simply providing information.(Volpp ea, 2009) Longer follow up studies of this type would be revealing.

Prognosis: Two-thirds of smokers express a desire to stop and one-third try to quit the habit each year, only 2% succeeding. At least 80% have returned to smoking within 12 months (Jarvis [2004] puts the number of quits sustained to 12 months at < 3%). Prognostic factors relating to quitting are summarised in the box. About half of all regular smokers die prematurely; stopping to smoke in middle age avoids the bulk of the risk. A Cochrane review found that nicotine substitution treatment increased abstinence up to twofold, but, even with psychotherapy and behavioural therapy, abstinence rates remain very low at 5-15%.(Lancaster ea, 2000) One 8-year follow up of smokers who took part in a randomised controlled trial of nicotine patch therapy found that just under half of the 9% who had stopped smoking for one year had relapsed, leaving 5% of all trial participants continuously abstinent, and relapse rates were similar for patches and placebo!(Yudkin ea, 2003) Counterintuitively, some workers, while reporting high smoking rates among the mentally ill, also suggest that this group may have substantial quit rates. Brief interventions in cardiac inpatients have been shown to help motivated lightly-dependent smokers.(Hajek ea, 2002; West, 2002) According to Molyneux,(2004) only 5% of people who quit smoking successfully continue to use medicinal nicotine regularly.

²⁴⁹² Snus is a moist powdered smokeless tobacco product containing a reduced amount of nitrosamines that is placed under the upper lip for long periods. It is considered a 'white collar' form of tobacco because it does not induce spitting. Boris Yeltsin was a devotee.

Prognosis*(a) For stopping smoking*

Motivation

Living with a significant other person

Hypnotisability

Using transdermal patch: male at least 40 years old

Concern about weight gain

(b) Against quitting

Smoking cannabis

Smoking some cigarettes soon after quitting

Prevention: The best strategy is not to start in the first place. A 10% increase in taxation would cut tobacco consumption by 5-6%. High cost of cigarettes is most effective for the poor, teenagers and females²⁴⁹³.

Children should be the prime targets for campaigners; older people respond less to health publicity.

Counselling of mothers may reduce passive smoking by children in the home; however, reductions in passive smoking in England since the 1980s is attributable to less smoking parents and not to parents who still smoke not smoking near their children. Advertising²⁴⁹⁴, which has its political protectors, should be banned, as it tends to target women and young people, emphasising the 'stylishness' of smoking. Such bans are effective in reducing consumption. Candy cigarettes may increase the chances of young people progressing to tobacco. Voluntary advertising restrictions are insufficient. Tobacco companies allow their advertisements to be seen in movies. Counter-advertising should be financially supported and tobacco company sponsorship of sports should be made illegal. Involving teenagers in an anti-tobacco company poster campaign may be effective in reducing the number of youngsters who smoke. An EU directive banning tobacco advertising was contested by the tobacco industry. The tobacco companies are not beyond bribing politicians in the Third World²⁴⁹⁵. (Sebriè & Glantz, 2006) Nigeria is suing tobacco companies for targeting its youth. (Anonymous, 2008b) The Republic of Ireland banned tobacco advertising and sponsorship from July 2000. England has been much slower than Ireland in this regard, and one Bill suggested that formula one racing should be exempt for four years! (Kmietowicz, 2002) Kawachi (2003) called for an independent nicotine regulatory authority for Britain.

The Irish *Public Health (Tobacco) Amendment Act 2004* is monitored by an Office of Tobacco Control. Smoking is banned in public places.²⁴⁹⁶

²⁴⁹³ Packs of 10 cigarette banned in Ireland in 2007 under Tobacco Amendment Acts 2002 and 2004.

²⁴⁹⁴ Advertising of tobacco products will be absent from Irish shops from July 1, 2009.

²⁴⁹⁵ One in 3 smokers live in China. (Wright & Katz, 2007) 70% of men aged 30-60 smoke in China. (Dobson, 2009)

²⁴⁹⁶ Among the provisions are no advertising (in-store/retail), a ban on sponsorship, a ban on smokeless tobacco products (known to cause cancer including mouth and GIT, and heart disease – see below), a restriction on where vending machines can be situated (clubs, bars, hotels – where they must be supervised and activated by a token – tobacco must be stored in a closed container), a ban on confectioneries resembling cigarettes, the use of age cards, powers to get information on and test the composition of products, prohibition of such terms as 'low tar' and 'mild', extension of smoke-free areas, and the appointment of enforcement officers. Health Boards may take proceedings against persons breaching the provisions of the Act. As of July 1, 2009, anyone who sells tobacco must be registered with the Office of Tobacco Control. There is evidence that legislation for smoke-free workplaces does protect non-smoking bar workers. (Allwright ea, 2005)

The European Parliament voted against a ban on smoking on its premises in 2007. (Spinney, 2007) Norway and Italy introduced similar legislation to the Irish Act although the new Italian health minister was talking of undoing prohibitions on smoking in 2005. (Anonymous, 2005) Scotland introduced its own ban in 2006 with beneficial effects on second-hand smoke exposure. (Akhtar ea, 2007) especially in non-smoking homes. (Haw & Gruer, 2007) The British Health Secretary deferred a limited smoking ban until 2008 in 2004 (Kmietowicz, 2004) and legislation was to spare pubs that do not serve food. (McIntosh, 2005; Woodall ea, 2005) In 2005 the British Health Secretary promised such legislation for 2007, to be reviewed in 2010. In February 2006, the British Parliament voted for a total ban on smoking in public places. In fact, Wales introduced a ban earlier than England in 2007. India banned smoking scenes in new movies in 2005. (Mudur, 2005) The European Court of Justice (Luxembourg) threw out EU legislation against advertising in 2002 insisting that the ban must be directed against items traded across frontiers, forcing Brussels to go through the process afresh. Many authorities have banned smoking in the workplace, public areas, prisons, and restaurants, except in designated areas. In July 2008, the German Constitutional Court upheld the case of small bars that held that because large bars had enough room to divide off areas for smokers the smaller establishments did not have this option, so throwing the German ban into disarray. Smoke-free workplaces protect against passive smoking and encourage smokers to quit or reduce consumption. (Fichtenberg & Glantz, 2002) Even in hospitals, support for smoking bans among staff varies between professionals, e.g. Stubbs ea (2004) found that smokers and nurses in an English psychiatric hospital were more permissive toward smoking on wards than were non-smokers and psychiatrists. A short-

Requirements of a national tobacco control policy are shown in the box.

Components of a national tobacco control policy²⁴⁹⁷

Increase price of and taxes on tobacco at rate above inflation
 Ban all advertising and sponsorship by tobacco industry
 Restrict smoking to designated areas (public places and work sites)
 Reduce passive tobacco exposure, including *in utero*
 Target people at-risk for *starting* to smoke
 “Proof of age” cards required when purchasing tobacco; retailers to be banned from selling tobacco (or worse, e.g. fine/imprisonment) if found selling to minors²⁴⁹⁸
 Education and information, including prominent health warnings (including on packets)²⁴⁹⁹
 Health personnel to provide good example
 Reduce profits of tobacco industry and explore viable economic alternatives
 Monitor trends in use of tobacco and efficacy of interventions
 Very cheap (? on prescription) and accessible nicotine replacement in adequate dosage (current doses may be too low in many cases) and other cessation therapies – all nicotine replacement treatment (NRT) products are free on the British NHS and on the GMS (medical card) in Ireland (but see Yudkin *et al.*, 2003)
 Publish research and disseminate results
 Properly funded national organisation to support and co-ordinate efforts: a tobacco regulatory authority
 Fund policy with revenue from increased price of cigarettes, as in Massachusetts (funding by surtax was withdrawn in California!)
 Prevent smuggling²⁵⁰⁰

Litigation²⁵⁰¹: Increasing numbers of people are winning claims because of the effects of passive smoking, and claims are also being brought because of active smoking, which can succeed even if smoking starts after government warnings are issued.(e.g. Zinn, 2002) One US company (Philip Morris) opened a headquarters far away from US litigation in Switzerland – the same company was found by a federal court to be in violation of civil racketeering laws over a 50-year period (deceit, manipulating cigarette design, and suppressing research) in 2006.(Blum, 2008) The US Supreme Court ruled in December 2008 that smokers could sue the tobacco companies for deceptive advertising practices that suggest that ‘light cigarettes are relatively safe.(Tanne, 2009)

lived ban on public smoking in Helena, Montana seems to reduce morbidity from heart disease.(Sargent *et al.*, 2004) Bans on teenage smoking in the home, in school, and in public places may be effective. In keeping with an EC/EU directive, health warnings were increased in size and details of tar and nicotine yield were added on cigarette packets in the UK in 1992 and health warnings were greatly enlarged in the Republic in 2002. However, despite calls for weaker cigarettes, smokers may compensate for low nicotine yield by puffing more often and deeper, and by smoking more cigarettes. From January 2001 all cigarette packets in Canada carried health warnings that occupy 50% of the front of the pack, although attempts to ban sponsorship of public events by tobacco companies was watered down by the Quebec Court of Appeal in 2005.(Spurgeon, 2005) Following the lead of Canada and Brazil, the EU hoped to follow suit and display such off-putting pictures as rotten teeth and cancerous lungs on packets in 2004 (UK started to do so from October 2008). This would not be a legal requirement. Changing to cigarettes with a lower tar yield may not reduce the chances of myocardial infarction if one continues to smoke. Education about the effects of smoking on the fetus is important. Young Irish children could until recently readily buy cigarettes from retail outlets and retailers are obliged to ensure that prospective customers are at least 18 years of age. However, compliance with such regulations is imperfect.(Mullen, 2009) The Government in England & Wales will increase the minimum age for buying tobacco from 16 to 18 on 1 October 2007. France introduced a total ban in 2008. Some countries allow for designated smoking rooms, e.g. Italy, Sweden, Finland, Iceland, Uganda and South Africa.(Koh *et al.*, 2007) The Netherlands banned smoking in enclosed places in 2007 but closed smoking rooms (where staff may not serve) were allowed; illegal flouting of the legislation continued in cafes at the end of 2008 (Sheldon, 2008) although these cafes removed ashtrays in 2010. Iran and Uruguay have total bans on smoking in public places, Syria following them in 2009.

²⁴⁹⁷ See also Jamrozik (2004a,b), Britton and Edwards (2008), and McKee *et al.* (2009).

²⁴⁹⁸ 23 cases were taken to court in Ireland during 2008 for sales of tobacco to minors resulting in 19 convictions.

²⁴⁹⁹ Australia introduced plain cigarette packets with pictures of diseases in 2010.

²⁵⁰⁰ Price increases following taxation are offset by tobacco smuggling; over 10% of the market share is illicit; and the tobacco industry has been accused of involvement.(Arnott *et al.*, 2008)

²⁵⁰¹ Record individual compensation payments of \$35 bn and \$28 bn (€29 bn, stg. £18 bn) in 2001 and 2002 respectively were handed out in California. The tobacco industry may have deliberately undermined WHO’s anti-smoking efforts by manipulating public opinion. Some American insurance firms owned by tobacco companies have charged smokers almost double for term life insurance! Tobacco companies pressurised companies producing nicotine replacement products to tone down anti-smoking messages. One small US tobacco firm, Liggett, broke ranks, agreeing to settle claims and admitting to the disease-causing and addictive roles of tobacco, in order to get immunity from litigation.

In conclusion, the tobacco industry simply wants to sell their product and has no inherent interest in public health²⁵⁰². It is guilty of undermining the messages of health agencies. Tobacco dependence is a chronic disorder requiring repeated attempts aimed at eventual abstinence. Practical counselling and social support are important ingredients in management, as are sustained-release bupropion hydrochloride (e.g. Zyban) and the various nicotine replacement preparations. At least one of these therapies should be offered to smokers. The present author agrees with Howell (2002) that smoking cessation products should be free to all who wish to stop smoking, not just to those who qualify for medical cards. Doxepin, and probably other antidepressants, have also reduced nicotine craving. Further research is needed to determine the efficacy of pharmacological interventions. Many adult smokers started by buying three cigarettes from shopkeepers whilst underage, a failure of the state to protect them.

Methyl alcohol (methanol)

Mortality from methanol²⁵⁰³ (wood alcohol) poisoning is about 20% because of a metabolic acidosis from toxic metabolites (formaldehyde and formic acid²⁵⁰⁴). It can cause a haemorrhagic encephalopathy. The clinical features include confusion, ataxia, and visceral disturbances. Optic atrophy and cystic necrosis of the putamen may also occur. Treatment strategies include gastric lavage, ethanol or fomepizole (competes for alcohol dehydrogenase so inhibiting formic acid production), folate, bicarbonate, and haemodialysis.

Isopropyl alcohol (isopropanol, rubbing alcohol)

This is found in a number of products, e.g. hair tonic and after-shave lotion. It is converted to acetone, which can be detected in breath (odour), blood and urine. It can cause euphoria, ataxia, dizziness, headache, nausea, vomiting, haematemesis, nystagmus, confusion, coma, hypotension, and respiratory depression. Intoxication lasts about 12 hours. Most cases respond to supportive measures; gastric lavage and haemodialysis are options. Thiamine may be useful.

Ethylene glycol

This is found in antifreeze, windshield washer fluid, and radiator coolants. It is metabolised by alcohol dehydrogenase. A number of poisonous organic acids (e.g. oxalic) are formed. The person appears drunk but does not smell of alcohol. There can be tachycardia, hypertension, pulmonary oedema, metabolic acidosis, hypocalcaemia, myositis, coma, and convulsions. Calcium oxalate crystals form. Without treatment, renal failure often follows. Cranial neuropathies may develop late. Treatment is basically the same as for methanol poisoning: IV ethanol or fomepizole in order to inhibit metabolism. Thiamine and pyridoxine may also help. Severe poisoning is an indication for haemodialysis (which means ethanol or fomepizole dose should be increased) or haemodiafiltration.

Absinthe

This is a green, distilled, highly alcoholic, anise-flavoured spirit derived from herbs (e.g. flowers and leaves of *Artemisia absinthium*²⁵⁰⁵). It fell out of favour in Europe but has made a comeback. It contains the neurotoxin thujone. Opinion varies on its psychoactivity but it has been blamed for such phenomena as delirium and hallucinations. Rizvi et al (2010) have reported a case of acute suicidality that emerged during absinthe consumption.

(Ethyl) alcohol (ethanol)²⁵⁰⁶

'If the storm gets too loud, I take a glass too much to stun myself'. Vincent Van Gogh (1853-1890)

Epidemiology: Not everyone who drinks (ethyl) alcohol²⁵⁰⁷ will develop significant problems from its use. 4% of the global burden of disease is attributable to alcohol, equalling the mortality and morbidity associated with tobacco and hypertension. (Room et al, 2005) Only a quarter of people with alcohol-use disorders seek help, mostly from their GP, and they represent similar numbers in general practice as do hypertensive and diabetic patients. (Schuckit, 2009)

²⁵⁰² In 2007 Philip Morris announced that it would open a research laboratory in the USA. For a discussion on whether and how to collaborate with the tobacco industry see Gray. (2008)

²⁵⁰³ Methanol is present in antifreeze and solvents.

²⁵⁰⁴ Alcoholism is associated with *increased anion gap acidosis* via a number of mechanisms (lactic acidosis, ketosis of starvation, and poisoning with ethylene glycol or methanol). Anion gap = main cations ($\text{Na}^+ + \text{K}^+$) – anions ($\text{Cl}^- + \text{HCO}_3^-$).

²⁵⁰⁵ Also called *Wormwood*. Absinthe is sometimes known as *Green Fairy* due to its colour and is said to have been a favourite of Oscar Wilde.

²⁵⁰⁶ The older term alcoholism is retained here because the author believes in its broad utility. Also, it is a mistake to view alcohol dependence as an all or none phenomenon – it comes in all grades. (Hore, 1991)

²⁵⁰⁷ Ethanol or $\text{C}_2\text{H}_5\text{OH}$ or ETOH .

In 1991 85% of the US population ever used alcohol, 51% being current users at that time. The US National Longitudinal Alcohol Epidemiologic Survey (Grant, 1997) sampled people 18 years or older and found lifetime and past year prevalences of alcohol dependence of 13.3% and 4.4% respectively; males outnumbered females regarding alcohol use and associated disorders. The US National Epidemiologic Survey on Alcohol and Related Conditions²⁵⁰⁸ (Stinson et al., 2005) found a 7.35%²⁵⁰⁹ 12-month prevalence of alcohol use disorders in a representative American sample; co-morbid alcohol and substance use disorders had a prevalence of 1.10%.

Alcohol is the most important deadly ingredient in fatal road-traffic accidents (RTAs: Bellis et al., 2009; Dedford et al., 2009), especially on Saturday nights²⁵¹⁰. The legal age for purchasing alcohol in many US states was reduced to 18 during the late 1970s followed by an increase in RTA deaths. The legal age was raised to 21 in 1984 with the opposite effect. Nearly 50% of the roughly 35,000 annual fatal RTAs in the USA during the early 1990s were alcohol related, someone, usually the driver, being intoxicated, and 5% of drunk drivers killed had already had their licences suspended or revoked! Even aircraft pilots may underestimate the duration of alcohol's effects. (Modell & Mountz, 1990) Impaired psychomotor performance also leads to death from falls, drowning and burns.

Alcohol limits for drivers in the Republic of Ireland, 2009 (from December 1994)

80 mgs/100 mls of blood²⁵¹¹

35 micrograms/100 mls of breath

107 mgs/100 mls of urine²⁵¹²

Alcohol limits for drivers in the Republic of Ireland from September 2011

Road Traffic Bill 2009 passed by Dáil in June 2010

20 mgs/100 mls of blood for learner and professional drivers

50 mg/100 mls of blood for other drivers

European blood alcohol limits for drivers, 2009 (mgs/100 mls of blood)

0.0 Malta, Romania, Slovakia, Czech Republic, Hungary

0.2 Norway, Poland, Sweden

0.3 Russia

0.5 All other countries, including Turkey and North Cyprus

0.8 Luxembourg, Malta, Republic of Ireland (*vide supra*), Switzerland, UK

0.9 South Cyprus

(Germany is 0.3 if involved in an accident, otherwise 0.5)

Other countries, 2009 (examples)

Australia – varies with part of country; Brazil – zero; Canada – 0.8; China – 0.2; Congo – no limit; Egypt – 0.5; India – 0.3; New Zealand – varies with age (< 20 years – 0.3, otherwise – 0.8); Nigeria – zero; Pakistan – alcohol banned; USA – 0.8 (if you are under 21 years and have a level of 0.1 your licence is suspended)

Drivers are less likely to drink if they perceive the risk of detection to be high. Random breath testing increases the perceived risk.

The proportion of a population drinking excessively is largely determined by the average consumption of that population. The latter is determined by price, (Kendall et al., 1983; Purshouse et al., 2010) licensing laws²⁵¹³, and customs and moral beliefs. Islamic countries, especially Saudi Arabia, do not officially allow alcoholic consumption. Jews have low alcoholism rates, even when they live in high-risk districts. People whose jobs carry a high risk of alcoholism include those who have ready access to alcohol (chefs, barmen, brewery workers, kitchen porters - even some laboratory workers), those on expense accounts (salesmen, executives), seamen, printers, vagrants, printers, ex-convicts, doctors, and patients in general. Estimates of

²⁵⁰⁸ This and the National Longitudinal Alcohol Epidemiologic Survey were conducted by the National Institute on Alcohol Abuse and Alcoholism (NIAAA).

²⁵⁰⁹ This seems low.

²⁵¹⁰ Cannabis is also associated with fatal road crashes. (Laumon et al., 2005)

²⁵¹¹ This can also be expressed as 80 mg/dL or 17.4 mmol/L.

²⁵¹² Alcohol can be detected in urine for 7-12 hours after the last drink.

²⁵¹³ Although conflict of opinion still exist here.

the proportion of alcoholics among doctors have ranged from 3-15%. Women drink more now than in the past, but this may be improving in England²⁵¹⁴. In England, 38% of men and 23% of women drank more than the upper recommended levels for the heaviest drinking day of the week²⁵¹⁵. (Sengupta & Hoyle, 2005) Average consumption of alcohol in England, Wales and Scotland in 2006 was 13.7, 13.5, and 11.6 units/week respectively. (Creagh, 2008) However, the proportion of men drinking more than 21 units/week fell from 29% to 23% between 2006-2006. A fifth of British adults drank in excess of double the safe limit on their heaviest day of the week in 2007. (Mashta, 2009) Drinking was highest in managerial and professional households, men were heavier drinkers than women, and women were more likely than men to do their drinking at home.

The social stigma associated with the presence of women in pubs has largely disappeared and they have more money to spend. Women are more prone to early cerebral damage despite lower 'peak' alcohol consumption²⁵¹⁶, they may seek help less readily than do men, and they are also more prone to liver damage.

Barriers that may reduce likelihood of women seeking help for substance abuse/dependence

Social stigma

Too busy with offspring or elder care

Fear of loss of children

Fear of drug-using partner

Lack of child care services

Lack of transport

Poverty/lack of health insurance

Perception that drug services are not geared toward women

Heavy, regular drinking occurs at a later age in women than in men but there is a shorter length of time before women develop problems: this 'telescoping' effect in women has been described for other drugs as well as alcohol. (Yates, 2002) 27% of 15-year-olds (29% in girls) in the UK admitted drinking at least 5 consecutive drinks in the previous thirty days (increased from 22% in 1995). Almost half of this alcohol came from their family homes! (Anonymous, 2008d)

Age when drinking began in National Epidemiologic Survey on Alcohol and Related Conditions (Hingson et al., 2006)

Before age 14 years – 47% dependent on alcohol at some point and 13% dependent in prior year

After age 20 years - 9% dependent on alcohol at some point and 2% dependent in prior year

Alcohol costs the Irish economy about €2.6 billion annually. Over 4% of British government revenue derived from alcohol taxes in the mid-1980s during which 750,000 people worked in the British drink trade. The UK government receives about £75 bn annually in excise duties on alcohol. The total annual economic, health and social costs associated with alcohol misuse in England is somewhere between £20-30 bn. (Sengupta & Hoyle, 2005; Hall, 2005; Parker et al., 2008) The US government received \$14 bn annually in revenues from alcohol during the early 1990s. However, the economic cost of alcohol in the US is nearly \$200 bn a year. (Kelly & Renner, 2008, p. 337) About £4m was spent in 1985 by British brewers and distillers on sports sponsorship.

Rates of first admission per 1000,000 for England for both sexes rose from 4 in 1970 to 9 in 1986. The OPCS in Britain gave the following figures for 1993: rate of alcoholism = 4.7% (3M:1F) and rate of drug dependence = 2.2% (2M:1F). Both problems were more prevalent among young adults, especially males aged 16-24 years.

²⁵¹⁴ 17% of women drank more than 14 units/week in 2000, but only 12% did so in 2006. (Creagh, 2008)

²⁵¹⁵ Gilvarry (2006) states that, in the UK, 38% of males and 16% of females aged 16-64 years have alcohol use disorder, and that 21% of males and 9% of females are binge drinkers.

²⁵¹⁶ Women do achieve higher peak alcohol levels than men for the same intake – gastric mucosal alcohol dehydrogenase may be less active in women than in men. Alcohol dissolves better in fat and women have a greater amount of fat and less body water relative to men.

Almost 10% of Irish government tax revenue in 1989 came from alcohol. In both Britain and Ireland national alcohol advisory and monitoring groups had to disband because of lack of central support.

Admission to Irish psychiatric facilities for alcohol-related disorders

1991 188.5 per 100,000 of the general population - second only to 'depressive disorders' (235.0): 35%
- 11% of male and female admissions; 5% of inpatients alcohol-related

1992 21% of psychiatric admissions received diagnosis of alcoholic disorder
- Greatest proportion of discharges (46%) within one week of admission.
1993 21% of psychiatric admissions
1994 20%
1999 19% - 44%
2001 18% - 46% of such admissions left within one week*
2002 19% - average length of stay was only 13.8 days
2006 14%
2005 14%

*Admission rate for alcoholism in 2001 was 231.7 and 94.9/100,000 for males and females respectively. Follow up to 2005 confirmed that alcoholic disorders are a common reason for re-admission.(Daly ea, 2007)

The male to female admission ratio for alcohol-related disorders fell from 6:1 in 1968 to 2:1 in 2002.(Walsh & Daly, 2004) Admission rates vary between different services in Ireland,(Okonkwo & O'Shea, 2002) e.g. for 2004 county rates of first admission for alcoholic disorders/100,000 ranged from 68.9 in Co Wicklow to 9.4 in Co Cavan.(Daly ea, 2005)
Ireland had the highest increase in alcohol consumption among EU countries from 1989 to 1999 with an increase in per capita consumption of 41%! Ten other EU countries showed a decrease in consumption.

Alcohol consumption in Ireland²⁵¹⁷

Year	Litres pure alcohol/head of population
1998	11 ²⁵¹⁸
2000	14.2 ²⁵¹⁹
2001	14.3
2006	13.4

Cider consumption increased greatly and a big increase in consumption of spirits was largely a result of 'designer drinks'. About 25% of accident and emergency visits were related in some way to alcohol²⁵²⁰. Hospital-bed days due to alcohol-related disorders in Ireland increased from 55,805 in 1995 to 117,373 in 2004.(Mongan ea, 2007) Public order offences increased by 97% during 1996-2000 again largely related to alcohol.

Ireland topped the European list for binge drinking (> 5 pints or its equivalent/sitting) at 32 binges/year, Britain coming second with 28 binges. Also, Ireland spent more per household on alcohol (> €1,600/household/year) than anyone one else in Europe.²⁵²¹ According to the Office of Tobacco Control, Irish 16 and 17 year olds spend €145m on alcohol/year, i.e. €20.09 each/week.(Feely, 2008)

²⁵¹⁷ Figures vary widely wide source. According to Farren (2008) Ireland has the fourth highest alcohol intake in the EU (13.5 L/adult/year) and the highest level of binge drinkers in Europe (34% vs. EU average of 10%).

²⁵¹⁸ Second place in Europe.

²⁵¹⁹ EU average was 9.1 litres of pure alcohol/capita.

²⁵²⁰ This figure was 35% in the UK in a 2003 estimate.

²⁵²¹ In 1999, Ireland spent €1,675/household on alcohol (Denmark next at €531, UK spent €397, and Greece only €146): €1,195 on beer, €248 on spirits, and €232 on wine. According to the CSO, Ireland (Britain in brackets) in 1958 consumed 64.3 L (79.1) of beer and 1.2 L (1.1) of spirit/head of pop.

Alcohol in Ireland (Health Service Executive, 2008)

28% of injuries attending A&E are alcohol-related (A-R) – mainly present midnight to 6 am
 ¾ of these are male; almost ½ are 18-29 year-olds; 13% are alcohol-dependent
 1995-2004: 11,745 discharges for A-R injuries
 1995-2002: 92% increase in A-R discharges
 1994-2003: liver cancer had highest increase in cancer rates (10.7% increase in females and 7.4% in males)
 Unprotected sex: often A-R, especially younger adults (STIs increased by 217% during 1995-2004)
 1990-2006: 7,078 killed on roads, 2,462 being A-R
 1996-2002: public order offences increased by 247% (from 16,384 to 56,822)
 1996-2005: juvenile A-R offenses increased by 438% (from 784 to 4,217)
 1996-2002: 470% increase in public drunkenness
 46% and 42% of homicide perpetrators and victims intoxicated
 44% of respondents to a survey experienced harm by own/other's alcohol use
 63% of women reported alcohol use during pregnancy (of whom 7% drank 6 or more drinks weekly)

A study from Cork (O'Connor et al., 2008) suggests that university students are starting to drink earlier than heretofore and that they have little awareness of safe drinking levels.

The risk of accidental death in Taiwan is significantly associated with alcohol use disorder and with other common psychiatric disorders, especially when the two are combined. (Gau & Cheng, 2004)

Aetiology: Findings related to the aetiology of alcoholism as recorded in the third edition of this textbook are summarised in the box.

Aetiology of alcoholism: early findings and suggestions

Danish adoption studies - increase in alcoholism among the sons of alcoholics

Swedish studies - in some cases transmission is through the male line only but in others it affects both sexes
 Social factors/culture may account for some of the sex differences, e.g. the sex ratio (male: female) is 3:1 in the USA but 1.28 in Korea (Mack et al., 2003); peer-reared female macaques with the 1/s serotonin transporter genotype show a fondness for alcohol, (Barr et al., 2004) an example of an interaction of genes and rearing condition

Learning theory: classical and operant conditioning; modelling, relief of withdrawal symptoms by alcohol acts as a reinforcer for further drinking

Opinion differed on the role of underlying psychiatric problems predisposing to alcoholism – Klerman (1989) found that a substantial proportion of alcoholics had coexistent psychiatric disorders, especially schizophrenia, affective disorder, and dysthymia, other drug abuse, anxiety disorders²⁵²² (especially panic disorder) and PTSD, and he believed that non-medical therapists minimised the extent of psychiatric comorbidity in alcoholics. Kushner et al. (1990) felt that alcohol problems in those with agoraphobia and social phobia might be due to drinking alcohol in order to self-treat anxiety, that panic disorder and GAD could arise from excess alcohol intake, but that simple phobia was independent of alcohol. However, not all studies support a relationship between life-long anxiety and alcoholism. (Schuckit & Hesselbrock, 1994)
 P300 amplitude reduction in sons of alcoholics may be genetic²⁵²³ and lead to disinhibition; this phenomenon may be shared with childhood externalising disorders, antisocial personality disorder, and other substance use disorders. In their review of the literature on the P300 in alcoholism, Gamma & Liechti (2002) conclude that a small/reduced P300 amplitude is an endophenotype²⁵²⁴ in children and adolescents marking the risk for alcoholism/other substance abuse/various externalising (and perhaps internalising) disorders. However, they also admit that the similarity of P3 findings in smokers (nicotine) and alcohol-dependent people suggests that 'a substantial part of the P3 amplitude reduction seen in alcoholics or other substance-dependent individuals' might be explained by 'uncontrolled nicotine co-dependence'! Variation in the beta EEG band is highly heritable. Increases in beta power have been noted in alcoholics and their children and have been linked to chromosome 4p (an area containing genes for GABA receptors).

²⁵²² Anxiety may resolve up to 8 weeks after achieving abstinence, the prognosis being worse in those cases that persist. (Chick, 2007, p. 168)

²⁵²³ P3 amplitude appears to be linked to 4q close to the gene for alcohol dehydrogenase.

²⁵²⁴ An endogenous characteristic resulting from the genotype.

Kindling - a concept which has been used to 'explain' a number of conditions, such as alcoholism and relapse in bipolar affective disorder; in the case of experimental animals, a major motor seizure will occur eventually from intermittent electrical stimulation of the brain with a current which was originally insufficient to produce overt behavioural effects; this effect is generated with more ease in the limbic system than in the cortex; it is surmised that it reflects a permanent change in neuronal excitability

Three main models of familial influence on alcohol problems have been suggested: *family disease* model (assumption of roles of alcoholic or co-dependent that perpetuate the problem), *family systems* model (alcohol keeps the family unit together despite consequences), and *behavioural family* model (antecedents and consequences – classical and operant conditioning, and modelling).

Somewhere between 40-60% of the variance in alcohol abuse/dependence is accounted for by genes. There have been proposed linkages of alcoholism to the MNS blood group locus on chromosome 4 and a particular allele of the D2 receptor gene on chromosome 11q, although these reports lack replication and some workers have reported no linkage. Alcoholism, sociopathy and depression may run in families but their interrelationship is complex – there may be a tendency for a greater incidence of the first two diagnoses in males and the last diagnosis in females, although social changes may modify this observation. Hasin and Grant (2002) found that past alcohol dependence increased the current risk of having major depression more than fourfold. Alcoholics have been shown to have a significantly reduced frontal blood flow (largely associated with duration of drinking) which is more marked if there is associated dissociality. Twin and adoption (and combined twin-adoption) studies support an inherited tendency to develop alcoholism in both sexes.(e.g. Kendler ea, 1994) Children of alcohol-dependent parents who are reared by non-alcohol dependent adoptive parents have 3-4 times the risk of developing dependence on alcohol than do adopted children whose biological parents were non-alcoholic. People whose mothers drank when they were in the womb have increased chances of developing alcohol disorders themselves.(Alati ea, 2006) Lappalainen ea (2002) found an increased frequency of the Pro7 allele of a functional neuropeptide Y polymorphism in alcohol-dependent subjects versus controls. The sons of alcoholics have shown abnormalities of the P300 visual evoked response (reduced amplitude and delayed latency), a measure of visual information processing. The exact relationship of the abnormal P3 to alcoholism is controversial, one suggestion being that it actually relates to conduct disorder/antisocial personality disorder. Some people may have a genetic propensity to alcoholic brain damage, possibly related to variants in enzymes involved in B1 metabolism. Alcohol is broken down mainly via the alcohol dehydrogenase/aldehyde dehydrogenase pathway. At relatively high levels of alcohol intake the cytochrome P450 enzyme system becomes involved in the metabolism of alcohol, and this factor may have a role in the development of physiological tolerance.

ALDH2*2 allele (catabolises acetaldehyde more slowly than ALDH2*1) may be a protective factor against alcoholism, but psychological expectation may be more powerful determinants.(Hahn ea, 2006) Variants of GABRA2 on chromosome 4p are associated with the power of beta oscillations in the EEG and to alcohol dependence, or at least to impulse control since they may also be important in conduct disorder and substance abuse.

Animal and human studies suggest that 5-HT uptake inhibition (with, e.g. SSRIs) may reduce craving for alcohol. Smaller amygdala volume in alcohol-dependent subjects appears to be associated with alcohol craving.(Wrase ea, 2008) Early onset alcoholism may be associated with greater serotonergic abnormality and more antisocial behaviour. Alcohol potentiates selective 5-HT₃ receptor-mediated ion currents, an effect blocked by selective 5-HT₃ receptor antagonists like ondansetron. There is some evidence of an effect of ondansetron in reducing alcohol intake in cases with onset before 25 years of age but not in later onset cases.(Johnson ea, 2000) SPECT has revealed reduced brainstem serotonin transporter availability that correlated with lifetime alcohol consumption and with ratings of anxiety and depression during withdrawal. Deficiency of the active mitochondrial form of aldehyde dehydrogenase, common in Orientals, predisposed to a 'flushing response' on ingestion of alcohol. This deficiency, due to a base pair mutation in a single gene, is said to protect against developing alcoholism but, most likely due to cultural changes, binge drinking has increased in Japan and Asians in Hawaii (who possess the variant) have increased their

alcohol intake despite any aversive effects²⁵²⁵. Mission native American Indian adults with alcohol dependence are more likely to have the ADH2*1 allele than the ADH2*3 allele for alcohol dehydrogenase (chromosome 4) compared to those who were not dependent.(Wall ea, 2003) The A1 allele of the D2 receptor on chromosome 12p has been suggested as possibly having some connection with alcoholism, although this finding is hotly contested.

A Boston male twin study (Liu ea, 2004) found substantial genetic influence for age at diagnosis of alcoholism (49%).

Motivation to drink alcohol may be mediated by opioid peptides²⁵²⁶. The reward effect of alcohol could be a result of GABA receptor potentiation (alcohol releases GABA, increases neurosteroid levels, and may increase function of a GABA_A receptor subclass: Krystal ea, 2006). Functional serotonin deficiency is postulated to occur in many addictions.

20-79% of alcoholics have an antisocial personality disorder, compared to 1% of the general population.

Alcohol has been described as a 'personality disorder in a bottle'.

Jews uncommonly have alcohol-related problems, which finding most likely relates to custom and moral beliefs. Availability is a major and obvious factor. An increase in the average consumption of alcohol is associated with an increase in the prevalence of heavy drinking and related problems. The drunkenness of children who can buy alcohol-containing sweet drinks is a modern concern. Employment may be a factor, e.g. Walker (1991) reported that women in professional jobs drink more than women in unskilled positions. Judges are said to be at increased risk of dying from alcohol-related diseases.

Cheapness, a relative characteristic, of alcohol is associated with increased consumption.

The modern view is that nature and nurture interact to produce alcoholism. A low-risk environment, such as not experiencing excess alcohol use by the family, may reduce the effect of high genetic loading.(Jacob ea, 2003) Twin studies that search for genetic influences assume that twins share the same environment.

There is evidence that twins living together are more likely to be concordant in their normal drinking habits than when they live apart.(Clifford ea, 1984)

Alcohol receptors?

No such receptors have been found

Therefore, does alcohol work by changing membrane fluidity (and thereby alter receptors/channels?

Acute and chronic alcohol use appears to effect many neurotransmitters (5-HT, opioid, GABA, glutamine) which may mediate reward from alcohol through modulation of dopaminergic neurones in ventral tegmental area and release of dopamine in nucleus accumbens.

Taxonomy: Alcohol abusers tend to remain alcohol abusers and alcohol dependent patients tend to remain alcohol dependent.

The ICD-10 (F10) and DSM-IV classifications are summarised in the table. 'Harmful use' in ICD-10 simply means that one is harming ones health whereas 'dependence' has the same meaning as for heroin.

Alcoholism can be divided into

Alcohol related problems - social, psychological or physical

Alcohol dependence - manifested similarly to any other physical dependence:

Secretiveness

Buying extra rounds

Gulping drinks

Drinking alone

Stocking up

Giving other activities up

²⁵²⁵ People who start smoking often experience disconcerting nausea, cough, and dizziness and yet, if social pressure is strong enough, may persist with the habit to the point of dependence.

²⁵²⁶ Male Rhesus Macaques will consume more alcohol if they carry a particular variant of the mu-opioid receptor gene.(Barr ea, 2007)

Preoccupation with drinking
 Tolerance
 Withdrawal symptoms
 Relief of withdrawals with more alcohol
 High relapse rate
 Loss of subjective feeling of control over drinking behaviour

Jellinek (1960) types of alcoholic

Alpha - drinks to relieve physical or psychological symptoms

Beta - physical complications due to cultural drinking pattern and malnutrition

Gamma - craves for alcohol, loses control of intake, and experiences abstinence symptoms

Delta - no social disruption but continuous intake of alcohol

Epsilon - bout drinking or dipsomania

Cloninger's²⁵²⁷ (1987) two types of familial alcoholism:

Type I - transmitted to men but women can also develop it, drinking starts late, strong gene-environment effect (severity influenced by environment), and loss of control over drinking

Type II - transmitted to men, drinking starts early, less environmental influence and more spontaneous seeking of alcohol, and history of criminality in biological father

Major classifications and alcohol

(a) ICD-10 classification of 'mental and behavioural disorders due to use of alcohol'

Acute intoxication – 7 subheadings

Harmful use²⁵²⁸

Dependence syndrome - 7 subheadings

Withdrawal state – uncomplicated or with convulsions

Withdrawal state with delirium – with/without convulsions

Psychotic disorder – schizophrenia-like, delusional, hallucinatory, polymorphic, depressive, manic, mixed

Amnesic syndrome

Residual and late-onset psychotic disorder* – flashbacks, personality/behaviour disorder, residual affective disorder,

dementia, other persisting cognitive disorder, late-onset psychosis

Other and unspecified groupings

*This classification is a general one for psychoactive substances that may or may not apply to alcohol.

(b) DSM-IV 'alcohol related disorders'

1. Alcohol use – dependence and abuse

2. Alcohol-induced – intoxication, withdrawal (+/- perceptual disturbances), intoxication or withdrawal delirium, persisting dementia, amnesic, psychosis (+/- delusions or hallucinations), mood, anxiety, sexual dysfunction, sleep, & not-otherwise specified

Recognition: Alcoholism (like SLE and syphilis) is one of the great mimics and can present in a myriad of ways and affect any aspect of the alcoholic's or his or her dependants' lives. GPs and non-psychiatric junior hospital doctors may not be good at identifying alcoholics (or asking about alcohol), and psychiatric trainees may be only somewhat at documenting the alcohol consumption of patients but they still often fail to record drinking levels.(Barnaby ea, 2003) We may be ambivalent about our own drinking, ignorant of and complacent towards the effects of excessive drinking, and share the common belief that no one tells the truth about their consumption of alcohol.

The elderly patient is a classic pitfall for missed diagnosis.(McInnes & Powell, 1994; Dunne, 1994; Farragher ea, 1994) Reduced physiological reserve and metabolic efficiency, plus increased volume of distribution (increased fat/muscle ratio) leads to higher blood alcohol levels with greater likelihood of

²⁵²⁷ Babor's Types A and B resemble Cloninger's Types I and II respectively.(Babor ea, 1992)

²⁵²⁸ The difference between *hazardous* use (puts one at risk of harm) and *harmful* use (harm has already occurred) of a substance is contained in the words themselves.

intoxication and harm. Performance impairment, often subtle, is greater in older people than can be accounted for by blood alcohol concentration²⁵²⁹. (O'Connell & Lawlor, 2008, p. 647) A reduced intake does not necessarily mean safe levels, e.g. the elder may reduce his consumption because of decreased tolerance.

Non-intoxication in the presence of a blood alcohol level in excess of 200 mg/dL is pathognomonic of alcoholism. (Wise & Rundell, 2005, p. 157) The Michigan Alcoholism Screening Test (MAST) was devised by Selzer in 1971 (25 weighted questions²⁵³⁰). Pokorny later shortened it to a 10-question test. It is used as a screening test for detecting alcohol-related problems. The *brief MAST Questionnaire* is shown in the box. Mayfield ea (1974) devised the *CAGE Questionnaire* in 1984 (see also Ewing, 1984).²⁵³¹ The *Alcohol Use Disorders Identification Test*²⁵³², (AUDIT; Saunders ea, 1993) a 10-item screening instrument covers alcohol consumption, dependence, and consequences.

Some screening tests for alcoholism

THE BRIEF MAST QUESTIONNAIRE

Circle correct answers*

- | | | |
|--|---------|--------|
| 1. Do you feel you are a normal drinker? | YES (O) | NO (2) |
| 2. Do friends and relations think you are a normal drinker? | YES (O) | NO (2) |
| 3. Have you ever attended a meeting of Alcoholics Anonymous (AA)? | YES (5) | NO (O) |
| 4. Have you ever lost friends/girlfriends/boyfriends because of drinking? | YES (2) | NO (O) |
| 5. Have you ever got into trouble because of drinking? | YES (2) | NO (O) |
| 6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking? | YES (2) | NO (O) |
| 7. Have you ever had delirium tremens (DTs), severe shaking, heard voices or seen things that were not there after heavy drinking? | YES (2) | NO (O) |
| 8. Have you ever gone to anyone for help about your drinking? | YES (2) | NO (O) |
| 9. Have you ever been in hospital because of drinking? | YES (5) | NO (O) |
| 10. Have you ever been arrested for drunk driving or driving after drink? | YES (2) | NO (O) |

*The numbers in parentheses are the scores for each response. A score of 6 or more is registered as POSITIVE. The scores are not shown to the user in the form in which the questionnaire is used in practice, but they are given here for convenience sake.

THE CAGE QUESTIONNAIRE

Have you ever felt you should cut down on your drinking?

Have people ever annoyed you by criticising your drinking?

Have you ever felt bad or guilty about your drinking?

Have you ever had a drink first thing in the morning (eye-opener) to steady your nerves or to get rid of a hangover?

The cut-off point for alcoholism is between 2 and 3.

Each affirmative answer gets a score of 1. The maximum score is 4. A score of 2 or more is suggestive of alcoholism.

One unit of alcohol equals a half-pint glass of beer, lager or stout, a glass of wine or sherry, or a single measure of spirits.

1 unit of alcohol

8-9 G (sources vary) of (absolute) alcohol (a measure of convenience)

Increases blood alcohol by approximately 15-20 mg/dl

The amount that is metabolised in 1 hour

²⁵²⁹ Physical and cognitive status and concurrent medication contribute.

²⁵³⁰ Scoring of MAST: 0-4 no alcoholism; 5-6 possible alcoholism; > 6 probable alcoholism. Versions for geriatric use include G-MAST and brief G-MAST.

²⁵³¹ The CAGE has high specificity but only modest sensitivity. (Sackett, 1996, pp. 15-21) A negative CAGE does not rule out alcohol misuse.

²⁵³² Score of 8 or more in AUDIT = harmful/hazardous drinking; at least 13 in females and 15 in males = dependence. The *Drug Use Disorder Identification Test* (DUDIT, Stuart ea, 2003), modelled on the AUDIT, is an eleven-item self-report measure that screens for substance-related problems (other than alcohol). AUDIT can be useful in screening for problematic drinking histories in patients attending general hospitals because of self-harm. (Holdsworth ea, 2010)

Heavy drinking is not synonymous with physical dependence on alcohol.

Alcoholism is a major problem in industry and identification is based on unacceptable behaviour, impaired performance, lateness, 'inexplicable' accidents, and excessive absenteeism. Having excess drink on each occasion of drinking (say > 5 drinks) is as important as the overall intake when it comes to social and personal complications. (Room *et al*, 1995) This is the classic Irish pattern. The 'Monday morning syndrome' is too well known to require further description here. Between 8 and 14 million working days were lost through drinking in the UK in 1985, and absenteeism through alcohol misuse was estimated (Anonymous, 1989) to cost about stg £700m a year. The annual cost of alcohol misuse in Britain for 1990 was estimated at stg £2 bn if one includes ill health, crime, accidents and absenteeism. The direct annual specialist treatment costs in 1990 in the US and UK respectively was \$10.5 bn and stg £400m. Treatment of illnesses and injuries due to alcohol costs the British Government in the early twenty-first century up to £176 bn annually, total costs (absenteeism, crime, etc) reaching as high as £20

bn. (www.number10.gov.uk/files/pdf/interim-report.pdf) Barry (2003) gives the healthcare costs related to alcohol for the Republic of Ireland in 1999 as €279,000,000 and the total cost to society at €2,366,000,000. This takes no account of the effects on health, relationships, and child development.

About 25% of acute male admissions to medical wards, and an even higher percentage in the case of acute surgical emergency admissions, are related to alcohol misuse.

A number of tests are suggestive of excessive alcohol intake. Although not fully accepted (having low specificity for alcohol and often abnormal in ill non-alcoholics), the following tests are suggestive of alcoholism: A raised serum gamma glutamyl transpeptidase (GGT or γ GT) reflects heavy alcohol consumption during the preceding weeks²⁵³³. A raised mean corpuscular volume (MCV), a toxic effect on erythropoiesis, reflects long-term drinking habits but is not particularly sensitive or specific²⁵³⁴. A raised GGT due to alcohol to about half the index level after about three weeks of abstinence whereas a raised MCV takes longer to normalise and will therefore not help in relapse detection. Carbohydrate-deficient transferrin (CDT) is an alternative marker of excessive alcohol ingestion and may be more accurate than GGT for drinking during the previous fortnight. (Conigrave *et al*, 2002) Liver disease does not lead to raised CDT unless it is severe²⁵³⁵. Perhaps these tests are more useful if measured in series rather than acutely. If someone looks sober with a high blood alcohol level this suggests a regular heavy alcohol intake - the levels can still be high 24 hours after the drinking has stopped²⁵³⁶.

Reasons for misdiagnosis of excess alcohol consumption in the elderly (O'Connell *et al*, 2003)

Non-disclosure

Low index of clinical suspicion

Low referral rate because seen as understandable (poor health and life changes) and untreatable

Atypical (falls, confusion, depression) or masked (comorbid physical or psychiatric disorders) presentation

Non-applicability of 'sensible limits' (metabolic changes, ill health, increased sensitivity to alcohol)

Lack of consequences (social, legal, occupational)

Focus on recent (rather than lifetime) intake by diagnostic criteria and screening instruments

Self-disclosure of alcohol intake by elderly Irish interviewed in their homes showed a significant positive association between consumption and being male and widowed. (Greene *et al*, 2003)

Psychiatric problems: Deliberate self-harm is associated with alcoholic disinhibition. It was held that 6-20% of alcoholics committed suicide, although the accepted figure has dropped below the lower of these two figures in recent years²⁵³⁷. The alcoholic who was seen as at the highest risk for suicide was older, socially isolated, male, had made previous suicide attempts of serious intent, was physically ill and had a

²⁵³³ Gamma glutamyl transpeptidase levels are also elevated with hepatic disease, obesity, and a number of drugs (e.g. anticonvulsants, statins, and antidepressants, particularly lofepramine). Serum aspartate amino-transferase (AST) has lower sensitivity for alcohol than does GGT.

²⁵³⁴ MCV is raised macrocytic anaemia, hypothyroidism, hepatic disease, and anticonvulsant drugs.

²⁵³⁵ However, few laboratories measure CDT.

²⁵³⁶ This fact is well known to the authorities who may catch drivers on the way to work the morning after a night of drinking.

²⁵³⁷ Farren (2008) points out that low mood before drinking may be greatly exacerbated by alcohol. He also believes that 25% of suicides are solely due to alcohol (alcohol is present in the bodies of 58% of Irish suicides).

poor work record, and had recently lost a close relationship through death or separation. Elder abuse is usually related to chronic stress and low support, but a minority is associated with drug and alcohol abuse, sociopathy, intellectual disability, and various psychiatric disorders in the abuser, e.g. schizophrenia. (e.g. Wrigley, 1991)

Depression in alcohol misusers is often secondary to alcohol, although it may be primary in some cases (bipolar > unipolar depression). Opinion differs on how long a period of sobriety is required before an (alcohol-) independent diagnosis of depression can be made. A period of 2 weeks is often quoted. Certainly, alcohol use greatly complicates the management of depression. (Salloum et al., 2000) Disulfiram can precipitate depression. Tricyclic antidepressants may cause cardiotoxicity in combination with alcohol or in overdose (Anonymous, 2008c) and SSRIs are safer.

Alcoholics are at high risk for marital breakdown, unemployment, accidents, doing physical or psychological harm to others, becoming involved in unwise sexual encounters, and of imprisonment. Alcohol is a common cause of depression. It may also cause gradual coarsening of the personality and the emergency of sociopathic traits.

Syndromes associated with alcohol

Alcoholic dementia: Lishman (1987) suggested that this condition might account for at least 10% of all end-stage dementias. Intellectual function should be tested after a period of total abstinence. Exclude continued inebriation and control for the effects of general neglect. Radiological studies revealed decreases in brain volume in many chronic alcoholics. This is at least partially and very slowly reversible with prolonged abstinence: it is debated as to whether reversal is due to rehydration of the brain or repair of neurones or myelin. (Mann et al., 1993) Autopsies of alcoholics revealed a significant decrease in cortical neurone numbers in superior frontal cortex with no difference from controls in terms of number of neurones in motor cortex. In both cortical areas there was evidence that alcoholics had smaller, shrunken neurones than controls.

Possible causes of cognitive disorders in alcoholics include premorbid intellectual deficit, direct ethanol neurotoxicity, neurological complications of alcohol (e.g. Korsakoff's), thiamine or nicotinic acid deficiency, recurrent head trauma, and hepatocerebral degeneration. There is controversial evidence that light to moderate drinking may reduce the chances of developing dementia, even when other variables like smoking are controlled for. (Ruitenberg et al., 2002; Stampfer et al., 2005; Fratiglioni et al., 2008, p. 395) More common than dementia is subtle cognitive dysfunction that may interfere with understanding of medical advice and adherence to a plan of treatment.

Alcoholic hallucinosis: This state may follow immediately from DTs or may commence whilst still drinking. Most cases clear up quickly after drinking is stopped although hallucinations may return if drinking restarts. The auditory hallucinations occur in the presence of a clear sensorium and may take the form of 'noises'²⁵³⁸, conspiratorial and threatening whispering, accusatory voices, etc. The patient may become paranoid, hostile or suicidal as a result, or he/she may take flight or hide. A few cases may have schizophrenia (5.3%, 11.5%, and 19% in Bendetti [1952], Victor & Hope [1958], and Cutting [1978]) – such cases are more likely to have a family history of schizophrenia and poorer premorbid adjustment. Treatment includes detoxification from alcohol and neuroleptics for hallucinations. The therapist may try to stop neuroleptics after a few months. ECT may sometimes be required.

*Delirium tremens*²⁵³⁹ (*Rats, DTs, alcohol withdrawal delirium* in DSM-IV): This occurs in less than 5% of cases in alcohol withdrawal. (American Psychiatric Association, 2002, p. 300) Often occurs when alcohol intake is stopped, such as following hospitalisation. Usually starts at night. It lasts from 2-7 days (sometimes weeks in the elderly – may resemble dementia). Features include intense fear, restlessness, illusions, delusions, visual hallucinations²⁵⁴⁰, tremulousness, ataxia, vestibular dysfunction²⁵⁴¹, hypertension, tachycardia, leucocytosis, impaired hepatic function, and pyrexia. An interesting phenomenon which may occur during the DTs is the carrying out of occupationally related activities, e.g.

²⁵³⁸ One patient of the author heard 'crashing glass' that he interpreted as deliberately meant to be upsetting.

²⁵³⁹ Term coined by the English physician Thomas Sutton (1767-1835) in 1813. The DTs is sometimes known as Saunders-Sutton syndrome. William Saunders (1743-1817) was a Scottish physician.

²⁵⁴⁰ E.g. little animals (microzoopsia).

²⁵⁴¹ The patient feels the floor is moving or that he is rising as if in a lift (elevator).

the barman who 'pulls pints' for the other patients with the bars of his cot (*occupational delirium* or *professional delusions*). Fever may be part of the core syndrome or due to a complication such as aspiration pneumonia. High blood pressure, tachycardia, and tremor may be obscured by medication that the patient is taking, e.g. calcium channel blockers, beta-blockers, and alpha-2-adrenergic agonist drugs. The mortality rate from DTs has fallen due to better detection and medical management, decreasing over the years from 20% to c. 1%. Treatment involves sedation (e.g. alprazolam or chlordiazepoxide in large doses²⁵⁴²), thiamine, folate, multivitamins, a high-carbohydrate diet, and the reversal of metabolic disorders. Haloperidol may be needed for psychotic agitation. Infection requires attention. Death can be due to cardiovascular collapse, infection, and self-injury²⁵⁴³ when restless. If pneumonia²⁵⁴⁴ occurs the death rate can climb to 25%. Subdural haematoma, pneumonia, and meningitis should be considered in the disorientated alcoholic. The dosage of drugs should be tailed off to zero over a number of days. The cumulative effects of sedatives may cause hypostatic pneumonia if they are prescribed in high dosage for too long, especially with an IV infusion of chlormethiazole (Heminevrin) which may also cause death from respiratory depression²⁵⁴⁵. Ethanol could potentially be used to treat the DTs and is less cumulative than Heminevrin: 30 mls initially, followed by 10 mls every hour in 50% dextrose. Fluids should be replaced sparingly because alcoholics have a reduced ability to excrete water and a tendency to cerebral oedema.

Black-outs: This refers to memory lapses ('memory blackouts') following a heavy bout of drinking despite observers not noting any significant change in level of consciousness. (It therefore differs from amnesia secondary to gross impairment of consciousness due to very high levels of alcohol.) It can occur in normal drinkers. It is more likely to be abnormal if it occurs frequently or if the episodes of amnesia last for days. The drinker cannot remember where he left his car, who was with him at the time, and so on. Interestingly, people may find their way home unaided and not remember doing so. State dependent phenomena may sometimes occur, e.g. he can only complete a letter or remember at which hotel he left the car when intoxicated again. It should be noted that blackouts can be caused by BZDs, especially those of high potency like triazolam. (Greenblatt et al, 1991)

Pathological (idiosyncratic) intoxication (manie à potu): This has been used as a defence in courts and refers to the occurrence of extreme intoxication despite the intake of a relatively small amount of alcohol. Many experts doubt its existence. It is not included in DSM-IV or ICD-10.

Hypoglycaemia: Factors responsible include malnourishment (low hepatic stores of glycogen) and inhibition of hepatic gluconeogenesis by alcohol. Care should be taken because it is possible to induce Wernicke's encephalopathy by injudicious replacement of glucose in a thiamine (B1)-deficient patient. Ethanol-induced hypoglycaemia does not respond to glucagon. Treatment is with glucose **and** vitamin B1. Children who take alcohol (not necessarily in large quantity), binge drinkers, and chronic alcoholics have relatively little glycogen reserve in their livers and may present in a comatose state with hypothermia.

Fever: This may occur during alcohol withdrawal. Causes are hypovolaemia, lung (incl. aspiration and TB)/meningeal/peritoneal (esp. with ascites – ideal culture medium – bacterial peritonitis can occur in the absence of abdominal pain/tenderness or leucocytosis)/urinary tract (incl. catheter-related) infection, alcoholic hepatitis²⁵⁴⁶, and acute²⁵⁴⁷ and chronic²⁵⁴⁸ pancreatitis. Consider CSF examination in confused patients.

Hypertension: About a quarter of alcoholics have systemic hypertension, often resolving (to various degrees) with abstinence. Always consider excess alcohol intake in hypertension that is poorly controlled.

Retrobulbar neuritis and optic atrophy: These are classically associated with methanol but can occur with ethanol. The retrobulbar neuritis usually comes on insidiously and causes central loss of vision, typically red-green blindness.

²⁵⁴² Use lorazepam if there is very poor liver function. Propofol may be effective when everything else fails.

²⁵⁴³ These patients put themselves at risk and may fall from a height or otherwise injure themselves.

²⁵⁴⁴ Pneumonia in the alcoholic may be caused by unusual pathogens, e.g. anaerobes and gram-negative organisms such as *Klebsiella pneumoniae*. (Moss & Burnham, 2006)

²⁵⁴⁵ Clomethiazole with alcohol is very likely to depress breathing.

²⁵⁴⁶ The cardinal pointer is rapid onset of jaundice +/- pyrexia, ascites, proximal muscle loss, and, in severe cases, encephalopathy. The liver is usually big and tender. (Lucey et al, 2009)

²⁵⁴⁷ Gallstones, alcohol, endoscopic retrograde cholangio-pancreatography (ERCP), and idiopathic cases account for 9 out of 10 cases of acute pancreatitis.

²⁵⁴⁸ 8 out of 10 cases in the West are accounted for by alcohol misuse.

Epilepsy: Many alcoholics experience convulsions. There are many causes. Focal CT abnormalities are unlikely if there are no focal neurological abnormalities and if the answer is in the affirmative to 50% or more of CAGE items. When they form part of a withdrawal state they may be referred to as 'rum fits' (can occur from day 1-14 after cessation or diminution of alcohol intake). Other causes, such as a subdural haematoma, should be considered.

Neuropathy: This is usually a polyneuropathy, with sensory, motor and autonomic signs: numbness, paraesthesiae, burning dysesthesia, pain, weakness, muscle cramps, gait ataxia, loss of tendon reflexes (including ankle jerks), defective perception of touch and vibration sensation. Autonomic disturbance is less common and may carry an increased risk of death. Sensory disturbance takes on a glove-and-stocking distribution. Treatment: if the patient stops drinking and if nutrition is improved the prognosis should be good.

Myopathy: This is more common than one would think from the number of cases diagnosed in clinical practice. There are a variety of possible causes, such as a direct toxic effect of alcohol or hypokalaemia. It can be acute and necrotizing, or have a more insidious onset. The acute form may occur during an alcoholic binge, when the patient develops weakness, tenderness, and swelling of the affected musculature. He may develop dysphagia and congestive heart failure. There may be elevated CPK levels and myoglobinuria. The chronic form is more common and pain is less prominent - there are muscle weakness and atrophy, especially affecting the hip and shoulder girdles.

*Liver disease*²⁵⁴⁹: A steady daily intake of alcohol is more hazardous to the liver (cirrhosis) than is intermittent drinking. Cirrhosis usually occurs with an intake greater than 40 G in men and 20 G in women. The person has been drinking at such levels for at least 5 years (usually > 10 years) before developing cirrhosis. It is interesting that some chronic heavy drinkers do not develop cirrhosis.

Foetal alcohol syndrome: This is described elsewhere.

Marchiafava-Bignami disease: This uncommon condition, described in 1903, is often diagnosed at postmortem. It affects chronic alcoholics who develop symmetrical degeneration of myelin in the central part of the corpus callosum. The cerebellar peduncles may also be involved. Neurological features include ataxia, hemiparesis, dysarthria, aphasia, apraxia, coma, and grand mal seizures. Most cases have psychiatric manifestations, e.g. personality change, confusion, mania, paranoid states, various delusions, depression or dementia. There are 3 possible courses: early coma with fatal outcome, prolonged survival in a demented state, and, rarely, recovery. Lesions can be seen on CT or MRI: necrosis of corpus callosum and the adjacent subcortical white matter.

Cerebellar degeneration: This is due to degeneration of Purkinje cells in the cerebellar cortex, possibly because of thiamine deficiency. The patient has usually been drinking for many years. (Moderate longterm alcohol intake causes Purkinje cell loss before any macroscopic atrophy appears.) It may have an insidious or an abrupt onset. Gait ataxia (broad-based gait) and dysarthria occur. Nystagmus is rare. Treatment involves stopping drinking and taking thiamine. The patient may then stabilise or improve.

Central pontine myelinolysis (osmotic demyelination syndrome): This rare disorder of cerebral white matter (Adams *et al.*, 1959) has many causes. Rapid correction of hyponatraemia (common in beer drinkers, esp. when replacing vomited fluids with hypotonic fluids) may be a factor in the aetiology (although not invariably so: Ibrahim & Hennessy, 2007), the condition presenting a day to a week later. This hyperosmolality may affect brain water levels. The patient is usually an alcoholic but alternatively he may suffer from non-alcoholic hepatic disease (including Wilson's disease), hyperemesis gravidarum, malnutrition, burns, cancer, Addison's disease, anorexia, or hyponatraemia due to diuretics. It is a rare complication of liver transplantation. (Surman & Prager, 2004, p. 664) There is a triangular area of pallor at the base of the pons. There are demyelinated axons with preserved cell bodies and (not always) cavities in the centre of the lesions. The patient may have paraparesis, quadriparesis, dysarthria, dysphagia, inability to protrude his tongue, various tendon reflex changes, the presence of Babinski's sign, abnormal conjugate eye movements, and the 'locked-in' syndrome (normal consciousness, paralysed, can communicate with eyes and eyelids). MRI scans are especially useful in advanced cases for showing up the lesions. High-resolution CT can also detect the lesion during life.

²⁵⁴⁹ Discharges for alcohol-related liver disease in Ireland rose by 147% in the period 1995-2004.

Ischaemic strokes in young males were reported in association with alcohol during the 1980/90s in the US, Sweden and Scotland.

The Amnestic syndrome (ICD-10) or disorder (DSM-IV): Wernicke and Korsakov²⁵⁵⁰ described their patients in 1881 and 1889 respectively. Wernicke (of 'receptive dysphasia' fame) described an acute neuropsychiatric reaction to severe vitamin B1 deficiency with nystagmus, abducens and conjugate gaze palsies²⁵⁵¹, gait ataxia, and global confusion. (Most cases of Wernicke's encephalopathy present with delirium alone²⁵⁵²: Harper *et al*, 1986) All of Korsakoff's cases had polyneuritis and so he called it 'psychosis polyneuritica'. The lesion is usually in the posterior hypothalamus and nearby midline structures. Less commonly there are bilateral hippocampal lesions (in this type there is less tendency to confabulate – confabulation and loss of insight into memory loss may be most marked in thiamine-deficiency cases). Wernicke's encephalopathy is best seen as the acute end of a spectrum with Korsakov's (or Korsakoff's) psychosis (or syndrome) at the chronic end, i.e. the Wernicke-Korsakov syndrome. The core of the chronic condition is an inability to form new memories with or without confabulation²⁵⁵³. One can usually demonstrate that certain forms of memory capacity are retained, e.g. those not requiring a verbal component like visuospatial and geographical memory: the classic example is the inpatient that has no problem negotiating his way to and from the pub! There may be a hereditary susceptibility related to genetic polymorphism for the transketolase enzyme that requires thiamine as a co-factor²⁵⁵⁴. (Blass & Gibson, 1977) The causes of the syndrome are alcohol, hunger strikes, the life of a prisoner-of-war, anorexia nervosa, thyrotoxicosis, GIT ulcers and cancers, intestinal obstruction, vomiting (hyperemesis gravidarum), haemodialysis, post-encephalitis (e.g. Herpes simplex), puerperal sepsis, anoxia (e.g. CO poisoning), vascular lesions (e.g. infarction of the thalamus, subarachnoid haemorrhage) and gastric/bariatric surgery (Foster *et al*, 2005). The mechanism in alcoholism, malnutrition and malabsorption is thought to be thiamine deficiency. Other causes are bilateral temporal lobectomy, tuberculous meningitis, and tumours of the third ventricle. In cases with slowly expanding brain tumours, the amnesia will be progressive. Wernicke's encephalopathy may be precipitated by alcohol withdrawal and perhaps by the first meal. **One should never give glucose IV to an alcoholic without first making sure that he has enough thiamine** (e.g. Pabrinex, a parenteral multivitamin preparation) **because Wernicke's encephalopathy may be precipitated**. Jackson and Teece (2004) found oral thiamine as effective as parenteral thiamine in the emergency department. It is often stated that it is pointless giving in excess of 50 mgs of thiamine daily because the body cannot absorb any more than that. However, absorption is often poor in alcoholics, and the present author gives at least three times this dose. (*Poor response to thiamine may indicate hypomagnesaemia, which responds to magnesium sulphate.*)

In the famous Victor *et al* (1971) study of 245 patients with the acute Wernicke-Korsakov syndrome (most of whom were chronic alcoholics) 17% died early on, all except 4% developed Wernicke's encephalopathy, and 84% of those followed up developed a typical amnesic syndrome. Once the condition became established, 50% never got better, 25% had a partial recovery, and only 25% had a complete recovery. In practice, there is no point in expecting the full clinical picture to be seen in life. Harper *et al* (1986), in a necropsy study, found that 80% of patients with the Wernicke-Korsakov syndrome were not given this diagnosis during life. Only a small percentage had classical signs. Therefore, it is essential to have a high index of suspicion in 'at risk' groups, especially alcoholics. Investigation of thiamine status may be helpful, and if the diagnosis is suspected, parenteral thiamine should be given. The EEG may be relatively normal or show diffuse slowing CT scans in Korsakoff's psychosis. Korsakoff's psychosis may show areas of reduced density in the dorsomedial thalamus and MRI in Wernicke's encephalopathy has shown hyperintense areas surrounding the third ventricle and aqueduct.

Sexual dysfunction: Alcohol is directly toxic to the testis causing a reduction in germ cells, a reduced area of the seminiferous tubules, injury to Leydig cells, reduced plasma levels of testosterone, testicular atrophy, impotence and diminished libido.

Enterocyte dysfunction: Damage to subcellular organelles can cause folate deficiency and steatorrhoea.

²⁵⁵⁰ Variable spelling in the literature.

²⁵⁵¹ In practice, ocular disturbance affects only a **minority** of cases.

²⁵⁵² The suddenly ataxic, confused patient may be mistakenly diagnosed as simply drunk!

²⁵⁵³ Patients are often uninterested in their lack of past memories. There may also be perseveration (stuck in the one groove).

²⁵⁵⁴ Reduced red cell transketolase is a marker of thiamine deficiency.

The offspring of alcoholic parents are at increased risk for phobic and anxiety disorders, antisocial symptoms, and abuse of alcohol and other substances.

Physical problems: The severity of intoxication at a given alcohol concentration is typically greater when the concentration is rising than when it is falling²⁵⁵⁵. This possibly reflects the occurrence of acute tolerance to alcohol during a single episode of drinking. Smoking slows gastric emptying and thereby delays alcohol absorption.

Sudden death is not uncommon in the alcoholic population, e.g. from myocardial infarction, epilepsy, pneumonia or accidents. Death certificates rarely mention alcohol. Anderson (1988) estimated that there were 28,000 deaths each year in England and Wales associated with alcohol consumption in people aged 15-74 years. In a study of Swedish conscripts aged 18-19 years, Andreasson *et al.* (1988) found that a high alcohol consumption (more than 250 G/week) carried a 2.1 times greater chance of dying over 15 years than did a moderate consumption (1-100g./week). 36% of all deaths were due to violence, suicide or probable suicide.

In a prospective study at an Irish general hospital, Maguire (1988) looked at the relationship between alcohol and acute hospital admissions. Of 197 consecutive admissions, 19.3% were alcohol-related. 15% were positive on screening for alcohol, 17% of all patients admitted were heavy drinkers and were mainly males. 42% of road-traffic accidents and 67% of overdoses were alcohol-related. Alcohol problems and alcohol-related cognitive impairment were found, retrospectively, to contribute significantly to the difficult-to-discharge group of acute patients in Cork. (Popoola *et al.*, 2008) Another study from Cork (Bradshaw *et al.*, 2008) found that alcohol use disorders were common among general hospital admissions and are often undetected or documented in case notes.

Some physical problems in alcoholics

Fatty infiltration of liver, hepatitis²⁵⁵⁶
 Cirrhosis²⁵⁵⁷, hepatoma, oesophageal varices
 Zieve's syndrome²⁵⁵⁸
 Hepatorenal syndrome²⁵⁵⁹
 Gastritis, peptic ulcer, haematemesis, and pancreatitis²⁵⁶⁰
 Anaemia, macrocytosis, thrombocytopaenia, platelet inhibition
 Smoking-relating cancers²⁵⁶¹
 Osteoporosis
 Proximal myopathy +/- myositis
 Cardiomyopathy
 Atrial fibrillation (holiday heart syndrome)²⁵⁶²
 Increased effect of other drugs
 Fetal alcohol syndrome
 Various infections²⁵⁶³, including TB
 Gout²⁵⁶⁴

²⁵⁵⁵ 'Mellanby effect'.

²⁵⁵⁶ In *alcoholic fatty liver*, a reversible condition if the patient abstains, fatty acids are not oxidised and triglyceride production increases. There are usually no symptoms but abdominal pain, nausea and vomiting may occur. Alcoholic hepatitis, associated with cell death, inflammation and a disproportionate rise in AST (relative to ALT), can be fatal. Right-sided abdominal pain, fever, icterus, ascites and, sometimes, encephalopathy, may be present.

²⁵⁵⁷ In cirrhosis there is loss of hepatocytes and fibrosis with the outlook being poor if the patient continues to drink.

²⁵⁵⁸ The rare association of alcoholic hepatitis consisting of transient hyperlipidaemia, icterus, and haemolytic anaemia.

²⁵⁵⁹ This consists of acute renal insufficiency due to severe liver dysfunction. There may be hypotension, hypertonic urine, low urinary output, low urinary sodium, and indicators of advanced liver disease. The kidneys are normal and the cause may be vasoconstrictive. Pre-renal uraemia from other causes needs to be considered.

²⁵⁶⁰ *Acute pancreatitis* carries a 10-40% mortality rate. Chronic pancreatitis leads to pancreatic insufficiency, malabsorption, and chronic pain with the possibility of analgesic dependence.

²⁵⁶¹ Controlling for smoking, wine may be less likely to cause oropharyngeal and oesophageal cancer than is beer or spirits.

²⁵⁶² This may occur despite having a normal heart during excessive intake of alcohol or whilst withdrawing from alcohol.

²⁵⁶³ Chronic alcoholics are at increased risk of post-operative infection. This may be related to immune suppression. (Spies *et al.*, 2002)

Alcohol depresses granulocyte function so that one may see a case of serious systemic infection and a low or normal white cell count.

²⁵⁶⁴ According to Choi *et al.* (2004) who studied men, alcohol is strongly associated with an increased risk for gout. Beer confers a greater risk than spirits and moderate wine intake does not increase the risk.

Relatively low alcohol intake may have a protective effect on the heart, (e.g. Jackson *et al.*, 1991; Mukamal *et al.*, 2003) although the margin between what is safe and what is harmful is narrow (Doll *et al.*, 1994b; Fuchs *et al.*, 1995; Bobak *et al.*, 2000) and the evidence for any protection is not certain. (Hart *et al.*, 1999) Also, the role of alcohol in protecting the heart may vary with the sex of the patient²⁵⁶⁶. (Tolstrup *et al.*, 2006) This alleged protective effect may be due to increases in the levels of HDL₂ and HDL₃, subfractions of high-density lipoprotein cholesterol²⁵⁶⁷. However, indiscriminate advice to non-drinkers to take up alcohol for health reasons is extremely inappropriate. Alcohol may reduce the chances of starting a pregnancy. (Jensen *et al.*, 1998)

Metabolic problems associated with alcoholism include hypoglycaemia (fasting or reactive), ketoacidosis, hyperuricaemia, hypomagnesaemia, hypertriglyceridaemia, and hypercortisolaemia with non-suppression on the DST²⁵⁶⁸. Moderate intake of alcohol in healthy people may increase insulin sensitivity and possibly reduce the risk of non-insulin dependent diabetes.

Fatal residential fires can arise from many sources (living in a mobile home, no fire detector, etc), but alcohol abuse is one of the commoner causes.

Causes of death include cirrhosis, cancer²⁵⁶⁹ (mouth, pharynx, larynx, liver, breast cancer in women), injuries, etc. Smoking approximately doubles the mortality risk. Official alcohol-related deaths for the Republic of Ireland for 1990, 1995 and 1999 were 106, 146 and 269 respectively.²⁵⁷⁰

Acute effects of alcohol may involve disruption of glutamatergic neurotransmission by inhibition of the response of the NMDA receptor. Prolonged inhibition of NMDA receptors might then lead to supersensitivity (up-regulation) of these receptors. Schumann *et al.* (2008) reported that variations in the NMDA NR2A subunit are associated with positive family history, early onset alcoholism, maximum number of drinks in adults, and risky adolescent drinking habits.

Alcohol and TCAs have a 3-phase relationship. During acute alcohol intake TCA first-pass metabolism is blocked leading to up to trebling of TCA plasma levels. During medium term alcohol intake CYP enzymes are induced causing lowering of TCA levels. Finally, during chronic alcohol ingestion there is a fall in hepatic CYP enzyme concentration and reduced liver mass and possibly portacaval shunting with increased TCA plasma levels.

Alcohol withdrawal symptoms may be due to a reduced inhibitory function²⁵⁷¹ and/or increased activity of excitatory systems²⁵⁷². Nevertheless, CSF GABA levels do not appear to differ between abstinent alcoholics and normal controls or between alcoholics with or without a history of withdrawal seizures. If a person drinks heavily at a single sitting they may experience hangover²⁵⁷³ effects. They may also experience mild withdrawal symptoms: insomnia, restlessness and increased REM sleep. Rarely, transient, generalised choreoathetoid movements may occur during alcohol withdrawal.

Alcohol withdrawal (Ling *et al.*, 2003)

Uncomplicated

Starts hours after stopping alcohol, lasts 1-2 days: tremor, headache, irritability, some autonomic overactivity, photophobia

²⁵⁶⁵ Kelly *et al.* (1971) showed that high-potency IV vitamins B and C could reduce the subjective effects of alcohol intoxication. Michael Kelly (personal communication, 1978) used IV vitamins as an aide to distinguish decreased levels of consciousness due to alcohol from that due to head injury, the former being responsive (more alert) but not the latter. Apart from cranial trauma, **alcoholic coma** (excess alcohol alone or alcohol-induced hypoglycaemia) must be differentiated from other pathology, e.g. lung or meningeal infection, bleeding from the GIT, or liver failure. Rarely there may be a need for IV fructose or peritoneal dialysis to speed up the decline in blood ethanol concentration.

²⁵⁶⁶ The Tolstrup *et al.* (2006) from Denmark looked at men and women aged 50-65 years. Women were protected by drinking more and men by drinking more often!

²⁵⁶⁷ Alcohol also inhibits thromboxane and platelet aggregation as well as enhancing thrombolysis.

²⁵⁶⁸ Can also develop a pseudo-Cushing's syndrome.

²⁵⁶⁹ Acetaldehyde is known to be carcinogenic. (Proschl & Seitz, 2004).

²⁵⁷⁰ These seem on the conservative side since alcohol misuse is said to contribute to as many as 22,000 deaths each year in England. (Sengupta & Hoyle, 2005)

²⁵⁷¹ Reduced GABA activity or decreased activity of the α -2 adrenoreceptor.

²⁵⁷² Potentiation of NMDA by depletion of magnesium or overactivity of the catecholaminergic system and CRF.

²⁵⁷³ Various factors contribute to this, e.g. dehydration (meningeal stretching?) and acetaldehyde.

Complicated**[1]**

- (a) similar to uncomplicated but with anxiety, increased reflexes, transient hallucinations, and greater autonomic disturbance
- (b) alcoholic hallucinosis
- (c) seizures
- (d) DTs

[2]

Protracted withdrawal syndrome (PWS) -lasts weeks-years and may not be unique to alcohol, e.g. opiate (hypotension, hyperalgesia, low tolerance for stress), BZD or cocaine (craving) users may report similar experiences
 Most common features of PSW: EEG changes, irregular anxiety/muscular tension, tremor, depression, breathing/pulse/blood pressure, sleep problems, fatigue, and poor short-term memory. PWS may carry greater risk of relapse.

Acute management: Detoxification is with a benzodiazepine in reducing doses, e.g. chlordiazepoxide or alprazolam for the average patient or lorazepam if there is significant hepatic insufficiency. Anticonvulsants such as carbamazepine (e.g. 800 mg/day) can be used instead of BZDs, but there is nothing to be gained from combining the two. (Lingford-Hughes *et al*, 2004) Vitamins are replaced and physical complications are sought and treated. Preparations containing multivitamins are available for oral and parenteral use – thiamine can be injected on its own or in a multivitamin preparation such as Pabrinex. Anaphylaxis has been described in association with parenteral vitamin (IV > IM) injections. Beta-blocking drugs such as propranolol have been used to reduce the risk of arrhythmias and to manage prominent tachycardia and tremor. Should a neuroleptic be required it is better to use haloperidol because it is less likely to cause seizures and is safer than many other agents in the presence of liver disease. Most patients with mild-to-moderate withdrawal symptoms do not require in-patient detoxification, but can be treated safely and effectively as outpatients, with considerable cost savings. (McCollam *et al*, 1992; Okonkwo & O'Shea, 2002) Inpatient treatment should be considered for patients with serious medical illness, a history of serious withdrawal symptoms or seizures, mental state changes, or marked autonomic lability.

Longterm management: Vaillant (1999) states that 'In alcoholism, as in much of medicine, we dress the wound; we do not heal it'.

The idea of rejecting a patient for a liver transplant because of a history of excess alcohol intake *per se* is ethically flawed. (Masterton, 2000)

Disulfiram (Antabuse) or calcium carbimide²⁵⁷⁴ cause nasty symptoms if taken before alcohol by increasing production of acetaldehyde. (See later)

Aversion therapy is rarely used today because of associated ethical problems and low effectiveness.

Disulfiram was once commonly used in aversion therapy (alcohol given at the same time). Other agents that were used for this purpose were emetine and apomorphine.

Alcoholics Anonymous (AA)²⁵⁷⁵, with AI Anon for relatives and partners, ACOA for 'adult children of alcoholics' and AI-Ateen for the teenage children of alcoholics. (Synanon is an American organisation for drug addicts). AA gives immediate help to people from other members, it insists on total abstinence, it holds regular meetings, and it does not appeal to all cases. The alcoholic must confess his problems to the group. Sponsorship of one AA member by another AA member offers help during a crisis. Some alcoholics like AA, others do not. Some object to references to God or a 'Higher Power'. There is some degree of self-selection in AA attendance, and while there is some evidence that it may not be more efficacious than other interventions (Walsh *et al*, 1991) the general consensus is that it helps many alcoholics. Problems for research include anonymity among attendees and a stated prohibition on engagement in research.

The *Minnesota Model*²⁵⁷⁶, commonly used in the US, dates to the 1950s and conceptualises alcoholism in biopsychosocial and spiritual terms to be treated holistically in a variety of settings by multi-professional

²⁵⁷⁴ No longer available.

²⁵⁷⁵ Founded in Akron, Ohio in 1935 by Dr Bob S (Robert Smith), 1879-1950, and Bill W (Wilson), 1895-1971. The first European meeting was held in Dublin in 1946. The *Big Book of Alcoholics Anonymous* is a form of bibliotherapy. Bibliotherapeutic approaches to alcoholism are somewhat superior to doing nothing at all but may not be as efficacious as more extensive interventions – the best results seem to be for those cases who seek treatment (**not** severe cases) and offer specific strategies such as setting goals or showing how one can cope without resorting to drinking. (Patton *et al*, 2008, p. 315)

²⁵⁷⁶ Dan Anderson PhD (1921-2003, psychologist from Minneapolis) and Nelson Bradley MD (Canadian, medical superintendent) witnessed institutionalised alcoholics at Willmar State Psychiatric Hospital, Minnesota and decided to attend AA meetings to see what they could learn from them. They became interested in two programs based on the philosophy of AA: Pioneer House (founded 1948 to treat alcoholics with families) and Hazelden (founded 1949 to treat professionals). The 12-Step approach was manualised in 1992:

teams with abstinence as the goal. The Twelve Steps of AA are seen as essential. Motivational enhancement and CBT strategies (to tackle unhelpful thinking - 'stinkin' thinkin'') are used. It is generally recognised as being effective.(Project MATCH Research Group, 1998)

Certain centres use specialised techniques, e.g. Glasser's reality therapy,(Glasser, 1965) a confrontational technique. CBT, social behaviour and network therapy,(UKATT Research Team, 2005a,b) and motivational enhancement²⁵⁷⁷ are other techniques used. Longer duration in treatment correlates with better outcome but, since this does not hold up with random assignment to different lengths in therapy, the relationship is probably biased by better-motivated clients choosing to stay in treatment for longer.(APA, 2002, p. 294)

Various attempts have been made to teach alcoholics to control their drinking, e.g. showing him a film of himself when drunk, teaching him to stop gulping drinks and how to identify stimuli to drinking and to find alternative ways of dealing with them. It is as yet very difficult to predict who can control their drinking. Buspirone²⁵⁷⁸ (5-HT_{1A} agonist) and SSRIs seem to reduce craving for alcohol.(O'Shea, 2000)

The RCPsych recommended a 10-point code to help people drink sensibly:

Don't drink every day of the week (a 2-3 day break gives the body a chance to recover)

Don't use alcohol to treat emotional problems

Don't drink alone

Don't use alcohol as a hypnotic because tolerance causes a rapid onset of the tendency to increase the amount consumed

Don't drink alcohol whilst taking other drugs

Don't drink alcohol on an empty stomach (food delays the absorption of alcohol)

Try to introduce a non-alcoholic drink during sessions

Sip drinks (do not gulp)

Pace yourself (aim to be the slowest drinker in company)

Always dilute spirits.

According to the RCPsych (1979) if you drink half a bottle of spirits or 8 pints of beer per day you are at high risk for dependence²⁵⁷⁹. The College proposed so-called 'safe levels', e.g. 4 bottles of beer per day, 4 doubles of spirits or one bottle (standard size) of wine. Increases in the number of units considered to be safe as suggested by the British government in 1995 met with deserved criticism! The relationship between dose of alcohol consumed and mortality may be stronger for young people.(White ea, 2002)

Employee health programmes wherein alcohol-related problems are monitored and detected cases are directed to treatment agencies are important. However, alcohol problems reappear before work problems do and close monitoring is advisable for at least a year after resumption of work.

Opinion on whether controlled drinking is possible for some alcoholics is still divided,(Tobin ea, 1993) although most programmes advise total abstinence. It is extremely difficult to foretell which problematic drinkers can control their alcohol intake in advance.

Pharmacotherapy

Drug therapy should form part of a package that aims to improve psychosocial outcome.

Verapamil delays the elimination of alcohol with prolonged feeling of intoxication, which may prove dangerous when driving. The hepatotoxic effect of paracetamol is increased in chronic heavy drinkers because the production of its hepatotoxic metabolite is increased and its metabolism is diminished. Binge drinking whilst taking metformin increases the risk for lactic acidosis.

Disulfiram: Work done in Copenhagen in 1940s showed that diethylthiuram disulphide ingestion caused certain symptoms if even small amounts of alcohol were taken subsequently.(O'Shea, 2000) Efficacy

'Twelve-Step Facilitation'. This led to Project MATCH, a randomised, controlled, multi-site study. The Minnesota Model has spread internationally.

²⁵⁷⁷ In *motivational enhancement therapy* (individual or group), designed to help people who seek help, the therapist creates an atmosphere of respect and adopts a non-judgemental/non-confrontational stance. The client is asked to use his own skills and resources for change, the responsibility being his. Resistance is met by a change in tactics. A meta-analysis (Burke ea, 2003) suggested that this approach is helpful in reducing alcohol consumption, at least in the short term.

²⁵⁷⁸ Buspar was withdrawn, December 2009.

²⁵⁷⁹ Lower levels should not necessarily be viewed as safe.

largely depends on fear of a reaction. It is ineffective if not taken: supervision by a responsible adult helps to ensure effectiveness. The recipient feels hot in the face, develops intense flushing, the scleral vessels become dilated and there are palpitations, dyspnoea, nausea and headache. The reaction tends to abate in a few hours and the patient is left feeling sleepy. After he has oxidised the alcohol he feels well again. Disulfiram interferes with the excretion of acetaldehyde (irreversible binding with ALDH), an intermediary product in the oxidation of ethyl alcohol. A severe reaction is treated with vitamin C 1 Gram and an antihistamine such as mepyramine maleate IV.

The oral solution of the protease inhibitor amprenavir contains propylene glycol which is metabolised by aldehyde dehydrogenase; if the latter enzyme is inhibited by disulfiram the patient may develop propylene glycol poisoning. Therefore, do not give amprenavir and disulfiram to the same patient.

Side effects of disulfiram include fatigue, skin disorders²⁵⁸⁰, impotence, a metallic or garlic taste and hepatotoxicity. Opinion differs on the potential for liver damage, some authors suggesting regular LFTs. Disulfiram²⁵⁸¹ can cause delirium or a psychosis in clear consciousness, probably by increasing mesolimbic DA via inhibition of dopamine beta-hydroxylase. This includes a tendency to exacerbate schizophrenia²⁵⁸². One criticism of using disulfiram²⁵⁸³ is that the dose given is too low. Giving the patient an experience of an 'antabuse effect' before discharge from hospital is much less popular (and of questionable ethics) than heretofore. Disulfiram is a good crutch for those who are motivated.²⁵⁸⁴ Neuropathy (including optic neuritis) from disulfiram is rare in low doses; it usually takes several months to come on and it usually clears up if the drug is stopped early. Fatal liver reactions are rare (1/25,000 treated/year). A combination of isoniazid and disulfiram can cause ataxia. Delirium may result when disulfiram and an MAOI (e.g. isocarboxazid) are co-administered. Disulfiram inhibits CYP2E1 oxidase which, potentially, could lead to toxicity from diazepam (not lorazepam), TCAs, carbamazepine, phenytoin, or warfarin. Disulfiram metabolites inhibit P450 3A4 and so can lead to toxicity from immunosuppressant drugs. (Cornelius ea, 2003)

Other causes of antabuse reactions

- Metronidazole (Flagyl)
- Carbimide²⁵⁸⁵
- Pargyline²⁵⁸⁶
- Coprine²⁵⁸⁷
- Cephamandole (parenteral cephalosporin)
- Procarbazine²⁵⁸⁸
- Oral ketoconazole
- Griseofulvin (rare)
- Paraldehyde
- Chloramphenicol
- Percutaneous absorption of monosulfiram (Tetmosol - anti-scabetic agent)
- Chlorpropamide (Diabinese – a sulphonylurea that reduces blood glucose levels), some people experience marked facial flushing if they take alcohol (blocked by naloxone and reproduced by an enkephalin analogue with opiate-activity - this response might be inherited as a dominant trait along with diabetes mellitus)

²⁵⁸⁰ Disulfiram mobilises stored nickel which may lead to 'recall' dermatitis in people who are allergic to nickel.

²⁵⁸¹ Or rather its diethylthiocarbamate metabolite.

²⁵⁸² Use only low doses in schizophrenic patients.

²⁵⁸³ This author often prescribes one tablet of 400 mg three times a week.

²⁵⁸⁴ This author has certainly seen alcoholics who drink on regardless!

²⁵⁸⁵ *Citrated calcium carbimide* was introduced in the 1950s and it gives a milder reaction than disulfiram with alcohol. However it was subsequently withdrawn from the marketplace. Carbimide reversibly inhibits aldehyde-NAD-oxidoreductase and it does not inhibit dopamine-beta-hydroxylase.

²⁵⁸⁶ Antihypertensive agent.

²⁵⁸⁷ Coprine or coprin is found in the Common Ink Cap mushroom *Coprinus atramentarius*. Coprine inhibits acetaldehyde dehydrogenase.

²⁵⁸⁸ Cancer chemotherapy agent and weak MAOI.

- Paraldehyde – not to be given with disulfiram as latter blocks paraldehyde metabolism with formation of acetaldehyde

Surgical implants of disulfiram have been tried but they have been largely abandoned because of evidence of a lack of both pharmacological and clinical effects due to insufficient blood levels. Improvements in assessing compliance by testing for metabolic products of disulfiram are possible. One could test for diethylamine in the urine and carbon disulphide in the breath.

Alcohol comes in many guises, including certain vitamin preparations and cosmetics.

Chlormethiazole (Heminevrin): This is a hypnotic, anxiolytic and anticonvulsant and is derived from the thiazole moiety of thiamine. The pharmacology is not clear, apart from GABA enhancement. It has a short half-life of 6-8 hours. Alcohol increases the bioavailability of chlormethiazole; it possibly impairs its normally extensive first pass hepatic metabolism. Barbiturates and chlormethiazole have additive effects. Chlormethiazole potentiates phenothiazines and butyrophenones. In cirrhosis there is a tenfold increase in the bioavailability of chlormethiazole. Cross-dependence is common. Chlormethiazole can cause nasal tingling, rhinorrhoea, conjunctival irritation and GIT upset. It has been given by infusion for toxemia of pregnancy and status epilepticus. Too much fluid load (IV) can cause hyponatraemia. It is toxic in overdose, causing deep coma and a centrally mediated respiratory depression. This author prefers chlordiazepoxide or alprazolam when detoxifying alcoholics. In its former distinctive colour chlormethiazole was known 'on the streets' as 'duck eggs'.

SSRIs: There is controversial evidence that SSRIs may reduce craving for alcohol²⁵⁸⁹. High doses (e.g. fluoxetine 60 mg daily) may or may not moderately reduce alcohol consumption. (Lingford-Hughes, 2002) 5-HT₂ blockers like ritanserin have not been helpful.

*Acamprosate*²⁵⁹⁰ (*Campral EC*), which reduces craving for alcohol²⁵⁹¹, seems to stimulate GABAergic neurotransmission and inhibit excitatory amino acids like glutamate. Acamprosate suppresses elevated c-fos expression it has been shown to inhibit calcium channel upregulation in rodents withdrawing from alcohol. The aversive effects of ethanol withdrawal coincide with a reduction in dopaminergic activity in the mesolimbic system and an increase in the release of glutamate in the nucleus accumbens; there is also increased expression of brain c-fos, an immediate-early gene. It should be started just after detoxification. (Lingford-Hughes, 2002) Like other such treatments, at least some form of counselling should accompany its prescription. Dosage is 2 (333 mg/tab) tablets 3 times a day if the patient is more than 60 Kg in weight²⁵⁹². Food reduces its availability. In fact, the drug is poorly absorbed from the GIT and several days are required before useful blood levels are reached. It is secreted in urine and breast milk and is not significantly metabolised. It is not bound to serum proteins. One year of treatment post-detoxification is recommended, longer if the patient relapses. It does not interact with alcohol. Treatment should continue despite lapses/relapse. It is not advised to prescribe it to children or the elderly. It should be avoided if the serum creatinine is over 120 micromol/L, if there is severe liver failure²⁵⁹³, if the patient is pregnant (teratogenic in rats), or during breastfeeding. Side effects include diarrhoea, nausea, vomiting, bloating, abdominal pain, pruritus, various rashes, and, probably at the placebo rate, fluctuations in libido. Bismuth relieves GIT symptoms, but the dose may need to be reduced for severe or persistent problems. Overdose may lead to hypercalcaemia. The calcium in acamprosate may inactivate tetracyclines. Acamprosate may be combined with disulfiram (Lingford-Hughes, 2002) or naltrexone. (Kiefer et al, 2003) *Naltrexone (Revia, Nalorex)*, previously used for the management of heroin dependence, was first used to treat alcohol dependence in the US. Animal work suggested that naltrexone would reduce craving for alcohol. Naltrexone competitively binds with opiate receptors and antagonises the actions of exogenous opioids. The theory is that alcohol is reinforced by the action of endogenous opioids: transgenic mice lacking beta-endorphin reduce voluntary alcohol consumption relative to normal (wild-type) mice²⁵⁹⁴. The

²⁵⁸⁹ According to Farren (2008) SSRIs are not helpful in non-depressed alcoholics overall, and fluoxetine may worsen early-onset alcoholism whereas sertraline may ameliorate late-onset alcoholism.

²⁵⁹⁰ Calcium bis-acetyl homotaurinate. It resembles GABA structurally.

²⁵⁹¹ This was first noticed in animals.

²⁵⁹² 2 tabs mane + 1 tabs midday + 1 tab nocte for lighter patients.

²⁵⁹³ Childs-Pugh classification C.

²⁵⁹⁴ People with a particular mu opioid receptor polymorphism may respond better to naltrexone. (Farren, 2008)

blockade of endorphin activity when alcohol is imbibed results in attenuated dopamine release from the nucleus accumbens. It can cause nausea (usually mild and transient) in some patients. Liver toxicity can occur with high doses of naltrexone²⁵⁹⁵. 80-90% is extracted and metabolised in the liver²⁵⁹⁶. The half-life is 10 hours²⁵⁹⁷. There is a low terminal elimination phase half-life (96 hours). If there is any likelihood of opioid use/dependence then a naloxone²⁵⁹⁸ (Narcan) challenge²⁵⁹⁹ must be carried out unless it can be confirmed that the patient has been opioid free for the previous 7-14 (some say longer) days. Attempts to overcome blockade by taking huge doses of opioids can threaten life. Medical need for opioids may require larger doses than usual, with the danger of respiratory depression. Side effects include nausea, vomiting, diarrhoea, constipation, fatigue, nervousness, irritability, anxiety, somnolence, headache, dizziness, poor appetite, disturbed sleep, abdominal pain or cramps, increased or decreased energy, joint and muscle pain, thirst, nasal drip, low mood, rash, delayed ejaculation, reduced potency, and chills. Not all research agrees that naltrexone is effective (Krystal ea, 2001) and there have been reports of depression and suicide associated with it.(Lingford-Hughes, 2002)

Injectable naltrexone (Vivitrol) is available in the US. Once-monthly injections improve compliance. Problems arise if the patient needs analgesia²⁶⁰⁰.

Tiapride, a non-addictive substituted benzamide, has effects of DA receptors. It reduces withdrawal symptoms and promotes abstinence, and is said to have anxiolytic and antidepressant properties.

Topiramate, a sulphamate fructopyranose, may inhibit mesocorticolimbic DA release by increasing GABA and reducing glutamate activity respectively. There is some evidence that it assists people to remain abstinent (Johnson ea, 2003, 2004, 2007; Swift, 2003), although evidence tends to be based on short-duration study and use of self-reports.

Ondansetron, a 5-HT₃ antagonist, reduces DA release in the mesocorticolimbic system. It reduces alcohol consumption in rats and may be of some benefit in humans²⁶⁰¹.

Pabrinex: This is a high potency mix of vitamins B and C. It comes as IM (7 ml) and IV (10 ml) preparations, each containing 2 ampoules²⁶⁰² that are drawn up into a syringe to mix them just before use. It can cause hypotension and mild paraesthesiae. If mild allergic reactions are experienced (sneezing or mild asthma) it should not be used again. Repeated injections of preparations containing high concentrations of vitamin B1 can cause anaphylaxis, which should be anticipated.

Baclofen (*Lioresal*, *Baclopar*): This GABA-B receptor agonist, a voluntary muscle relaxant, may reduce craving for alcohol.(Addolorato ea, 2007)

Others: Acupuncture, ACE inhibitors, DA agonists (bromocriptine, lisuride), and thyroid hormones have had their advocates. BZDs should generally be avoided longterm in persons prone to alcohol abuse or dependence, but there is a small group of patients where their use may 'maximize abstinence and minimize morbidity from alcohol'.(Lingford-Hughes, 2002, p. 557)

Prevention: The outlook is that of a chronic, relapsing disorder. Cross dependency with other drugs is common. Prevention is difficult. The price of alcohol could be raised. In 1990, the Irish spent more on alcohol than their government spent on the health services! In British Columbia advertising was banned but the TV and radio from the US carried the advertisements across the border. The USSR had a big problem with alcoholism and no advertisements, although relaxation of controls in the Russian Federation saw a worsening of the problem²⁶⁰³. Alcohol (and tobacco) is a major contributor to premature mortality in Russian males.(Leon ea, 2007; Zaridze ea, 2009) A 2004 English Cabinet report (Cabinet Office, Prime Minister's Strategy Unit, 2004) does little to reduce harm caused by alcohol and leaves too much to the goodwill of the drinks industry. Controlling the hours of opening of bars and cutting down on off-licence sales gives equivocal results. Health education is desirable but the results are hard to measure. US states

²⁵⁹⁵ Check LFTs at baseline and at intervals.

²⁵⁹⁶ First pass metabolism.

²⁵⁹⁷ Sustained release depot naltrexone is under development.

²⁵⁹⁸ Causes briefer withdrawals than naltrexone.

²⁵⁹⁹ 0.2 mg Narcan IV – if no adverse reaction at 30 seconds give 0.6 mg IV and observe for 30 minutes for withdrawals.

²⁶⁰⁰ Try a non-opioid first. If opioids are needed they may need to be given in larger doses and more often than usual.

²⁶⁰¹ Especially in early-onset alcoholism.(Farren, 2008)

²⁶⁰² 5+5 ml for IV, 5+2 ml for IM.

²⁶⁰³ Intriguingly, the upper house of Russia's parliament struck down a bill outlawing public drinking in 2004! The Duma (lower house) allowed a lobbyist from the tobacco industry to have 'light' included in cigarette advertisements in 2008!

that raised the legal drinking age to 21 had less suicide in their 18-20 year olds.(Birckmayer & Hemenway, 1999)

Prohibition in the USA during 1920-33 was not sustainable and may have been at least partly responsible for the so-called 'Capone Era'.

In a twelve-month follow up of two groups of alcoholics, one given various and intensive interventions and therapy and the other given advice only, the outcome was the same on several parameters.(Edwards ea, 1977) Similar findings were reported from a meta-analysis of 20 controlled studies.(Moyer ea, 2002)

Evidence for the effectiveness of brief interventions (e.g. confrontation, advice, counselling, information) for problem drinking in a general hospital remains controversial.(Emmen ea, 2004) Also, the few trials that have followed up patients for long enough suggest that the effects of brief interventions do not last beyond a year.

Vaillant (1996) followed up two groups of alcohol dependent patients: by age 60, 18% and 28% of college students and inner-city dwellers respectively were dead, 11% of the former and 30% of the latter groups were abstinent, relapse was less likely if sobriety was maintained for five years, and a return to controlled drinking was uncommon.

Gilder ea (2008) assessed 580 American Indians. 254 had DSM-III-R alcohol dependence. The rate of remission was 59%. Remission was associated with female sex, married status, earlier onset, and self-reported alcohol-linked depression. Non-remission was associated with drinking despite knowledge of associated medical problems and self-reported alcohol-linked anxiety.

The main factors contributing to relapse are negative or positive emotional states, social influences, conflict with others, and the urge/temptation to take a drink.

1988 RCPsych consensus recommendations re alcohol

Overall reduction in consumption

Increase price²⁶⁰⁴

Reduce advertising

Increase licensing hours

Random breath testing²⁶⁰⁵ of drivers

Reduce permissible levels of blood alcohol for drivers²⁶⁰⁶

Men to drink no more than 21 units/week

Women to drink less than 14 units/week²⁶⁰⁷

Government should fund campaigns against alcoholic misuse

Beverages should be clearly labelled with strength and amount of alcohol contained in them

Alcohol education for medical students and doctors

Medical profession to lead by example

Available/adequate/early help for every problem drinker

Help for the families of problem drinkers

Increase research funding

2008 British Medical Association (BMA, 2008) alcohol control recommendations

Reduce access – control hours of sale and outlet density; increase taxes (proportional to alcohol content; outpace inflation)

Enforce licensing laws - no sale if underage; cut out sale of drinks like 'alcopops'²⁶⁰⁸

Reduce drink driving – reduce legal limit from 80 to 50 mg/100ml; random testing of drivers

Education and health promotion – put guidelines on labels

Early intervention and treatment – routine screening and brief intervention to decrease hazardous drinking; expand specialist services for excess drinkers

²⁶⁰⁴ Perhaps less tax on low- or non-alcoholic drinks.(Hall, 2005) Alcohol was 54% more affordable in the UK in 2003 than in 1980.(Gilmore & Sheron, 2007)

²⁶⁰⁵ Breathalyser test for alcohol invented by Martin Wright, National Institute for Medical Research, London, UK, 1967.

²⁶⁰⁶ Especially for the first two years of driving.

²⁶⁰⁷ The pregnant woman should either not drink at all or only now and again.

²⁶⁰⁸ Flavoured alcoholic drinks aimed at youth.

Despite increasing evidence of the damage caused by alcohol, neither the government nor the public appear to want to do very much about it. Dunbar *et al.* (1987) suggested random breath testing and a zero limit for learner and first year drivers because they are more likely to have accidents even with low levels of alcohol in their blood. Prevention strategies can be divided into primary²⁶⁰⁹ and secondary²⁶¹⁰. According to Room *et al.*, (2005) increasing taxation on alcohol,²⁶¹¹ reducing its availability, and measures against drinking-and-driving are effective policies. They stress that ‘population-based approaches have been neglected in favour of approaches oriented to the individual that tend to be more palliative than preventative’.

Neuropsychiatry

Brian O'Shea

'What man can know the intentions of God? Who can divine the will of the Lord? The reasonings of mortals are unsure and our intentions unstable; for a perishable body presses down the soul, and this tent of clay weighs down the teeming mind'. (Book of Wisdom, 9:13-14)

'Mental health professionals continue to employ a mind-brain dichotomy when reasoning about clinical cases'. (Miresco & Kirmayer, 2006)

'It's an open question whether the human brain, with its ineffable complexity, is capable of understanding itself'. (Dew, 2009)

This section covers heterogeneous disorders which may present with, or be complicated by mental symptoms, there existing however a known or suspected organic aetiology.²⁶¹² The uninformed may jump to a false diagnosis of psychogenic disorder when the unexpected occurs, e.g. in the case of *geste antagoniste* (tricks patients discover to overcome neurological problems) as when a patient with dystonia can run but not walk or can walk in reverse but not forwards; the patient with spasmodic torticollis (cervical dystonia) may be able to control the spasm by pressing on the ipsilateral or contralateral chin; or the person who ameliorates blepharospasm by singing or pressing on the lateral canthus. On the other hand, psychogenic disorders, if continued for long enough, may produce secondary somatic effects (e.g. abnormal posture that persists during sleep).

Links between neurological and psychiatric disorders may arise in different ways

Neurological insult may produce focal disorders like frontal lobe syndrome or generalised conditions like dementia and, most likely, schizophrenia

Depression, anxiety or conversion disorder may arise, e.g. as a reaction to neurological disorder

Neurological disorder may exacerbate personality traits

Personality disorder may present as neurological disease, as in factitious disorder

Cost

McHugh et al (2007) reported on cost of 'disorders of the brain' (DOB) in Ireland. The most relevant groupings are shown in the table. Costs (€ at 2004 prices) per inhabitant of DOB were €227 (direct healthcare), €116 (direct non-medical) and €443 (indirect), with a grand total of €775. Mood disorders were the most costly DOB. 'Intangible' costs (suffering, quality of life²⁶¹³, etc) were not calculated. For comparison, total costs (in €) for migraine, epilepsy, CVA, MS, Parkinson's disease, and cerebral tumour were 64, 37, 35, 17, 12, and 9 respectively. DOBs consume 3% of GNP and two-thirds of this is accounted for by "raditional" psychiatric disorders (€2.035 bn out of €3.049 bn).

²⁶¹² Placing a disorder or syndrome or symptom in this section is largely a matter of convenience and should not be construed as meaning that other disorders have no biological basis. DSM-IV has dropped the term 'organic' to avoid the probably mistaken assumption that 'functional' disorders do not have an organic component.

²⁶¹³ *Quality of Life in Alzheimer's Disease Scale* (QoL-AD; Logsdon et al, 1999), for completion by carers or patients, has 13 items including physical/mental health, relationships, finance, and an overall evaluation. It can be used with all degrees of dementia. To get the best view of quality of life one should seek the views of as many people as possible. Staff are influenced by behaviour/dependency and patients may be anxious or depressed.

Costs/inhabitant of certain disorders in Ireland (€) (McHugh et al, 2007)

<i>Disorder</i>	<i>Direct healthcare</i>	<i>Direct non-medical</i>	<i>Indirect</i>	<i>Total</i>
Mood	56	0	195	251
Addiction	33	7	89	129
Anxiety	47	0	46	93
Dementia	13	66	0	79
Psychoses	38	7	0	45

The cost of dementia to the UK economy is £17 bn (€24 bn) (Strachan et al, 2008; Burns & Iliffe, 2009a) and carers save UK tax payers £6 bn annually. (Butler, 2008) Ireland has only one neurologist per 202,000 of the population.

Cerebral anoxia

This may be acute (restlessness and anxiety, clouding of consciousness, and poor concentration proceeding to coma and death or to memory difficulties, dementia and temporal lobe epilepsy) or chronic (personality change and cognitive deficits). (cf. carbon monoxide poisoning below)

Four types of anoxia/hypoxia

Anoxic anoxia - insufficient O₂ reaches blood, e.g. not enough O₂ present in breathed air

Anaemic anoxia - low blood haemoglobin level or O₂ is displaced by another gas such as CO

Hypoxia - may be due to, e.g., lung disease; mild hypoxia causes increased cerebral blood flow that is partly compensatory

Ischaemic hypoxia - follows reduced cardiac output, cerebrovascular accident (CVA), and cerebral vasospasm due, e.g., subarachnoid haemorrhage or migraine

The term *delayed post-anoxic encephalopathy* refers to those few cases that 'recover' from a comatose state secondary to hypoxia or ischaemia, enjoy lucidity for days to weeks, and present with delirium and a movement disorder. There is severe demyelination. The basal ganglia are involved to a variable extent. A few patients die or are left demented but most cases improve gradually as far as cognition is concerned but the outlook for disorders of movement, such as parkinsonism or spasticity, is less good.

Cerebral malaria²⁶¹⁴ is present when asexual parasites are found in blood film and patient has impaired consciousness and the cause is not another encephalopathy (e.g. bacterial meningitis or viral encephalopathy). The antimalarial drug mefloquine (Lariam: half-life 14 days) can cause neuropsychiatric disorders persisting for several days.

Contraindications for mefloquine therapy

Psychiatric disorder

Epilepsy

Cardiac conduction disorders

Renal/hepatic impairment

First trimester of pregnancy

Lactation

Coma

There are six coma stages: alert, drowsy (responds to verbal commands), unconscious and withdraws from pain, unconscious and decorticate (flexes limbs to pain), unconscious and decerebrate (hyperextension of limbs to pain), and unconscious with zero response.

²⁶¹⁴ **Cerebral malaria:** especially with malignant tertian (*falciparum*) – pyrexia (rarely fever is absent), delirium, severe headache, disturbed behaviour, coma, seizures, retinal haemorrhages, papilloedema, cerebellar ataxia, dysphasia, hemiplegia, and hemianopia may occur.

The *Glasgow Coma Scale* (Jennett & Bond, 1975: see box) is the accepted standard for assessing coma. The score can be given as a single figure (e.g. GCS = 15) or as the response in each of its 3 sections (e.g. GCS = 465).

Glasgow Coma Scale (see text for scoring)	
<i>Item</i>	<i>Score</i>
Eyes open:	
Spontaneously	4
To speech	3
To pain	2
Never	1
<i>Best motor response:</i>	
Obeys commands	6
Localises pain	5
Flexion withdrawal	4
Decerebrate flexion	3
Decerebrate extension	2
No response	1
Best verbal response:	
Orientated	5
Confused	4
Inappropriate words	3
Incomprehensible words	2
Silent	1

Brain death

This may be defined as the irreversible loss of two brainstem functions: the possibility of future consciousness and spontaneous breathing. (Wijdicks, 2001) Such a definition became necessary with the advent of mechanical ventilation and the use of human tissue and organs for transplantation. One must be aware that coma/apnoea due to hypothermia, metabolic or endocrine conditions, electrolyte/acid-base balance/glycaemic problems, sedative drugs, and neuromuscular-blocking agents or other poisons may be associated with recovery after prolonged time periods. Tests used include cranial nerve motor responses to pain, lack of spontaneous breathing despite receiving ventilation with 100% oxygen or 5%CO₂/95%O₂, and corneal/vestibulo-ocular (caloric)/gag or cough/oculo-cephalic (eyes follow head if brainstem intact: doll's eye movements)/pupillary (light) reflexes. Pupils are fixed and can be of any diameter (usually dilated). The presence of spinal reflexes does not negate a diagnosis of brain death. Whilst an isoelectric (flat) EEG would be expected in someone with brain death the EEG is no longer a prerequisite in the determination of that state.

Under normal circumstances the ascending reticular formation (ARF) helps to maintain a healthy cortex in an active mode. Minimally conscious patients show some, rather vague, response to noxious stimuli. Persistent vegetative states follow cerebral cortical damage (e.g. severe trauma) in the presence of a normal ARF/brainstem; the patient appears to be awake but has little or no perception. In the locked-in syndrome the cerebral cortex and ARF are intact but the ventral pons is damaged caudal to the oculomotor nerve nuclei (see box). Irremediable brainstem damage is the equivalent of brain death, i.e. the patient is dead.

Locked-in syndrome (Nordgren et al, 1971)

May follow lesions such as high brainstem infarction or central myelinolysis

Can also follow traumatic brain injury or drug overdose

Normal consciousness (fully aware), tetraplegia, bilateral facial palsy, and paralysis of lateral gaze

Cannot speak or move

Can think and reason

Since vertical gaze is intact, patients may try to communicate with eyes (and eyelids) in a form of Morse

Some general medical disorders²⁶¹⁵

Acute intermittent porphyria (AIP)

AIP²⁶¹⁶ is inherited as an autosomal dominant trait with incomplete penetrance²⁶¹⁷. There is a deficiency of the enzyme porphobilinogen deaminase²⁶¹⁸. In 90% of cases the disease is latent. If enzyme inducers are taken enzymes proximal to the deficient enzyme increase in activity and the concentrations of delta-aminolaevulinic acid and porphobilinogen increase, causing neuronal damage with subsequent myelinolysis.

Precipitants of attacks (O'Shea, 2000; Kauppinen, 2005; Smoller ea, 2008, p. 872; Harrison & Kopelman, 2009, p. 671)

Barbiturates
Luteal phase of menstrual cycle
Oestrogens and progesterone (incl. contraceptive pill and hormone replacement therapy)
Tamoxifen
Anabolic steroids
Dichloralphenazone
Phenylbutazone
Glutethimide
Anaesthetics
Alcohol
Methyldopa
Diclofenac
L-DOPA
Sulphonamides
Erythromycin
Phenytoin
Valproic acid
Carbamazepine
Benzodiazepines
Tricyclic antidepressants
Sulpiride
Fasting
Acute infection
Cocaine
Amphetamines
Smoking²⁶¹⁹

In the absence of a precipitant, the diminished enzymatic activity is usually insufficient to cause a build up of precursors. Relatively safe drugs include aspirin, narcotic analgesics, penicillin, tetracycline, streptomycin, paraldehyde, propranolol, and chlorpromazine and probably clozapine, olanzapine, fluoxetine, paroxetine, and clomethiazole. It is essential to check with manufacturers' prescribing information before giving medicine to patients with porphyria.

Clinical features

²⁶¹⁵ See also Moore.(2001)

²⁶¹⁶ The **porphyrias** are a group of seven rare inherited metabolic disorders, each due to a partial deficiency of a particular enzyme in the haem biosynthesis pathway. The porphyrias include cutanea tarda (most common type worldwide: develops after fourth decade with cutaneous symptoms and chronic liver disease), acute intermittent, aminolaevulinic dehydratase deficiency, erythropoietic protoporphyria, congenital erythropoietic, hereditary coproporphyria, and variegate porphyrias. Attacks of acute porphyria may be due to acute intermittent, hereditary coproporphyria, or variegate forms of the disease and these cannot be distinguished clinically.(Kauppinen, 2005) The notion that George III of England (1738-1820) suffered from porphyria is still debated.(O'Shea, 2000) An alternative explanation is arsenic poisoning from medications prescribed by physicians.(Cox ea, 2005)

²⁶¹⁷ Many mutations in PBGD gene in chromosome 11q23.3.

²⁶¹⁸ Uroporphyrinogen-1-synthetase.

²⁶¹⁹ Smoking may be a potential precipitant of porphyric attacks, possibly by altering oestrogen metabolism and induction of hepatic mono-oxygenases.

Acute abdominal pain
 Pains in limbs and back
 Headaches
 Tachycardia
 Nausea, vomiting
 Severe constipation
 Peripheral neuropathy
 Seizures in 20%
 Negative laparotomies
 During attacks: depression, restlessness, abnormal behaviour, organic brain syndromes and psychoses

The diagnosis is made by analysis of the urine (stored in dark and sent rapidly to the laboratory) for porphobilinogen and delta-aminolaevulinic acid. False positive results may occur with phenothiazines, plumbism, and fever. Avoidance of precipitants is essential. Improved carbohydrate intake reverses attacks caused by excessive fasting.

Causes of urine discolouration after it is left standing for some time include porphyria, alkaptonuria, and L-DOPA.

Adrenocortical leucodystrophy

This X-linked disorder presents in adults with adrenal insufficiency, personality change, long tract signs, and dementia.

Alien hand syndrome/sign

Described 1908 by the German Kurt Goldstein

Damage to the corpus callosum and frontal lobes (supplementary motor area)

One of the weirdest experiences in medicine: a hand acts as if it had a mind of its own

Patient says that one hand, nearly always the left, is out of control and behaving independently, sometimes leading to self-harm!

Activities carried out by the hand may be simple or complex

It may reverse movements carried out by the opposite limb, even repeatedly so, e.g. right hand opens a drawer, only for left hand to reverse this manoeuvre

So-called murderous alien hand has been described: as seen in some Hollywood movies, the hand may try to choke its owner or may knock her spectacles off her face!

Interpretations by the patient vary from the neutral ('my hands are in disagreement') to the quasi-delusional ('Martians appear to control my hand').

Some mimics of alien hand:

Asomatagnosia - denial of ownership of a limb

Levitation - simple rising of a limb in parietal damage or progressive supranuclear palsy

Mirror movements - other limb imitates the primary movements of the opposite limb – may be normal or may occur, e.g. in hemiplegics

Grasp reflex

A fuller discussion is provided by Moore.(2001) MacGowan ea (1997) described cases of CJD presenting with alien hand sign.

Alien limb phenomenon

Person complains that he has no control over the movements of the limb

An advanced form of asymmetric limb apraxia: subject knows what needs to be done but cannot perform a simple task such as holding a pen

Ipsilateral rigidity and bradykinesia

Described in cases of corticobasal degeneration, a cause of gradually progressive asymmetric cognitive and motor impairment

Arsenic poisoning

Sources of arsenic: mines, silicon chips, insecticides

Acute cases: GIT symptoms and delirium, perhaps with seizures, and garlic odour from breath; sensory polyneuropathy follows

Chronic cases: dementia, painful polyneuropathy, and cutaneous hyperpigmentation; Mees' lines are transverse white lines in the nails

Insecticides containing high levels of nicotine

Nausea/vomiting/diarrhoea

Tachypnoea

Irritability, headache

Convulsions, coma, death

Asperger's syndrome²⁶²⁰

Clinical features (see Berney, 2004)

'Autism without language disturbance'* (Stone, 1997)

Speech: pedantic, lengthy, stereotyped, aprosodic speech

Impaired non-verbal communication

Peculiar social interaction, socially awkward (gaucheness)

Break the normal rules of social engagement

Talk 'at' rather than 'to' others

May avoid the gaze of others or seem to look through others

Odd or awkward body language

Lack of empathy and sympathy

Resistance to change

Clumsy or stereotyped motor movements

Hypertrophied skills or circumscribed interests²⁶²¹ (e.g. collecting facts and figures of little practical value)

Few friends

*Asperger patients have no delay in general/non-social language development. People with Asperger's syndrome must be distinguished from those with schizoid personality disorder. Teasing may lead to social withdrawal in Asperger cases.

The relationship of Asperger's syndrome to Kanner's syndrome (Q.V.) is controversial²⁶²². (Green et al, 2003, p. 516) Various case reports have suggested different brain changes in Asperger's syndrome, e.g. atrophy of the left temporal lobe or atrophy of central brain areas and cerebellum on the left side. MRI in one study suggested that cerebral grey matter volume is enlarged in autism, with Asperger cases coming between autistic cases and control subjects in this regard. (Lotspeich et al, 2004) This is similar to the MRI findings of Toal et al (2010) who found that frontal and temporal grey matter is increased in autism but not in Asperger cases. McAlonan et al (2009a) found greater white matter volumes (on MRI) around the basal ganglia in high-functioning autism (HFA) than in Asperger's syndrome and these two groups of patients had greater values than were found in controls; HFA children had relatively less frontal and callosal white matter in the

²⁶²⁰ Hans Asperger (1906-1980), an Austrian physician, described this disorder in 1944 under the heading of *Autistischen Psychopathien* or 'autistic psychopathy'. Psychopathy refers here to psychopathology or generic personality disorder.

²⁶²¹ Asperger referred to his patients as 'little professors'.

²⁶²² The Expert Group on Mental Health Policy, (2006, p. 245) among many others, favour placing Asperger's syndrome within the autistic spectrum.

left hemisphere, the same applying to Asperger's syndrome but this time in the right hemisphere. Other MRI work suggests that children with Asperger's or autism interpret faces as if they were non-face objects. Increased prefrontal N-acetylaspartate on MRS appears to correlate with obsessional behaviour.(Murphy ea, 2002) Reductions in cortical 5-HT_{2A} receptor binding have been reported in adult cases that might underlie abnormal social communication.(Murphy ea, 2006) Oxytocin infusions may reduce negative, repetitive behaviours in autism and Asperger's syndrome.(Hollander ea, 2003) There is a report of the presence of a non-DNA mutation (epigenetic) in the gene coding for the oxytocin receptor in autism.(Gregory ea, 2009)

Fitzgerald and Corvin (2001) discuss the diagnosis of Asperger's syndrome in some detail and Fitzgerald (2004) suggests that a wide variety of famous people had Asperger's syndrome. Green ea (2003, p. 516) state that Asperger's syndrome has 'become very popular as a diagnosis among parents and professions...led to overuse...many children with disrupted peer relationships, such as those with ADHD and even early antisocial personality [being] mistakenly diagnosed'.

A primary focus should be on improving social competence, e.g. direct instruction, role play, modelling, social stories (illustrated stories used to determine what people are doing, feeling, and thinking), practice with peers in real-life situations, and use of constructive feedback.(Toth & King, 2008) Skills may be broken down into manageable sub-skills.

Autosomal dominant cerebellar ataxia (spinocerebellar ataxia)

A wide number of mutations involving different genes on different chromosomes have been described, and there are genetic tests for this disorder. Onset is usually in young or middle aged adults, although it can start in children or the elderly. There is atrophy of cerebellum, pons, and inferior olives (MRI should be used). The main features are progressive cerebellar ataxia, dysarthria, and nystagmus. Dementia and psychosis (Rottnek ea, 2008) have been reported. It is different from Friedrich's ataxia, which has a recessive mode of inheritance.

Benign essential tremor²⁶²³

Onset at any age; the most common tremor disorder (chiefly affects the hands); often get a positive family history

Possibly inherited as dominant trait with variable penetrance²⁶²⁴

Often misdiagnosed as Parkinson's disease (Benito-León & Louis, 2007)

Titubation occurs more often than in Parkinson's disease and there is no rigidity or bradykinesia

Usually static or extremely slowly progressive

Predictors of progression include asymmetrical tremor and initially unilateral tremor

May respond to beta-blockers (atenolol, propranolol, nadolol, sotalol), topiramate, primidone, gabapentin, a small amount of alcohol (the patient may become dependent), or benzodiazepines (BZDs)

Botulinum A toxin has been used for hand tremor

Medication-induced postural tremor

A fine postural action tremor may be associated with many drugs, e.g. lithium (increased lithium levels lead to coarsening of tremor, twitches/fasciculation), beta-agonists, dopaminergic drugs, stimulants, caffeine, antipsychotics, antidepressants, and anticonvulsants. Essential tremor, also postural, resembles drug-induced postural tremor. The tremor of drug-induced Parkinsonism is of a lower frequency, is exacerbated by rest, and there will be other features of Parkinsonism. Physiological tremor (low amplitude, due to muscle fibre recruitment during contraction) becomes enhanced (increased amplitude) when muscle contraction is maintained. Such enhanced tremors respond to beta-blockers.

²⁶²³ This is also called essential/familial/senile/juvenile tremor or Minor's syndrome.

²⁶²⁴ Usually the tremor disappears when the limbs are still and in some families tremor is more obvious when performing certain actions, e.g. writing.

Bismuth poisoning

Used for diarrhoea and H pylori infection

Depressed, irritable, or euphoric

Insomnia

Delusions or visual hallucinations (rare)

There may be delirium, tremor, myoclonus, ataxia, or seizures

Carbon disulphide poisoning

Used as a solvent (rubber and viscose rayon industries) and in various insecticides

Can cause mixed polyneuropathy, Parkinsonism, CVA, headache, dizziness, diminished libido, anorexia, psychosis, poor attention/memory/vigilance, impaired psychomotor skills, and visuospatial dysfunction

Slowly developing personality change has been reported, e.g. unstable moods, temper attacks, apathy

There may be diffuse leucoencephalopathy

Carbon monoxide poisoning

CO is colourless and odourless

Classically (but uncommonly) the patient is cherry-red, commonly there is cyanosis

Commonly occurs accidentally in environments subject to defective heating or exhaust ventilation; may be taken deliberately by inhaling car exhaust fumes; methylene chloride in paint strippers is converted to CO

Early symptoms are headache, nausea, dizziness, tiredness, malaise, cough, weakness, disorientation,

hyperventilation (a flu-like presentation), followed by psychosis, delirium, seizures and coma

Chronic low-level exposure causes depression and cognitive dysfunction

Acute cases may die or recover fully

About 2% of survivors have chronic sequelae such as Parkinsonism and a Korsakoff-like amnesic state following coma and delirium

Other permanent effects include disorientation, moodiness/irritability/aggressiveness, memory problems, cortical blindness, ataxia, and apraxia

Dysmnestic syndromes usually recover if due to subarachnoid haemorrhage but outlook is less certain if the cause is cerebral hypoxia, e.g. CO

Globus pallidus, hippocampus and cerebral cortex show patchy cell loss

May be confluent areas of demyelination in deep white matter of cerebral hemispheres

Management: remove patient from exposure source; normobaric oxygen (some work suggests that hyperbaric oxygen is better, but this is controversial: see Weaver, 2009); identify and eliminate source

Charles Bonnet syndrome

This is an uncommon disorder²⁶²⁵ due to ongoing neural activity in the visual system (that is lacking stimulation from the sense organ). Classically there are dynamic, colourful, mute and pleasurable visual hallucinations with full insight into their hallucinatory origin. Consciousness is clear. It is associated with eye (macular degeneration, glaucoma, cataract – but vision can be normal) rather than cerebral disease.

Activity has been recorded in the ventral extrastriate cortex during visual hallucinations in such cases, and the content of hallucinations (e.g. colour) activated the appropriate cortical area.(Blakemore, 2002)

Management is that of the eye disease, explanation, reassurance that the patient is not mentally ill, increased domestic lighting, reducing social isolation, and, much less certainly, atypical antipsychotics and anticonvulsants. Some cases get relief when complete blindness is reached.(Jacob ea, 2004)

Auditory variant of Charles Bonnet syndrome

Persistent auditory hallucination (often musical – choirs, show bands, choirs, etc), with preserved insight, in the absence of cognitive decline. Management is as for the visual variety.

²⁶²⁵ The syndrome was described in 1760 by the Swiss philosopher Charles Bonnet (1720-90) who observed it in his grandfather.

Choking

Choking as a problem in psychiatric patients was recorded during the nineteenth century, (Warner, 2004) well before the advent of modern psychotropic drugs. 218 Irish psychiatric inpatients died suddenly or unexpectedly during 1983-92, 22 (10%) from asphyxia: 14 choked²⁶²⁶ and 8 aspirated. (Corcoran & Walsh, 2003) The Heimlich manoeuvre was difficult to use in obese cases. The authors suggest checking for (and investigating) dysphagia, supervision at meal times, review of anticholinergic (impaired gag reflex) and neuroleptic drugs, staff education²⁶²⁷, and consideration of feeding by gastrostomy for patients with cognitive impairment and recurring choking episodes.

An Australian study (Ruschena *et al.*, 2003) found that risk of choking is increased in schizophrenia and organic psychiatric illness. The risk was increased if the patient was treated with thioridazine or lithium. Tardive dyskinesia (TD) may be a factor in choking, as may possibly be schizophrenia itself because of impaired swallowing. (Goff & Shader, 2003, p. 579; Warner, 2004) Eating habits, such as eating too fast, may be a factor in choking. Because choking deaths are rare, determining magnitude of any risk found is problematic.

Chorea²⁶²⁸

Non-repetitive, jerky, semi-purposive, face and trunk movements usually caused by lesion in caudate nucleus. Causes include genetic (e.g. Huntington's disease), infective (encephalitis, Sydenham's chorea), drugs (L-DOPA, phenothiazines – also a cure!), metabolic (pregnancy, anovulants, hyperthyroidism, hypoparathyroidism), and vascular (SLE, polycythaemia). Treatment includes dopamine (DA) receptor antagonists (neuroleptics), DA depletion (tetraabenazine, reserpine), and GABA enhancement (sodium valproate).

Morgan syndrome

Potentially fatal, fibrillary chorea of probable autoimmune causation

Can occur as a paraneoplastic condition

Characterised by involuntary activity of muscle fibre, excessive sweating, and insomnia

Chorea gravidarum

Chorea may be induced by pregnancy or by the contraceptive pill

May have been a childhood history of Sydenham's chorea

Benign familial chorea (hereditary chorea without dementia)

Rare autosomal dominant disorder with no intellectual decline

Usually starts in childhood – usually does not progress further in adulthood, but can do so

Head, face and upper limbs chiefly affected

Must be differentiated from Huntington's disease

Cleft lip and palate

Numerous potential factors of psychiatrist interest may influence the development of these anomalies although the weight of evidence is not strong for some: maternal smoking (alcohol less consistently) during pregnancy, folate and zinc deficiency, anticonvulsants (especially benzodiazepines, phenobarbital, and phenytoin), corticosteroids, first trimester viral infection, and numerous genetic syndromes. (Mossey *et al.*, 2009)

Compulsive water drinking

²⁶²⁶ Average age 51 years, which is younger than fatal choking cases in the general population; 12 were in hospital for > 5 years; main ICD-9 diagnoses: 4 organic psychoses (2 had frontal lobe atrophy at autopsy), 3 intellectually disabled, 6 schizophrenic, and 1 bipolar affective disorder.

²⁶²⁷ Long-handled forceps, mechanical suction, cricothyrotomy needles, and Mendlesohn manoeuvre.

²⁶²⁸ Gk, *choreia*, dancing: as in choreography.

Trainees in psychiatry who spent time in older psychiatric institutions saw chronic schizophrenic patients with their heads under the taps drinking large quantities of water. This led to haemodilution and hyponatraemia. Why institutionalised patients, with a wide variety of diagnoses, should drink excess water is poorly understood. It may partly be iatrogenic (xerostomia secondary to drugs) or a result of their psychopathology ('psychogenic [primary] polydipsia') or boredom. Psychogenesis is far from proved. Some patients will drink bath water or urine if they cannot get anything else. Many drugs may contribute, e.g. nicotine, thiazide diuretics, carbamazepine, chlorpropamide, tolbutamide, clofibrate, cyclophosphamide, and vincristine. Delusions may underlie some cases. Supervision, monitoring of weight, occupation, social activities, and attention to medication if possible should help. Initially, water restriction is essential. It should not be confused with nephrogenic diabetes insipidus (*giving ADHD for compulsive water drinking may exacerbate water overload and cause hyponatraemia*). Increasing the dose of neuroleptic may actually reduce water consumption. (Crammer, 1991) There is some early evidence that clozapine may reduce water consumption in psychiatric patients. (see Goff & Shader, 2003, p. 576)

A normal adult can excrete 15 litres of water daily, but retention of water occurs if intake exceeds this rate. Water retention may be due to the syndrome of inappropriate secretion of antidiuretic hormone. (Q.V.)

Effects of water intoxication (WI): hyponatraemia, and encephalopathy (restlessness, confusion, lethargy, nausea, diarrhoea, vomiting, muscle twitching, ataxia, convulsions, stupor, coma, and even death)
Complications of WI: recurrences of same, bowel and bladder dilatation, hydronephrosis, renal failure, malnutrition, projectile vomiting, cardiac failure, dementia, hernias, incontinence, and spinal fractures due to loss of calcium

Hyponatraemia from water intoxication may be missed unless blood is drawn in the afternoon. In established water intoxication all fluid intake should be stopped and urinary excretion should be awaited. Over enthusiastic correction of hyponatraemia may be a cause of pontine demyelination.

Diabetes insipidus (DI, 'watery sieve'²⁶²⁹)

ADHD (vasopressin) normally binds to the V2 receptors in renal collecting tubules. This action stimulates adenylate cyclase with the eventual insertion of aquaporin water channels. More water is reabsorbed and urine is concentrated. Polyuria leads to polydipsia in DI. In central DI²⁶³⁰ there is not enough ADHD coming from the neurohypophysis whereas in nephrogenic DI ADHD action on the kidneys does not lead to the expected response²⁶³¹. DI should not be confused with diabetes mellitus, psychogenic polydipsia, renal disease, and excess water intake due to phenothiazines. The primary problem in DI is water loss whereas that in psychogenic polydipsia is excess water intake. Nocturia is much more common in DI than in psychogenic polydipsia.

Compulsive utilisation (utilisation behaviour)

In compulsive utilisation, a frontal lobe disorder, the patient will employ anything to hand even whilst knowing that they should not do so. Lhermitte (1983) gave the example of the patient who put on three pairs of spectacles at the one time simply because they were available! Joseph (1996) illustrates compulsive utilisation by the example of a patient who has a hammer and nail placed in front of him and is told not to use them: he never the less hammers in the nail. A patient might see a hypodermic syringe and inject the examining physician! (Baddeley, 2008) A more mundane example would be a person inappropriately drinking someone else's tea.

Differential diagnosis

Alien hand

Mitgehen - patient moves in the direction of even slight pressure despite being told to resist

²⁶²⁹ As distinct from diabetes mellitus or 'sweet sieve'.

²⁶³⁰ The aetiology of central DI includes head injury, surgery, tumours of hypothalamus, TB, sarcoidosis, familial, and idiopathic.

²⁶³¹ The aetiology of nephrogenic DI includes lithium, excess calcium, longterm excess water intake, hypokalaemia, and genetic.

Forced grasping/groping - frontal lobe damage causes person to grope/grasp object seen/felt
Paradoxical intention - psychological ploy e.g. telling a couple to keep fighting in order to stop them arguing

Corticobasal ganglionic degeneration (CBD)

A mostly sporadic condition lasting 4-10 years before death, CBD starts as an asymmetric cortical atrophy in the parietal and posterior frontal lobes and spreads from there. There are neuronal loss and astrocytosis, with abnormal filaments in ballooned cells. This progressive, incurable condition starts in the seventh decade with asymmetric rigid akinetic Parkinsonism of an upper limb (dystonia may mask this presentation in some cases) that is refractory to levodopa. It presents with difficulty carrying out some movement functions. At least half of cases eventually become demented. Yoclonus, postural instability, and alien hand sign may occur. Tau²⁶³² protein (64 and 68 kDa) accumulates in a number of cerebral areas. In some families there are reports of mutation of the tau gene.

Dentatorubropallidoluysian atrophy

This is inherited as an autosomal dominant trait with an expanded trinucleotide (CAG) repeat at 12p12-13²⁶³³. Like Huntington's disease, dentatorubropallidoluysian atrophy is a polyglutamine disorder. There is neuronal loss and gliosis, especially in dentate and red nuclei, globus pallidus, 'corpus Luysii' (i.e. subthalamic nucleus), and other areas. It may commence in childhood or adulthood. The commonest presentation in adults includes ataxia, chorea, and dementia. Children often have dementia and myoclonus. It is a progressive disorder.

Domoic acid poisoning (Cendes et al, 1995)

Very rare sequel to ingesting mussels
 Domoic acid is excitotoxic
 Can cause atrophy of hippocampi and complex partial seizures

Disintegrative disorder (disintegrative psychosis of childhood, Heller's syndrome)

This condition was described by the Austrian educator Theodore Heller in 1908 as *dementia infantilis*. A previously normal child, more commonly a boy, undergoes massive regression between 2-10 years of age. There is severe acquired autism (early normal development distinguishes it from Kanner's syndrome), (usually) loss of cognitive skills, and no evidence of brain degeneration or schizophrenia. Epilepsy may complicate the picture. Rapin (1997) and Green et al (2003, p. 515) include it in the autistic spectrum. The disorder is 60 times rarer than Kanner's syndrome, the prevalence being about 22/million. (Hussain, 2007) Despite claims in the early literature, an association of childhood disintegrative disorder with specific underlying medical/neurological diatheses has not been upheld.

Dystonias

There are various dystonic syndromes. (Drug-induced dystonias are not discussed here.) They are caused by abnormal brain function, usually in the basal ganglia. It has been suggested that dystonia is due to release of premotor cortex from thalamic control. They used to be considered 'psychogenic' in origin. There are sustained muscular contractions affecting almost any part of the body, frequently causing twisting or repetitive movements or abnormal postures.

Different syndromes are frequently named according to site affected, e.g. blepharospasm, writers cramp, and spasmodic torticollis
 Usually starts in one part of body as focal dystonia
 All dystonic movements and postures are exacerbated by attempts to move
 May be progressive, especially when starting in a young person

²⁶³² Tau gene is on chromosome 17.

²⁶³³ The gene is called atrophin. Surviving nerve cells contain intranuclear inclusions consisting of abnormal atrophin-1.

Progression is to segmental or multifocal dystonia, or even generalised dystonia
 Hemidystonia is due to structural cause in > 80% of cases, e.g. stroke, head injury, or brain tumour
 Wide range of disorders can cause secondary dystonia, e.g. Huntington's disease, Wilson's disease²⁶³⁴,
 Parkinson's disease, Lesch-Nyhan syndrome, head trauma, homocystinuria, kernicterus, viral encephalitis,
 arteriovenous malformations, ataxia telangiectasia, neuroleptics and wasp stings
 Drugs causing acute dystonia include neuroleptics (including atypical antipsychotics), SSRIs,
 metoclopramide (antiemetic substituted benzamide), and certain antihistamines (e.g. used to combat
 seasickness)
 Buspirone can lead to persistent dystonia (LeWitt et al, 1993)
 Clozapine can reduce drug-induced dystonia, it can trigger dystonia (responds to anticholinergics or BZDs),
 and dystonia can occur during clozapine withdrawal (Lauterbach, 2000)

Success has been achieved in spasmodic torticollis (wryneck) by injecting botulinum toxin (binds permanently to nerve endplates, blocking Ach (acetylcholine) release – recovery over 8-12 weeks as new endplates grow – may need repeat injections up to 6 times per year) into the contralateral sternocleidomastoid and the ipsilateral splenius muscles.

Blepharospasm

Involuntary closure of eyelids
 Was often mistakenly seen as a form of conversion hysteria
 Primary cases occur alone (essential blepharospasm) or involve other parts of the face or body as well (Meige syndrome²⁶³⁵)
 May be secondary to eye disorders (e.g. conjunctivitis or disease of the cornea) or neurological disease, especially disorders of the brainstem and the basal ganglia (e.g. encephalitis lethargica, focal lesions, Parkinson's or Huntington's diseases)
 Neuroleptics may cause it
 Depression found in up to 30% of cases
 There is sometimes a family history of blepharospasm

Dopaminergic activity is important in regulation of blinking, and spontaneous blink rates are affected by several disorders, e.g. they are reduced in Parkinson's disease and increased in schizophrenia. Owens (1990) suggested that the Pisa syndrome is simply a form of tardive dystonia. Owens (2000) is a useful source of up to date information.

Bilateral stimulation of the internal globus pallidus improves primary generalised dystonia. (Vidailhet et al, 2005) Much more needs to be learned about this treatment ('deep-brain stimulation') before it can be recommended for other than refractory, severe cases. (Greene, 2005)

Dystonia Ireland²⁶³⁶ lists identified inherited dystonias as early-onset generalised dystonia (generalised/idiopathic torsion dystonia: most cases relate to DYT1 gene; twisting of distal limbs), dopa-responsive dystonia (Q.V.), paroxysmal dystonia (attacks of 'kinesigenic' dystonia that are brief and precipitated by sudden movements, or frequent and prolonged paroxysms of dystonic choreoathetosis), X-linked dystonia-Parkinsonism (on Philippine island of Panay; Xq13; focal then tonic dystonia progressing to Parkinsonism), myoclonic dystonia (jerks +/- more sustained contractions/postures), and rapid onset dystonia-Parkinsonism (abrupt onset). The focal dystonias are listed as blepharospasm, cervical dystonia (spasmodic torticollis), embouchure dystonia (affects brass and woodwind players), oro-mandibular dystonia, spasmodic dystonia (affects vocal cords), writer's cramp, and hemifacial spasm (not a true dystonia: irritation of VII nerve causes irregular unilateral facial muscle contraction). As well as these there are the secondary dystonias (*vide supra*). Significant advances have been made in the genetics of dystonia,

²⁶³⁴ Any young patient with hepatic dysfunction, movement disorder, and psychiatric symptoms (or any 2 of these) should be tested for Wilson's disease. Bizarre dystonic posturing may be dismissed as 'psychiatric'.

²⁶³⁵ Described in 1910 as *spasme faciale mediane*.

²⁶³⁶ Tel: 00-353-01-4922514. Fax: 00-353-01-4922565. E-mail: info@dystonia.ie. Web Page: www.dystonia.ie.

e.g. the DYT1 gene and Torsin-A protein (due to a GAG deletion) responsible for early-onset childhood dystonia.

Behavioural approaches such as EMG biofeedback may help. Drugs may be tried, e.g. clonazepam, baclofen, anticholinergic agents, and pimozide. Reducing or stopping neuroleptics, where possible, may help. Reserpine and tetrabenazine, DA depleting agents, have been used but are associated with depression and Parkinsonism. Myectomy and other surgical techniques have been employed. However, no drug is universally affective. Botulinum toxin injected around the eye may give relief for a few weeks but may cause a transient ptosis.

Influenza encephalitis

Usually lasts for days only

May be more common in children

EEG usually shows diffuse abnormality

Headache, vomiting, confusion, coma

Transient limb weakness/reflex changes

Post-viral depression

Less common: hallucinations, transverse myelitis and other spinal/nerve root problems, Guillain-Barré-like syndrome

Encephalitis lethargica (European sleeping sickness, Von Economo's disease²⁶³⁷, EL)

Delirium is followed by drowsiness²⁶³⁸. There may be personality change, obsessional states, oculogyric crises and Parkinsonism. It is due to damage to the substantia nigra, probably caused by influenza A virus. Lymphocytes infiltrate the brain. There is perivascular cuffing and gliosis. Any age group may be affected. Muscles are rigid, tremor is less than in Parkinson's disease, the skin is oily, sialorrhoea occurs, convergence problems are common, and many of the psychiatric problems are transient. EL has become very rare since the epidemic following the 1914-18 war. The Parkinsonian syndrome tends to remain static over time.

Friedreich's ataxia

9q13; expanded triplet repeat (GAA); Frataxin-intronic gene; recessive inheritance

Occasionally accompanied or preceded by schizophrenia-like psychosis with or without violent behaviour

Adult Gaucher's disease

Glucocerebrosidase deficiency (chromosome 1q21-22) and glucocerebroside accumulation in CNS and reticuloendothelial cells

May present with ataxia, behaviour problems, dementia and psychosis

Pantothenate kinase-associated neurodegeneration²⁶³⁹

Autosomal recessive

2 variants: type 1 (mutation of PANK2 gene), type 2 (PLA2C6 gene)

Atrophic, rusty brown (due to iron accumulation) globus pallidus

'Eye of the tiger' sign - decreased and increased signal intensity in the external and internal segments of the globus pallidus respectively on T2-weighted MRI scans

Wide range of age of onset, most often in children and adolescents

Extrapyramidal syndromes

Dementia supervenes

Death in 10-15 years

²⁶³⁷ Described in 1917 by Baron Constantin Von Economo (1876-1931): born in Trieste, studied and worked in Vienna; student of Wagner-Jauregg; did research on mechanism of swallowing.

²⁶³⁸ Von Economo described (a) a brief prodrome of fever and sore throat followed by (b) one of a number of acute presentations (somnolent-ophthalmoplegic, hyperkinetic, Parkinsonian, or any combination of these occurring in any order); all these were accompanied by various neurological disturbances (trismus, seizures, cerebellar signs, aphasia, neuralgia, ptosis, etc); acute cases could be associated with delirium, hypomania, oneroid states, and apathetic depression; and (c) chronic cases were associated with Parkinsonism (often with catatonic phenomena), oculogyric crises, and psychiatric (depression, mania, schizophrenia-like) problems. (McKenna, 2007, pp. 390-395)

²⁶³⁹ This was called *Hallervorden-Spatz disease* but Julius Hallervorden (1882-1965) and Hugo Spatz (1888-1969) received brains from the Nazi euthanasia programme and they have become written out of history!

Schilder's disease (diffuse cerebral sclerosis)

Rare demyelinating condition, sporadic and familial, rapidly fatal, may represent severe early-onset MS

Mostly occurs in children but may affect adults

Schizophrenia-like psychosis, paralysis, blindness, deafness, apathy, dementia, stupor, papilloedema

Greyish or brownish softening of white matter, especially occipital

MS-like CSF findings and smaller CNS lesions are same as in MS

Hashimoto's disease

High titres of anti-thyroid antibodies

Can affect either thyroid (thyroiditis with transient hyperthyroidism) or brain

Cerebral Hashimoto's disease (Hashimoto's encephalopathy²⁶⁴⁰) can cause delirium, myoclonus, and various seizure types or dementia (often with psychotic features) – there are high serum antithyroid antibody levels and it responds to corticosteroids (Chong ea, 2003)

Hereditary mental depression and Parkinsonism (Perry syndrome: Perry ea, 1975)

Rare, rapidly progressive, familial condition (autosomal dominant) with taurine deficiency

Severe neuronal loss in substantia nigra, without alpha-synuclein or tau pathology

Loss of NK-1R and TH immunoreactive neurones in ventrolateral medulla and 5-HT neurone loss in medullary raphe and ventrolateral medulla

Dynectin (DCTN1) mutations (Farrer ea, 2008) causing diminished microtubule binding and introcytoplasmic inclusions

Midlife depression eventually complicated by progressive Parkinsonism

Weight loss

Respiratory failure (central hypoventilation) ensues; death in 2-10 years

Hereditary progressive (DOPA-responsive) dystonia

Rare, dominant (chromosome 14q) disorder

Worsens as the day wears on

Reduced level of tetrahydrobiopterin (co-factor for tyrosine hydroxylase, the rate-limiting enzyme in DA synthesis)

Herpes simplex encephalitis²⁶⁴¹

The virus (HSV-1)²⁶⁴² affects the cortex of the medial temporal lobes and the orbitofrontal cortex. There is widespread cellular destruction and Cowdry type A inclusion bodies may be found in affected nerve cells. The patient quickly becomes very unwell. Classical symptoms include pyrexia, confusion, changes in behaviour, somnolence, amnesia, and partial complex seizures. There may be sensory problems, visual field defects, aphasia, and cranial nerve dysfunction. Delirium, often resembling DTs, proceeds to coma. Restless overactivity may follow recovery from coma. Mortality rates fell from 7 to 2 out of ten cases with the advent of antiviral drugs. If the patient survives there may be dementia (intellectual disability in children) with dysphasia, personality change, a Klüver-Bucy syndrome or a Korsakoff-like syndrome. Less common are emotional lability and schizophrenia-like psychosis. Following a non-specific phase, the EEG demonstrated *episodic* epileptiform temporal lobe activity. MRI shows high signal in the temporal lobes on T₂-weighted scans. The CSF has raised white cell numbers. PCR of CSF for herpes simplex DNA is positive in most (95%) cases, brain biopsy only being needed if CSF cannot be obtained. IV acyclovir should be used early. Valacyclovir is an alternative drug. Foscarnet may be needed in the immunocompromised since such patients may be resistant to acyclovir. Dexamethasone and mannitol are useful for cerebral oedema, but cerebral decompression may be required. Anticonvulsants are used for seizures. There were some early scares that fluoxetine might reactivate herpes infection.(Reed & Glick, 1991)

²⁶⁴⁰ First reported by Brain ea.(1966)

²⁶⁴¹ In general, some cases of viral encephalitis, of which HSV-1 is an example, can have a psychopathological rather than a neurological presentation, e.g. psychotic depression, mania, other psychosis or catatonia. There may be a mistaken psychiatric referral. In such cases there is an increased risk of extrapyramidal side effects (EPS), catatonia, or neuroleptic malignant syndrome (NMS) from use of antipsychotic drugs.

²⁶⁴² HSV-1 and HSV-2 are associated with labial (cold sore) and genital herpes respectively.

AIDS patients may be severely affected with severe haemorrhagic encephalitis and even an ascending myelitis. Other causes of encephalitis need to be considered, e.g. mumps and arbovirus. Type B HSV virus²⁶⁴³ is transmitted by the bite or scratch of a monkey (or even a splash in the eye) and is fatal in about 80% of cases.

Herpes zoster virus

This may invade the central or peripheral nervous system in AIDS patient and cause diffuse encephalitis. Neuronal and glial eosinophilic inclusion bodies indicate the presence of the virus.

Brain abscess

This may be disarmingly silent although the great majority of cases will have a source of infection that varies from middle ear infection to bronchiectasis²⁶⁴⁴. The patient may feel unwell, with some change in personality or minimal confusion. Headache, when present, may be unremarkable. Fever may not occur in longstanding cases. Because of the gradual nature of abscess expansion, intracranial pressure may be little affected and papilloedema may be a late finding. At a later stage the abscess may simulate a neoplasm with worsening headache, seizures (epilepsy in one-third of cases), personality change, and focal signs (depending on location, e.g. anosmia if the frontal lobe is involved). Meningism may be manifest. Rupture may be fatal. Lumbar puncture is unlikely to add much and carries a risk of coning. CT is usually adequate to make the diagnosis (ring-shaped hyperdense area with surrounding oedema). Treatment involves aspiration, excision, and antibiotics. Outcome is variable and epilepsy is a common sequel.

Hydrocephalus

This can be of one of three types: non-obstructive, communicating (secondary to brain atrophy), obstructive and non-communicating (secondary to blocked CSF flow within the ventricles), and obstructive and communicating (normal pressure hydrocephalus - secondary to a block of CSF flow in the subarachnoid space or failure of normal absorption).

Hydrogen sulphide (sewer gas) poisoning

Gas smelling of rotten eggs

Exposure in leather tanning, oil refining, and sourgas field work (natural gas production)

Interferes with cellular respiration, causing hypoxia

Exposed person can lose consciousness ('knockdown') and die or be left with permanent neurological sequelae

Motor signs include ataxia and tremor

Neurological symptoms may appear after apparent recovery

Less severe exposure can cause mucous membrane irritation, headache, nausea, confusion, dizziness, dyspnoea, chest pain, and bradycardia

Hyperekplexia (familial startle disease, Kok disease)

Rare hereditary disease that may be associated with mutation in glycine receptors

Excessive startle to unexpected noise, movement, or touch

Hypertonia, falling stiffly like a log, hyperreflexia, and unsteady gait may occur

Inappropriate antidiuretic hormone secretion (IAHS)

This has been reported in association with a wide variety of drugs, including carbamazepine, dothiepin, lofepramine and fluoxetine. The early symptoms of hyponatraemia (confusion, weakness, etc.) may mimic a psychiatric condition.

²⁶⁴³ Human infection with this neurotropic virus is very rare. Manifestations include a blister at the site of the bite, necrosis in many organs including brain, and, in many cases, ascending paraplegia. Following the death of a doctor in 1932, Albert Sabin (1906-1993) identified an unfilterable agent from autopsy material.

²⁶⁴⁴ The chief pathogens are streptococci, staphylococci, and E coli.

Rett's²⁶⁴⁵ syndrome/disorder

This is almost confined to females, is X-linked with mutation in the MeCP2 gene²⁶⁴⁶ in most classic cases, and has a prevalence of 0.8/10,000 girls. There is initial normal development during first months, then slowing of head growth, stereotypies (wringing/clapping of hands), truncal/limb ataxia, loss of interest in surroundings, severe language problems (expressive and receptive), psychomotor slowing, intellectual retardation.

Austistic disorder (autism, infantile autism)²⁶⁴⁷

The boundaries of this non-mendelian disorder(s) are not clear. Hence terms varying in restrictiveness from 'core autism' via the wider 'autistic spectrum disorders' and 'pervasive developmental disorders'. (Green ea, 2003, p. 503) Rapin (1997) described DSM-IV's pervasive developmental disorder (PDD) as 'the spectrum of autism' and divided it into autistic disorder/classical autism, Asperger's syndrome, pervasive developmental disorder not otherwise specified (perhaps the most common PDD), Rett's disorder and childhood disintegrative disorder (Q.V.). DSM-IV-TR does not allow a separate diagnosis of ADHD in the presence of a pervasive developmental disorder even when the diagnostic criteria for ADHD are present²⁶⁴⁸. Kanner²⁶⁴⁹ described autistic disorder, an idiopathic condition, in 1943. Prevalence among schoolchildren was said to be about 0.02-0.04%. Reported increases to 0.2-0.5% of schoolchildren may be due to more active search for cases and changes in diagnostic criteria, (Rapin, 2002; Green ea, 2003, p. 513; Honda ea, 2005) although a true increase cannot be ruled out. (Lauritsen ea, 2004) The prevalence of childhood autism in the Eastern Health Board area of Ireland²⁶⁵⁰ was estimated by McCarthy ea (1984) to be 4.31/10,000 (0.04%) children. These authors divided the 28 affected children on the multi-axial classification system into 3 groups: classical nuclear autism (50%), autism and profound intellectual disability, and autism and equally significant biological and/or psychosocial factors (21%). It is about 3-4 times more common in boys than in girls and can start any time during the first 24 months of life. Increasing numbers of children being diagnosed with autism in the UK during 1992-2000 may be related to a 20% drop in those diagnosed as having 'behavioural' and 'developmental' disorders matched by a 20% increase in those given the label of 'autism', i.e. a shift in diagnostic habit. (Jick & Kaye, 2003) Recent UK estimates of prevalence among pre-school children were 16/10,000 for core/classic autism and 62/10,000 for pervasive developmental disorders. (Chakrabarti & Fombonne, 2001) Again, such high figures might represent changes in approach to diagnosis rather than any real increase in numbers. Baron-Cohen ea (2009) in the UK estimate that the ratio of known to unknown cases of autism spectrum conditions is about 3 to 2 and, based on a school-based survey, that the spectrum prevalence is 157/10,000.

Numbers diagnosed with autism spectrum disorders over two decades increased by a factor of ten, from one in 4,000 to at least one in 400. (Honda ea, 2005) There is a seven-fold difference between the various US states in diagnosis rates. Bishop ea (2008) suggested that some adults diagnosed in childhood with developmental language disorder would now be diagnosed with autistic disorder.

The child may appear normal prior to its onset²⁶⁵¹. Parents have been reported as being of high intelligence and non-autistic relatives may have an excess of cognitive and speech problems. In reality there is no social class bias. The early notion of emotionally cold parents as a cause of this condition has been jettisoned unceremoniously.

Gardener ea (2008) conducted a meta-analysis and found insufficient evidence to state that any one prenatal factor is causative of autism. However, there was some evidence suggesting an increased risk if the patient was exposed to pregnancy complications. An association between having an older father and increased risk (1.8) for high-functioning autism has been reported from Japan. (Tsuchiya ea, 2008) There is evidence for increased paternal age in the genesis of autism spectrum disorder, whether through fresh mutations or

²⁶⁴⁵ Andreas Rett (1924-1997) a paediatrician in Vienna described this disorder in 1966.

²⁶⁴⁶ Encoding X-linked methyl-CpG-binding protein 2: in Rett's syndrome there is disruption of MeCP2 which is a protein that binds to methylated DNA.

²⁶⁴⁷ Gk. self. Also known as Kanner's syndrome or primary autism or childhood autism or simply 'autism'.

²⁶⁴⁸ This is at odds with the statement in *A Vision for Change* (Expert Group on Mental Health Policy, 2006, p. 245) that 'autism is no longer considered to be primarily a mental disorder'.

²⁶⁴⁹ Leo Kanner (1894-1981), born Austria and worked at Johns Hopkins Hospital, Baltimore. His original sample was subject to referral bias which probably explains why he associated autism with more successful parents!

²⁶⁵⁰ Later, and briefly, the Eastern Regional Health Authority, centred on Dublin.

²⁶⁵¹ However, the infant may show limited eye contact, little smiling or facial responses, and a dislike of being held. Mild variants (here one might include Asperger's syndrome) may not be recognised until just before or after starting school. (Tantum, 1988)

altered genetic imprinting.(Reichenberg ea, 2006) Previous studies, of different methodologies, had suggested a connection between older fathers and risk for autistic-spectrum disorder in offspring, including cases with intellectual disability, although not all studies confirm this association.(Larsson ea, 2005) There is no scientific evidence for a connection between autism or Crohn's disease and the MMR ('triple' or measles, mumps and rubella) vaccine²⁶⁵².(Anonymous, 2002a; Taylor ea, 2002; Chen ea, 2004; Smeeth ea, 2004; Baird ea, 2008; Charatan, 2009²⁶⁵³) There is some evidence for poor hearing, other perceptual difficulties, general cerebral dysfunction, receptive dysphasia, and a genetic element with variable penetrance. There is some preliminary evidence for accelerated head growth in infancy.(Courchesne ea, 2003) Israeli suggestions of a link between in vitro fertilisation (IVF) and autism (see Barron, 2010) are very preliminary and must take into account the relatively greater age of the mothers and higher incidences of prematurity and low birth weight. Autosomal recessive inheritance has been suggested. The pooled frequency of autism in the siblings of autistics is about 2.7%, 50 times that in the general population.(Le Couteur, 1990) It may be neuropathologically heterogeneous²⁶⁵⁴. Identical (MZ) twins concordant for autism and with obvious evidence of perinatal brain damage have been reported. The increased reports of obstetric complications may reflect foetal abnormality rather than aetiology.(Glasson ea, 2004) MZ co-twins are more likely to be concordant for autism as are DZ co-twins, 65% versus 0% respectively.(Pericak-Vance, 2003) Even though autistic people rarely have offspring the condition does not die out, suggesting that autism is only part of the potential phenotype. The genotype may be passed on via those with milder phenotypes (social and communication deficits and stereotyped behaviour has been reported in families where more than one sibling was autistic). Mutations in genes encoding neuroligins²⁶⁵⁵ might be involved in autism.(Chih ea, 2004) Deletions within the neurexin 1 gene on chromosome 2p have been reported in autism and in schizophrenia.(Rujescu ea, 2008) According to Guilmatre ea (2009) weakly to moderately recurrent copy number variations (CNVs), transmitted or occurring *de novo*, might have an aetiological or contributory role in autism, schizophrenia, and intellectual disability. Pinto ea (2010)²⁶⁵⁶ found in autism spectrum disorders a higher global burden of rare (< 1% frequency) CNVs compared to controls, especially for loci previously implicated in ASD and/or intellectual disability; there were a number of *de novo* and inherited events among the CNVs, sometimes in combination in a given family; many novel autism spectrum disorders genes (e.g. SHANK2, SYNGAP1, DLGAP2, and the x-linked DDX53-PTCHD1 locus) were implicated; and there was enrichment of CNVs disrupting functional gene sets involved in cellular proliferation, projection and motility, and GTPase/Ras signalling. Ramoz ea (2004) reported linkage and association between autistic disorder and two SNPs on chromosome 2q.²⁶⁵⁷ This suggests involvement of the aspartate/glutamate carrier. Weiss ea (2008) reported a microdeletion and microduplication on chromosome 16p11.2 that might account for 1% of cases²⁶⁵⁸. A large genome-wide study (Wang ea, 2009) reported an intergenic region between cadherin²⁶⁵⁹ 9 and 10 on chromosome 5p14.1 in autism spectrum disorder patients. About 2 of 3 cases are mentally retarded.²⁶⁶⁰ Affected children may appear superficially normal and perform deceptively well in some areas, such as constructional tasks or music. They may exhibit catastrophic reactions when attempting a task. They appear to inhabit a world of their own. 20%-25% of autistic children will develop seizures by the age of 18 years, usually starting in adolescence (especially likely if there is severe intellectual disability).

²⁶⁵² This hasn't stopped litigants being recompensed in the US.(Offit, 2008)

²⁶⁵³ US Court of Federal Claims rejected a connection with autism in 2009. Andrew Wakefield, the UK gastroenterologist who started the MMR controversy, was struck off by the GMC in 2010.(Kmietowicz, 2010)

²⁶⁵⁴ E.g. **Timothy syndrome** is an excessively rare autosomal dominant disorder with syndactyly, long QT, cardiac arrhythmias and malformations, and, in half of cases, facial dysmorphism. Autism or autistic spectrum disorder may be found. The average age at death is 2.5 years. Mutations occur in the CACNA1C gene on chromosome 12p13.3.

²⁶⁵⁵ A synaptogenic substance involved in pre- and post-synaptic differentiation.

²⁶⁵⁶ The research group included TCD involvement, e.g. Michael Gill.

²⁶⁵⁷ These finding are not universal.(Rabionet ea, 2006)

²⁶⁵⁸ 16p contains an excess of 'recent' duplications from the evolutionary standpoint.(Eichler & Zimmerman, 2008)

²⁶⁵⁹ **Cadherins** (calcium dependent **ad**hesion molecules) are type-1 transmembrane proteins that are involved in cell-cell adhesion and they require calcium ions in order to function.

²⁶⁶⁰ In a twin study, Hoekstra ea (2009) found that extreme autistic traits are substantially genetically independent of intellectual disability.

Some findings in autism (roughly as published)²⁶⁶¹

Reduced Purkinje cell counts in the cerebellum

Normal and abnormal brainstem auditory evoked potentials to high intensity stimuli in younger and older cases respectively
Abnormal brainstem auditory evoked responses using an ipsilateral masking procedure may delineate most autistics from most intellectually disabled children - further work is required on reports of prolongation of early brain auditory-evoked response inter-peak latencies in autism

Non-replicated report of hypoplasia of the cerebellar vermis in both retarded and non-retarded patients with autism on MRI

MRI: a number of cortical defects (e.g. macrogyria and cortical clefts) in studies with small numbers - may relate to defective neuronal migration during foetal life

MRI (males): brain enlargement due to increased brain tissue volume (increased grey matter) and enlarged ventricles

Enlargement of hippocampus in some but not all MRI studies (Rojas ea, 2004)

MRI: corpus callosum size may be relatively small in autism

MRI study from birth through age 2 years: generalised enlargement of cortical (gray and white matter) but not cerebellar volumes at 2 years in autism, the onset of enlargement likely being during the latter part of the first year of postnatal life (Hazlett ea, 2005)

Some MRI results have been entirely negative, as has some SPET (SPECT) studies, although there is a suggestion that metabolic maturation of the frontal cortex may be delayed

MRI on MZ twins: white matter growth may be reduced or delayed (Kates ea, 2004)

PET study of autistic children listening to speech-like sounds found diminished activation in left speech-related areas,(Boddaert ea, 2004) confirming previous results obtained in adults (Boddaert ea, 2003) Combined PET/MRI in high functioning autism: smaller and relatively inactivated right anterior cingulate gyrus areas relative to controls

MRI (Palmen ea, 2005): no differences between non-affected relatives and healthy controls

Non-specific hyperserotoninaemia in one-third of cases

Although cholinergic enzyme markers are normal in autism, many nicotinic (high-affinity) and moderate muscarinic M1 receptor measures in the cerebral cortex are lower than normal

Brain-derived neurotrophic factor level in basal forebrain is higher than normal

MRI: larger right amygdala at 3-4 years associated with more severe clinical course and worse outcome at 6 years of age (Munson ea, 2006)

Initial support for genotype-specific phenotypes for serotonin transporter gene promotor in autism (Brune ea, 2006)

MRI: autistic people with small amygdala slowest to distinguish emotional from neutral expression and show least eye region fixation (Nacewicz ea, 2006)

MRI: women with autistic spectrum have similar brain abnormalities to men (Craig ea, 2007)

MRI: adult autistic spectrum disorder (Asperger's, autism, and pervasive developmental disorder not otherwise specified) associated with small cerebellum and increase in peripheral CSF.(Hallahan ea, 2009)

MRI: adults with autism spectrum disorder with/without psychosis v healthy controls – all patients had decreased grey matter bilaterally in temporal lobes and cerebellum and increased grey matter in striatum; those with psychosis had reduced grey matter in frontal and occipital areas; psychosis is associated with reduced grey matter in of right insular cortex and bilaterally in cerebellum extending into fusiform and lingual gyri.(Toal ea, 2009)

MRI: amygdala volume was increased relative to control subjects in autism at age 2 years with no further relative increase at 4 years and amygdala volume was associated with joint attention that requires focusing on eye area of the face.(Mosconi ea, 2009a)

MRI: MZ twins discordant for autism (one with narrowly defined autistic deficits, the other with varying levels of such deficits – ages 5-14 years) compared with normal singletons: alterations in PFC, corpus callosum, and posterior vermis found in autistic children and these vary in degree with severity of autism phenotype (Mitchell ea, 2009)

MRI: In adults with autism spectrum conditions: specific local increase in cortical thickness of the fusiform gyrus and associated impairment of face processing; anatomical covariance between amygdala volume and increase in fusiform gyrus local thickness was significantly smaller in adults with autism spectrum conditions than in healthy controls (Dziobek ea, 2010)

MRI-PET: autism spectrum associated with larger right caudate and reversal of expected left-right hemispheric asymmetry, and lower relative glucose metabolic rates bilaterally in ventral caudate, putamen, and thalamus (Haznedar ea, 2006)fMRI study (Allen & Courchesne, 2003): compared to healthy controls, autistic patients showed significantly greater cerebellar motor activation (pressing a button v rest condition) and significantly less cerebellar attention (pressing a button on seeing a target stimulus v passive looking) activation

fMRI study(Müller ea, 2003): male autistics activated different brain areas from controls when doing finger press movements prompted by visually presented repeating 6-digit sequences

Minor obstetric problems in autism may reflect a genetically abnormal foetus (Le Couteur, 1993)

fMRI: possible amygdala hyperarousal in autism spectrum disorders in response to socially relevant stimuli; sustained amygdala arousal might contribute to social deficits (Kleinmans ea, 2009)

MRI: right-handed, non-mentally retarded boys with autism had decreased brainstem gray matter volume relative to controls (Jou ea, 2009)

fMRI: low levels of autistic traits are found when much of the anterior mid-insula had positive connectivity with the pregenual anterior cingulate cortex²⁶⁶²; increased levels of autistic traits are associated with negative connectivity between these 2 regions (Di Martino ea, 2009)

PET: high-functioning autism (20 men) has widespread decreased 5-HT transporter binding in brain (in the thalamus this correlated with obsessional symptoms/behaviour); dopamine transporter binding is increased in OFPFC and this inversely correlated with 5-HT transporter binding; the authors admitted that their sample was not typical of all adults in the community (Nakamura ea, 2010)

²⁶⁶¹ Neuroimaging results are difficult to interpret overall and there remains a danger of finding what is being sought!(Deb & Thompson, 1998)

²⁶⁶² The pregenual anterior cingulate cortex is important is important for 'theory of mind'.

MRS: autism spectrum associated with increased concentration of glutamate/glutamine and creatine/phosphocreatine in amygdala-hippocampal region but not in parietal region (Page ea, 2006)

Disturbed control of voluntary behaviour in autism spectrum disorders as reflected in repetitive behaviours may be due to alterations in frontostriatal systems as indicated by failures to inhibit prepotent responses (increased rates of prosaccade errors) on an antisaccade task; prosaccade errors were associated with the level of higher-order (compulsions, preoccupations, etc) but not sensorimotor behaviours (Mosconi ea, 2009b)

There is an increased incidence of fragile X, PKU, epiloia, and neurofibromatosis.

Clinical features include aloofness²⁶⁶³, gaze avoidance, attachment to unusual objects like spoons, obsession with maintaining the same routines and environment, catastrophic reactions, finger flicking close to eyes, flapping of hands, jumping, grimacing, turning, walking on toes, and mutism. There are also meaningless speech, immature speech, lacking in gestures, poor comprehension, lack of sense of humour, rage reactions, self-mutilation, incongruity of affect, aimlessness, and lack of involvement in childhood pastimes. I-you pronominal reversal and inappropriate echoing is often found in those who achieve speech. The 'autistic triad' consists of autistic aloneness, speech and language disorder, and an obsessive desire for sameness. Neuropsychologists report sequencing, abstraction and symbolic meaning deficits, and impaired ability to make socio-emotional discriminations and to use socio-emotional cues.(Bölte & Poustka, 2003) Socially and intellectually the prognosis is poor in most cases but a minority does reasonably well. Three good prognostic pointers are significant improvement by age 7 years, IQ of at least 60, and adequate speech development by 5 years. The speed with which other symptoms are discarded is a useful indicator of future adjustment. Autistic patients visually fixate on mouths and objects rather than the eyes of other people. Better and worse social adjustments are associated with fixation on mouths and objects respectively. The shorter the time spent fixated on eyes the stronger the likelihood of autism.(Klin ea, 2002) There is no specific treatment, therapies varying from vitamins to stimulants. Parents need reassurance, support and guidance. Tranquillisers and hypnotics may be needed, but there may be idiosyncratic reactions and non-responsiveness. Secretin (a gut hormone normally given by IV infusion but which can be administered transdermally or sublingually) received huge publicity in 1999 in the US as a dramatic treatment for autism. A small percentage of cases appeared to disimprove when given secretin and its usefulness was not confirmed in placebo-controlled studies.(Owley ea, 2001; Roberts ea, 2001) Efficacy of D-cycloserine therapy for social withdrawal is supported by a pilot study.(Posey ea, 2004) The main intervention comes under the heading of general education. Parents must be part of the treatment team. Behavioural approaches are of adjunctive status only and the French practice of 'packing' autistic children in cold wet sheets for long periods is highly controversial!(Spinney, 2007) Parents may deliberately intrude into the child's life in order to increase social interaction. Stimulants are not indicated for hyperactivity because they do not work and they may make it worse. Risperidone may reduce tantrums, aggression, and self-injurious behaviour,(Research Units on Pediatric Psychopharmacology Autism Network, 2002, 2005) at least while it is being taken. Similarly, risperidone was found to improve restricted, repetitive, and stereotyped behaviours and interests in autistic children, but to be ineffective in changing deficits in social interaction and communication.(McDougle ea, 2005) King ea (2009) found a lack of efficacy of citalopram in the treatment of repetitive behaviours²⁶⁶⁴ in children and adolescents with autistic spectrum disorders. Differential diagnosis includes constitutional shyness, fear (e.g. CSA), normal acting strange phase (6-7 months of age), schizoid personality disorder, simple schizophrenia, deafness (can be fluctuant with secretory otitis media), upset over family problems, depression, specific language impairment, brain damage, intellectual disability, Asperger's syndrome, OCD, and elective mutism. Schizophrenia is no more common in Kanner's syndrome than in the general population. In other words, these children do not grow up to be schizophrenic. Schizophrenia should not be diagnosed in patients with autistic disorder unless there is independent evidence (delusions and hallucinations) for it.(Nasrallah & Smeltzer, 2002, p. 41)

²⁶⁶³ Not all cases conform to the classic *aloof* stereotype. *Passive* cases will accept the approaches of other people, albeit passively or with level of contentment, and will approach others to have needs attended to. Finally, an *active-but-odd* group do make spontaneous if one-sided and persistent approaches.(McKenna, 2007, p. 408)

²⁶⁶⁴ These include stereotyped movements, inflexible routines, repetitive play, and perseverative speech.

Kufs' disease²⁶⁶⁵

Ceroid lipofuscinosis²⁶⁶⁶ in adults; sporadic or familial (recessive or dominant); with lipofuscin deposition in nerve cells, myoclonus, dementia, and cerebellar and extrapyramidal signs

Metachromatic²⁶⁶⁷ **leucodystrophy (O'Shea, 2010a)**

Autosomal recessive (multiple mutations described on chromosome 22q)

Decreased aryl sulphatase A levels in lymphocytes

A sphingolipid (sulfatide) accumulates in tissues

Diffuse loss of CNS myelin

Affected adult may develop cerebellar and long tract signs, neuropathy, behaviour disorders, personality change, psychoses, and progressive dementia

Mercury poisoning²⁶⁶⁸

Most medical devices containing mercury have been removed from circulation

In severe cases delirium proceeds to coma

Milder cases are tired, irritable, insomniac, and wish to be left alone, so-called 'erythrism'

Other complications include coarse tremor ('hatter's shakes'), sensorimotor neuropathy, nephrotic syndrome, uraemia, ptyalism, spongy haemorrhagic stomatitis, loose teeth, weight loss and GIT upset

'Pink disease' (acrodynia) is a childhood disorder, rare today, due to mercury-containing teething powders, nappy powders, ointments or worming formulations: the child is miserable and has skin rashes, muscle weakness and red extremities

SPECT may show hypermetabolism in the posterior cingulate cortex

The clinical picture varies depending on the type of mercury: organic mercury, as from contaminated fish, causes mainly neurological problems (neuropathy, ataxia, visual field defects) whereas inorganic mercury causes 'Mad Hatter's disease', i.e. mainly neuropsychiatric problems (irritability, depression, psychotic states)

Motor Neurone disease (MND, Lou Gehrig's disease, amyotrophic lateral sclerosis²⁶⁶⁹, **ALS)**²⁶⁷⁰

Most cases are sporadic and idiopathic

About 10% of cases run in families

Linkage studies have identified a number of genes, some autosomal dominant, others autosomal recessive

The first gene to be discovered was SOD1 (chromosome 21, autosomal dominant, encodes superoxide dismutase 1), the cause of ALS1

May develop frontal lobe dementia that follows a rapid course

Disturbed emotional responses with inappropriate and uncontrollable laughter and crying²⁶⁷¹

²⁶⁶⁵ Hugo Friedrich Kufs (1871-1955), Leipzig neuropathologist.

²⁶⁶⁶ The **neuronal ceroid lipofuscinoses**, a subgroup of the lysosomal storage disorders, are mostly autosomal recessive disorders. Childhood forms cause intellectual and motor deterioration, blindness, a variety of seizure types, and early death. Dementia is the main feature of the adult forms. The infantile form (Santavuori-Haltia-Hagberg disease) is mainly found in Finland while the late infantile form (Jansky-Bielschowsky disease) commences between 2 and 4 years of age and the juvenile form (Vogt-Spielmeyer disease, Batten disease) starts at 5-10 years of age. Kufs' disease starts in adults with progressive myoclonic epilepsy and sparing of the eyes. There are also congenital and a dominantly inherited adult form (Parry disease). For a further introduction see Steinlein.(2008)

²⁶⁶⁷ Metachromatic – chemical looks a different colour depending on wavelength of light.

²⁶⁶⁸ The old saying 'as mad as a hatter' referred originally to a condition developed by hatters who used **mercury** to hold down felt fibres on top hats. During the period 1953-67, a factory on Minamata Bay, Kyushu, Japan, deposited mercury waste into the sea. Many thousands developed different degrees of mercury poisoning ('Minamata disease'), some being fatal. Mercurialism was first reported in New Jersey in 1860 (5 years before Lewis Carroll's 'Alice in Wonderland'). Mercury is found in thermometers and sphygmomanometers (still used in Ireland in 2007: McKeon, 2009), folk cures, botanical preparations, contaminated fish (especially predators), explosives, seed dressings, dental amalgam, and (see pink disease) teething powders. The fetus may be at special risk for developmental reasons when mother consumes contaminated fish. The present author recalls the silver discoloration of gold wedding rings among female physiology staff when he was a student.

²⁶⁶⁹ Whilst in the US amyotrophic lateral sclerosis (ALS) is synonymous with MND, on this side of the Atlantic ALS is, along with progressive muscular atrophy, progressive bulbar and pseudobulbar palsy, and the rare primary lateral sclerosis, but one subtype of MND. However, these subtypes may merge into one another in the later stages of disease progression.

²⁶⁷⁰ The actor David Niven died of MND.

Neuronal degeneration in brainstem

Distressing to patient and family

Diseases causing psychiatric phenomena plus lower motor neurone signs, apart from MND, include HIV and the leucodystrophies

Multiple system atrophy

Idiopathic sporadic condition starting during 40s or 50s and patient dies in about 9 years

Variable atrophy of cerebral cortex, striatum, pontine nuclei, inferior olivary nuclei, and cerebellum

Cytoplasmic inclusions in oligodendroglia

Although mixed forms are commoner (especially with the passage of time), three presentations have been described: striatonigral, olivopontocerebellar²⁶⁷², and Shy-Drager (intermediolateral spinal gray matter involvement causing autonomic symptoms) variants

Suspect this diagnosis when there is Parkinsonism plus autonomic failure, pyramidal signs, vertical gaze palsy, or ataxia

There may be insomnia, diurnal somnolence, REM sleep behaviour disorder

Other problems may include depression, emotional lability, and mild frontal lobe syndrome dysfunction

Variable response to L-DOPA

Myasthenia gravis

Anti-nicotinic acetylcholine receptor antibodies are commonly found in this condition. Early signs include depression, hypochondriasis, hysterical reactions (*and* misdiagnosis of hysteria or feigning), diplopia, ptosis, general weakness (worse at night, if emotional, or during menstruation), difficulty with swallowing and mastication (may need to support jaw), a flattened expression (loss of normal wrinkles +/- a snarl, and inability to smile), and a nasal voice which fades with use. If a nerve is stimulated at 2-10Hz (repetitive stimulation test) action potentials do not vary in normals. In myasthenia gravis the amplitude may fall over successive stimulations²⁶⁷³. An EMG from a single muscle fibre should show stable times between muscle fibres from the same the same muscle unit but in myasthenia gravis the time between firing may vary.

Lithium is contraindicated because it blocks Ach release in therapeutic dosage. Because myasthenia gravis is associated with increased resistance to and slow recovery from depolarising muscle relaxants (e.g. during ECT), a reduction in dosage may be required. Unfortunately, such patients are very sensitive to non-depolarising agents. (Weiner et al, 2001, p. 34)

At least 10% of cases have a thymoma and Mediastinal tomography should be formed to check on thymic status (and to look for bronchogenic carcinoma in cases of Eaton-Lambert syndrome).

Neuroacanthocytosis (choreoacanthocytosis)

An often familial neurological disorder: autosomal recessive (VPS13A gene mutation at 9q21, coding for chorein)

Various psychiatric symptoms e.g. personality change, paranoid delusions, depression, anxiety, and OCD
Chorea, seizures, progressive dementia

Involuntary biting of lips and tongue in a few cases

²⁶⁷¹ **Involuntary emotional expression disorder:** This phenomenon, noted by Hippocrates and Charles Darwin, has been known under many names, e.g. affective/emotional lability, pathological affect, emotionalism, emotional incontinence/dyscontrol, pseudobulbar affect/crying, forced laughter or crying, and involuntary emotional expression disorder. It appears to be caused by disruptions of regulatory/inhibitory mechanisms in the cortico-limbic-subcortico-thalamo-cortico-cerebellar network and may involve 5-HT, dopamine, glutamate, sigma receptor neurotransmitters. Various treatments have been used, such as antidepressants, dopaminergic agents, and combined dextromethorphan-quinidine. (Rabins & Cummings, 2007)

²⁶⁷² T2-weighted scans may show 'hot-cross bun' sign (crossed lines) at base of pons.

²⁶⁷³ In the **Eaton-Lambert syndrome**, amplitude increases progressively over successive stimulations (so-called inverse myasthenia). Anti-nicotinic acetylcholine receptor antibodies are not found. There may be antibodies voltage-regulated calcium channels at the neuromuscular junction. Clinical findings may include proximal atrophy and weakness, ptosis, diplopia, xerostomia, and tendon reflexes that disappear but return when muscular effort is sustained. The syndrome is often (about 2 out of 3 cases) associated with neoplastic disease (e.g. oat-cell) and may precede signs of cancer by a very long period of time. Anticholinesterases are unlikely to be very effective. Steroids, immunosuppressants, 3,4-diaminopyridine, guanidine, and plasma exchange may reduce symptoms.

Spiky projections in red cells (acanthocytes)²⁶⁷⁴

Onset at any age

Organophosphate poisoning

Organophosphates²⁶⁷⁵ inhibit cholinesterase leading to increased availability of acetylcholine (Ach)

Acute exposure causes a cholinergic crisis

Symptoms include tension, anxiety, irritability, restlessness, and headache with high-level exposure

May be weakness, muscle fasciculation, tachycardia, small pupils, lacrimation, sweating, seizures, and coma

Proximal muscle weakness and hyporeflexia may follow later

Chronic low-level exposure associated with increased GHQ scores, reduced attention span and slowed information processing

These problems may persist after removal from exposure

Mood changes and memory problems may persist after an acute cholinergic crisis

Progressive multifocal leucoencephalopathy (PML)

Papovirus (JC, SV-40, etc) infection

Presents as dementia in immunocompromised (e.g. AIDS, Hodgkin's disease, sarcoidosis, leukaemia) individuals

Natalizumab may induce PML

Progressive cerebral destruction with demyelination

Multiple white matter lesions on MRI

Diagnosed by histology and virology of brain tissue

Huge astrocytes with distorted nuclei and abnormal mitotic activity

Inclusions in nuclei of oligodendroglia

Death usually follows after some months

Progressive supranuclear palsy (Steele-Richardson-Olszewski syndrome)

Dudley Moore (1935-2002), English comedian and actor, was a victim of this disease. In this rare²⁶⁷⁶ idiopathic disorder there is cell loss and gliosis in the basal ganglia, brainstem, and cerebellar nuclei, with relative sparing of cortical neurones. There are neurofibrillary tangles that, unlike in AD, consist of straight tubules. There is depletion of DA in the substantia nigra and basal ganglia and of choline acetyltransferase and glutamic acid decarboxylase in the basal ganglia. MRI may show midbrain atrophy. It commences in the sixth decade of life and continues for 5-10 years until death supervenes. Features include supranuclear paralysis of external ocular muscles²⁶⁷⁷ (especially in the vertical plane – patients have problems looking downward so that they miss steps on the stairs), dysarthria (slurred growling), pseudobulbar palsy²⁶⁷⁸, dystonic trunk and neck rigidity, cognitive dysfunction (extreme slowing of responses, apathy, difficulties recognising similarities, concrete interpretation of proverbs, and apparent memory difficulties²⁶⁷⁹), depression, social avoidance, psychosis, personality change, and labile emotions. There may be dysfunction of the cerebellum and pyramidal tracts. Frequent falling, often backwards, is a common presentation. Unlike Parkinson's disease cases, there is no tremor of the hands and there is a less favourable response to levodopa. Memory difficulties and behaviour/personality may occur in some cases due to fronto-temporal lobar involvement. At the latest stage there is a bedridden patient whose eyes are fixed centrally and all of

²⁶⁷⁴ Found in fresh wet smears of peripheral blood (may be missed if a number of specimens are not taken).

²⁶⁷⁵ Used for agricultural pest control, sheep dipping, as well as chemical warfare (Sarin, VX, etc).

²⁶⁷⁶ Incidence: 1/100,000 of pop.

²⁶⁷⁷ This may give rise to a stare reminiscent of the painting *Mona Lisa*.

²⁶⁷⁸ The full picture of **pseudobulbar palsy** (bilateral upper motor neurone lesion) includes emotional incontinence, difficulty protruding the tongue, dysphagia, dysarthria, and increased gag reflex and jaw jerk. The cause is bilateral interruption of corticobulbar fibres at some point between cortex and pons. Aetiology covers cortical infarction, lacunar infarctions in the sub-cortex, Alzheimer's disease, Binswanger's disease, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy, MS, head injury, Behçet's disease, amyotrophic lateral sclerosis, and progressive supranuclear palsy. Differential diagnosis of emotional incontinence (no control over laughing which may embarrass patient) include post-CVA emotionalism (congruent emotional display and feelings), inappropriate affect as in schizophrenia (may feel the opposite to the emotional display), and the labile mood of the manic (congruent display of affect and associated emotional feeling).

²⁶⁷⁹ Patients may get the correct answers if given plenty of time.

whose limbs are rigid. Specific tau gene mutations (64 and 68 kDa, as in CBD) have been reported in rare families with a similar syndrome. However, the majority has a negative family history and no single gene has yet been incriminated.

Disseminated candidiasis

Meningitis, vasculitis, abscesses

Occurs in immunocompromised patients

Lethargy, confusion, drowsiness, headache

There may be psychiatric symptoms

No evidence for occult *Candida* infection causing various physical and psychological problems

Cat-scratch fever

Bartonella henselae infection

Found in children who are bitten/scratched by a cat

Most cases have lymph gland involvement that remits spontaneously

Encephalopathy²⁶⁸⁰: lethargy, seizures, and combativeness

Rocky Mountain spotted fever

Infection with *Rickettsia rickettsii* (transmitted by tick bite)

Pyrexia, malaise, muscle pain, and headache followed by rash (starting at wrists and ankles)

There may be lethargy or delirium

Focal signs are not uncommon

Brucellosis

Acute infection: pyrexia, sweating, and muscle and head pain

Chronic infection (there may be no acute history): depression, fatigue, and various pains

CNS involved in 1 in 20 cases: meningitis, psychosis, cranial nerve involvement

Stammering (stuttering)

There is impaired continuous utterance with a complex, multifactorial, heterogeneous aetiology.

Developmental cases affect 1% of adults. Genomewide scans have suggested linkage at many chromosomal sites, e.g. on 12q in Pakistani families.(see Fisher, 2010) It is made worse by stress and interferes with psychological maturation. Scanning shows exaggerated right hemispheric activity suggesting abnormal motor control.(Breathnach, 2000) There have been a few published case reports of clozapine-induced stuttering.(e.g. Duggal ea, 2002; Lyall ea, 2007)

Stiff-person (stiff-man) syndrome (Moersch-Woltman syndrome)

This rare (affecting the sexes equally and being probably autoimmune in origin²⁶⁸¹) condition was described in 1956. It can start in children under 3 years (espc. infants, who are at risk for sudden infant death) or in adults (usually in 3rd to 5th decades). There are constant painful contractions and spasms of voluntary muscles (twisting and contracting may even fracture bones), especially the back and thighs; it may spread to the arms and neck. It is exacerbated by emotion, sudden noise or movement and alleviated by sleep. Kyphosis and lordosis may occur. Diazepam helps most cases. Other treatment options include

²⁶⁸⁰ Temperature may be only moderately raised.

²⁶⁸¹ Stiff-person syndrome may also be a paraneoplastic syndrome with antibodies against the synaptic protein amphiphysin.

baclofen, phenytoin, clonidine, tizanidine, IV immunoglobulins, physiotherapy, and rehabilitative techniques. Outlook is uncertain.

Sydenham's chorea (St. Vitus' dance)

This starts 1-6 months after the carditis of rheumatic fever. It is uncommon today. Average duration is 2 months.

Sydenham's chorea

Affects children 5-15 years of age

Onset insidious with grimacing, limb movements, etc

Movements can be exaggerated by making child hold a fixed posture, e.g. 'stand to attention' or 'stand on the ball of one foot'

During the illness the patient is listless, irritable, and emotionally labile

Explosive or halting speech may occur

50% have residual minor psychological problems

Obsessive-compulsive symptoms are over-represented.

About a quarter of cases eventually develop rheumatic valvular disease

MRI shows a swollen head of caudate nucleus

At postmortem, and therefore in severe cases, there are extensive microscopic haemorrhages. One-fifth of cases may recur when the patient starts on the contraceptive pill or when they become, usually for the first time, pregnant. Sydenham's chore may be caused by genetic susceptibility to cerebrovascular inflammation triggered by streptococcal infections. It might be related to hyperoestrogenaemia - girls more often than boys get it during puberty, and also, as seen above, there is the connection with the pill and with pregnancy. It is possible that a permanent increase in DA sensitivity occurs. Possible causes of the mental problems during the illness are increased DA sensitivity, exhaustion, and cerebro-vascular inflammation. Post-illness neurotic symptoms are said to be not uncommon. Because this disorder has its onset in childhood, the main psychological changes are behavioural: hyperkinesis, restlessness, emotional lability and, rarely, manic episodes. Treatment is largely symptomatic. The abnormal movements may be controllable with pimozide (Orap).

Systemic (disseminated) lupus erythematosus (SLE)

Small cerebral blood vessels may be affected in SLE, with scattered infarcts and bleeds. There is inflammation, damage, and intimal proliferation. There may be alternating narrowing and dilatation²⁶⁸² of vessels.

SLE onset peaks in women between late teens and early 40s; it is 9 times more common in females than males; and African and Asian ancestry carries increased risk. (D'Cruz ea, 2007) SPECT may show multiple perfusion defects. Oestrogen preparations (e.g. anovulants) may exacerbate SLE and increase the risk of thrombosis. Tests for anti-nuclear antibody (ANA: non-specific but sensitive) and for antibodies to dsDNA (double-stranded DNA) and Sm (Smith) antigen are appropriate investigations. SLE is notorious for the variety of neuropsychiatric guises under which it may present: epilepsy (any type), strokes, peripheral neuropathy, myasthenic syndromes, mild or psychotic affective disorders, dementia (see Sundquist ea, 2008), and uncommonly, transient recurrent hemiplegia. In one study (Thomas and Bresnihan, 1986) of 50 successive patients with SLE presenting to a tertiary referral rheumatology department, the following neuropsychiatric manifestations were noted; total (78%), headache (40% - recurrent, severe, migrainous type), depression (26%), peripheral neuropathy (18%), acute brain syndrome (14%), epilepsy (12%), paresis (10%), cranial nerve palsy (19%), ataxia (6%), chronic brain syndrome (6%), and (N=1) chorea (2%). Ruiz-Irastorza ea (2001) and Mak ea (2009) provide a much longer list of neuropsychiatric manifestations of SLE, of which delirium, anxiety, cognitive dysfunction, mood disorder, and psychosis are of particular relevance to psychiatrists. A number of syndromes associated with involvement of the peripheral nervous system have been reported, e.g. Guillain-Barré syndrome, polyneuropathy, and myasthenia gravis.

²⁶⁸² So-called 'beading': usually associated with vasculitis.

Subacute sclerosing panencephalitis (SSPE)

May follow measles infection or (rarely) after measles vaccination (latter has actually reduced SSPE incidence)

Usually in people under 11 years of age, M > F

High levels of measles antibody in CSF

Paretic curve on Lange's colloidal gold test

Paramyxovirus-like particles seen budding from cytoplasmic inclusions on electron microscopy

Transmissible to other species via intracerebral brain tissue inoculation

Initial distractibility, oppositionality, temper outbursts, and fall off in scholastic performance

Sleepiness and hallucinations, confined to bed by 6 months

Dementia, myoclonus, cortical blindness, chorioretinitis, optic atrophy, quadriplegia and coma

MRI (T₂-weighted) hyperintensity of occipital lobe and subcortical white matter, relative frontal sparing

Bursts of triphasic slow waves on EEG

Death within 12-36 months

Progressive rubella panencephalitis**Affects children exposed to rubella *in utero* and resembles SSPE****Thallium poisoning**

Usually due to ingesting rat/insect poison

Acute cases associated with GIT symptoms, delirium, seizures, painful sensory polyneuropathy, cranial nerve signs (loss of vision, double vision, facial palsy), and alopecia

Chronic ingestion associated with dementia, alopecia, and painful sensorimotor polyneuropathy

Tin poisoning

Can cause delirium and seizures

Trichloroethylene poisoning

Degreasing solvent

Exposure may occur occupationally or due to contamination of drinking/bathing water

Neurotoxicity may be due to trichloroethylene or to its derivative dichloroacetylene

Acute effects include headache, dizziness, nausea, vomiting, confusion and various levels of lowered consciousness

Facial anaesthesia, reduction in taste sense, ptosis/diminished pupillary responsiveness/constricted visual fields, dysarthria, flattened nasolabial folds, encephalopathy, and sensorimotor neuropathy may persist

Chronic exposure leads to anorexia, trigeminal nerve damage, fatigue, irritability, headache, paraesthesiae, dizziness, sleep/memory/concentration problems, sexual dysfunction, and peripheral neuropathy

Children may experience problems with hearing and speech

Tuberculosis

TB meningitis has experienced resurgence because of HIV. Basilar meningitis is usually insidious in onset and causes headache, a low fever, malaise, and delirium, with/without neck stiffness. There may be cranial nerve palsies (III, IV, VI, and VII). Hydrocephalus causes a dramatic clinical deterioration. A tuberculoma presents as a space-occupying lesion, often with seizures. Diabetes insipidus and hypernatraemia may follow hypothalamic involvement. Staining of CSF often misses the causative organism, culture is frequently positive (but takes 8 weeks), and PCR assay may reveal DNA from *M. tuberculosis*. The PPD may be negative in AIDS. MRI shows basilar meningitis²⁶⁸³ and, if present, tuberculomata. The fundus may

²⁶⁸³ Oedema, focal infarcts, exudate in basal cisterns, and hydrocephalus on MRI.

show choroidal tubercles. Early treatment is associated with good recovery but neurologically complicated cases may be left with a variety of sequelae²⁶⁸⁴. Untreated cases die in a state of decerebrate rigidity.

African trypanosomiasis

‘Sleeping sickness’ is transmitted by the tsetse fly. The early stages include, fever, weakness, glandular and skin involvement, with enlargement of liver and spleen. A chronic meningoencephalitis is associated with tremulousness, seizures, hemiplegia, apathy, somnolence, and coma. Psychiatric symptoms (irritability, aggression, apathy, inactivity, and psychosis) may dominate the clinical presentation and lead to psychiatric admission! (Brun ea, 2010)

Typhus fever

This rickettsial, body louse-borne disease damages the endothelium of small vessels with resultant thrombosis and necrosis. Glia, phagocytes and endothelial cells may form nodules. A rash appears on the fifth day. As the fever decreases there may be significant manifestations of CNS involvement: headache, delirium, stupor, coma, hemiplegia, bulbar signs, ataxic gait, optic neuritis, deafness, and meningism. CNS damage may be permanent. The CSF demonstrates increases in lymphocytes and globulin.

Whipple’s disease²⁶⁸⁵

Caused by the bacterium *Tropheryma whippelii*²⁶⁸⁶, the most common manifestations stem from joint and intestine involvement (steatorrhoea, weight loss, abdominal pain). Involvement of the CNS is associated with focal inflammation and necrosis and glial scars in many brain areas. PAS-positive macrophages are found in affected areas. MRI may help to locate lesions. CSF reveals a mild increase in lymphocytes with/without raised protein levels. Other tests include looking for PAS-positive macrophages in jejunum or CSF. There may be dementia, delirium, personality change, supranuclear ophthalmoplegia, hypothalamic syndromes, somnolence, convulsions, ataxia, myoclonus, secondary (to diarrhoea) B12 deficiency, and movement of the eyes when the jaw moves (oculo-masticatory myo-arrhythmia). Treatment is with antibiotics (penicillin or tetracycline +/- steroids).

Wilson’s disease²⁶⁸⁷ (hepatolenticular degeneration)(O’Shea, 2010b)

This autosomal recessive disorder has an incidence of about 1 per million. It results from one of a number of mutations in the ATP7B gene²⁶⁸⁸ on chromosome 13q.

Serum caeruloplasmin (hepatically derived copper-contain globulin) is greatly reduced²⁶⁸⁹, liver copper is increased, serum copper concentration is diminished unless fulminant liver failure ensues, urinary copper concentration is increased, and there is failure of incorporation of ⁶⁴Cu (radioactive copper with very short half-life²⁶⁹⁰) into caeruloplasmin. Bronze skin is usually a late manifestation of Wilson’s disease. The Kayser-Fleischer ring²⁶⁹¹ is due to copper deposition in Descemet’s membrane. Sunflower cataracts may be found. There is atrophy and brownish discoloration of the striatum, eventually with cavity formation. Opalski cells are large phagocytic cells found in the brain in Wilson’s disease. Cortical atrophy is mild. Confirmation of diagnosis is by liver biopsy. About 20% either present with psychiatric symptoms or are at least seen by a psychiatrist before definitive diagnosis. (Denning & Berrios, 1989)

²⁶⁸⁴ E.g. various forms of paresis, seizures, blindness, deafness, precocious puberty, diabetes insipidus, sleep problems, and intellectual disability.

²⁶⁸⁵ The American physician George Hoyt Whipple (1878-1976) described this condition in 1907.

²⁶⁸⁶ Rod-shaped as seen by electron microscopy.

²⁶⁸⁷ Samuel Alexander Kinnier Wilson (1874-1937), a London neurologist, described this condition in 1912.

²⁶⁸⁸ This gene encodes a member of the copper-transporting P-type adenosine triphosphatases which exports copper from cells. Numerous mutations have been described and these vary with country of origin.

²⁶⁸⁹ Nearly all plasma copper is bound to caeruloplasmin. Most Wilson’s disease cases have reduced caeruloplasmin synthesis. But, since 5% have a normal serum caeruloplasmin concentration, something else is required for the disorder to manifest itself.

²⁶⁹⁰ Hence a rarely performed test.

²⁶⁹¹ This ring is not only found in (the great majority of cases of) Wilson’s disease. It may also occur in autoimmune hepatitis and in primary biliary cirrhosis.

*Wilson's disease: psychiatric symptoms*²⁶⁹² (Denning & Berrios, 1989)

Aggression, irritability

Disinhibition

Impulsive, incongruous behaviour

Depression

Grimacing or unmoving expression (vacuous expression with open mouth)

Cognitive dysfunction

Psychosis (1%) and drug misuse (both uncommon)

Neurological signs occur in 40% or more of cases (dysarthria, flapping wrist tremor, wing-beating tremor at the shoulders²⁶⁹³, fluctuating limb rigidity, dysarthria, dysphagia, hemiplegia, coma attacks, dystonia, and choreiform movements. The kidneys may be affected as may the joints. Episodic haemolytic anaemia can occur. Cardiomyopathy and cardiac conduction problems have been reported. T2-weighted images may show the 'face of the giant panda sign'.²⁶⁹⁴ Younger age of onset carries a worse prognosis. The main treatments for Wilson's disease are copper chelating (e.g. penicillamine²⁶⁹⁵ and trientine [triethylene tetramine dihydrochloride]) and copper depleting (e.g. zinc and tetrathiomolybdate) drugs. (Lauterbach, 2000) Liver transplantation is sometimes used. Low copper diets are not part of treatment.

Wolfram syndrome (DIDMOAD)

Pathogenesis may involve anti-CNS autoantibodies. The posterior pituitary may be poorly developed or absent on MRI.

Wolfram syndrome

Rare – described in 1938 by Donald J Wolfram MD

Autosomal recessive – mutation in WFS1 gene, chromosome 4

DI - diabetes insipidus

DM - diabetes mellitus

OA - optic atrophy

D - deafness

Other manifestations - ataxia, dysarthria, nystagmus, dysdiadochokinesia, dysphagia, anosmia, and EEG changes

25% - psychiatric problems, e.g. severe episodes of depression, psychosis, organic brain syndrome, and impulsive physical and verbal aggression

Heterozygotes (carriers) also appear prone to significant psychiatric difficulties. A small number have demonstrable CNS changes such as pontocerebellar atrophy.

Amnestic disorders

Kayser-Fleischer ring

²⁶⁹² 195 cases: 60 given psychiatric assessment; half demonstrated psychiatric problems at some stage; one-fifth saw a psychiatrist before definitive diagnosis.

²⁶⁹³ Arms are abducted and elbows are flexed: movements resemble those of a startled bird.

²⁶⁹⁴ There is high signal intensity in tegmentum, hypointense superior colliculus, and preserved signal intensity in lateral pars reticulata of substantia nigra.

²⁶⁹⁵ Penicillamine can cause psychosis and seizures.

These disorders involve impaired memory²⁶⁹⁶. Directly as a result of a general medical disorder or trauma, there is transient (lasting less than one month) or chronic (> 1 month) impaired learning of new information or an inability to recall information that was learned in the past and the memory problem is not confined to a time when the patient is delirious or demented. Such conditions impair the patient's function and are new developments in their lives, i.e. there is a decline from premorbid memory ability. Immediate and remote memory is generally preserved. The patient may be disorientated. Often the patient cannot recall the causative incident. Insight is most often lacking. Confabulation is more common early on in the course of the disorder than in its late stages. The most common cause is probably head injury, although alcohol abuse/thiamine deficiency (dealt with elsewhere) is the classic cause. Known causes are many but include head injury²⁶⁹⁷, seizures, cerebrovascular disease, brain tumours, hypoglycaemia, hypoxia, carbon monoxide (CO) or heavy metal poisoning, Herpes simplex encephalitis, Klüver-Bucy syndrome, acute alcoholic blackout, Wernicke-Korsakoff syndrome, ECT, and drugs (benzodiazepines, barbiturates, MDMA, and intrathecal methotrexate). Acute onset is associated with such causes as cranial injury or CO poisoning. More insidious onset and chronic course is typical of drug abuse, prolonged exposure to toxins, or nutritional deficiency. Transient global amnesia is temporary amnesic syndrome that is discussed below. Most cases of amnesic syndrome are due to bilateral brain lesions involving areas such as thalamic nuclei (dorsomedial and midline), hippocampus, fornix, amygdala, and mammillary bodies. Rare cases are due to extensive left-sided damage. Some causes, such as electroconvulsive therapy, are not accompanied by typical brain lesions. Malingered and factitious cases must be considered in the differential diagnosis.

*Transient global amnesia (TGA)*²⁶⁹⁸

Migraine, epilepsy, Valsalva-induced venous return causing retrograde transmission of high venous pressure to cerebral veins, and reduced blood supply²⁶⁹⁹ to the temporal lobe and diencephalon are among suggested causes. SPECT demonstrated reduced blood flow in temporal and parieto-temporal areas, especially in the left hemisphere.

TGA

Episode of sudden loss of memory

Middle-aged/elderly patient suddenly unable to register new information from the senses

May last for a few hours

Memory for earlier events is as normal as ever

Depersonalisation and bewilderment are common

May quizz companions repeatedly

Patient remains alert

Complex functions such as driving do not seem to be adversely affected

Amnesia for events occurring during attack

Normal neurological examination

May be precipitated by neck movements

Benign

Recurrences are uncommon (< 20%)

Mimics: temporal lobe tumour, benzodiazepines +/- alcohol

TGA-like episodes may accompany sexual intercourse, epilepsy, general anaesthesia, migraine, cardiac arrhythmias, myxomatous disease of the mitral valve, and polycythaemia rubra vera.

²⁶⁹⁶ Eric Kandel (Nobel Prize in Medicine in 2000, sharing with Arvid Carlsson and Paul Greengard) was born in Vienna in 1929 and is a contemporary psychiatrist at Columbia University. He studied memory using the gill reflex of the sea snail *Aplysia* and found that the formation of memories occurs at synapses and thereafter different mechanisms and synaptic changes determine whether memory is stored for short or long term use.

²⁶⁹⁷ There is an argument for giving thiamine routinely to the head injured because of the fact that an amnesic syndrome is easy to miss in such circumstances.(Ferguson ea, 1997)

²⁶⁹⁸ Described by Fisher and Adams.(1964)

²⁶⁹⁹ Perhaps due to vertebro-basilar ischaemia.

813 Delirium

Latin *delira* (L. *de lira* out of the row or furrow) meaning 'off track', i.e. mad or crazy²⁷⁰⁰

Also known as *acute brain syndrome* or *acute confusional state*

Non-psychiatric medical clinicians were often, until recently, (incorrectly) taught that delirium was not an organic syndrome²⁷⁰¹ (Caplan ea, 2008, p. 227)

Aetiological factors are numerous, e.g. Behçet's syndrome, carbon monoxide, cysticercosis, bacteria, dementing disorders, drugs, drug withdrawal, embolism, endocrine disorders (including diabetes), epilepsy, heat stroke, heavy metals, histoplasmosis, hypertensive encephalopathy, hypoxia, paraneoplastic syndrome, mumps, normal pressure hydrocephalus, sarcoidosis²⁷⁰², trauma, vascular, viruses, vitamin deficiencies, Wilson's disease, etc

Aetiological factors act on a vulnerable brain to precipitate delirium

Most cases of delirium are multifactorial in origin

Common combination of dementia plus delirium sometimes called *beclouded dementia*²⁷⁰³

Abnormal EEG²⁷⁰⁴ favours diagnosis of delirium but normal recording does not rule it out (APA, 2002, p. 43)

10-30% of medical ill inpatients develop delirium, especially elderly (often prolonged delirium), post-surgical cases²⁷⁰⁵, AIDS (30-40% of hospitalised AIDS cases), terminally ill, burns, dialysis, and CNS lesions

Main causes in HIV patients are medication (e.g. zidovudine, efavirenz²⁷⁰⁶, isoniazid, dapsone, etc), drug use/withdrawal (e.g. alcohol, phencyclidine²⁷⁰⁷), infection (e.g. toxoplasmosis²⁷⁰⁸), neoplasms, and metabolic disorders (e.g. renal failure); anticholinergic drugs (including opioids) may exacerbate delirium

Common in psychiatric patients – iatrogenic, substance misuse, overdose, increased physical morbidity, geriatric depression associated with poor diet and fluid intake, etc

Deafness, poor sight, acute stress, bereavement, depression, brain damage, alcohol/substance dependence, and sensory deprivation are risk factors for delirium

Common in nursing homes – it may become more common outside hospital following shortened hospital stays and an increase in day-surgery (Brown & Boyle, 2002)

²⁷⁰⁰ *Typhus* (Gk) means 'mist' or 'cloud', a Hippocratic usage to refer to changed mental state in pyrexial states.

²⁷⁰¹ However, ancient physicians appear to have recognised that delirium was a disorder of the brain. They divided it into *phrenitic* (overactive) and *lethargic* (underactive) forms.

²⁷⁰² **Sarcoidosis** may be due to unknown environmental agents interacting with genetically susceptible individuals. The clinical aspects of sarcoidosis of most interest to the psychiatrist are fatigue (often with pyrexia, loss of weight, depression, malaise, and raised C reactive protein), CNS involvement (meningeal inflammation/infiltration, aseptic meningitis, diabetes insipidus, encephalopathy, vasculopathy, seizures, mass effects, and hydrocephalus), and peripheral nervous system effects (cranial nerve palsy [especially VII nerve] and small fibre neuropathy). (Dempsey ea, 2009) CNS involvement occurs in about 5% of cases. Psychoneurological symptoms can include apathy, self-neglect, problems with judgement, irritability, hallucinations, schizophrenia-like psychosis, diminished consciousness, and dementia. (Lovestone, 2009, p. 888) Sarcoidosis may be less common in smokers. (Innes & Reid, 2006, pp. 715 & 717)

²⁷⁰³ Perhaps 25% of cases are a combination of delirium and dementia.

²⁷⁰⁴ **EEG:** In mild delirium the EEG shows slowing of the dominant posterior rhythm whereas in severe cases one sees widespread theta and delta rhythms. Severe toxic or metabolic delirium may have triphasic waves instead of diffuse slowing. Withdrawal from alcohol and other sedatives is characterised by low voltage, fast activity. Structural problems are suggested by periodic lateralised epileptiform discharges. Uncommonly, one may diagnose non-convulsive status epilepticus.

²⁷⁰⁵ Especially cardiectomy, hip surgery, or transplantation.

²⁷⁰⁶ Efavirenz can also cause depression, insomnia, vivid dreaming, dizziness, and poor concentration. Such side effects usually resolve by one month and **usually** do not require discontinuation. *Efavirenz can give a false-positive cannabinoid test.*

²⁷⁰⁷ **Phencyclidine** intoxication is associated with ataxia, dysarthria, nystagmus, reduced pain responsiveness, altered body image, agitation, and assaultive tendencies.

²⁷⁰⁸ **Toxoplasmosis**, less common since the introduction of HAART, represents reactivated latent infection with the intracellular protozoan *Toxoplasma gondii*. There is acute meningoencephalitis, diffuse or focal. After a period of lethargy, there may be headache, confusion, and focal neurological signs. Neuroimaging usually shows many ring-enhancing basal ganglia and grey/white matter junction lesions. Pathologically there are scattered abscesses with encysted parasites. Thrombosis leads to necrosis. Treatment is with combined pyrimethamine and sulfadiazine.

Cryptococcosis (*Cryptococcus neoformans*), a fungus, may cause granulomatous meningitis with a thick basal exudate. Features may include malaise, headache, meningism, confusion, changed behaviour, raised intracranial pressure, focal neurological signs, and fungus stained with India ink or presence of cryptococcal antigen in the CSF.

The ascending reticular activating system²⁷⁰⁹ (RAS) of the mesencephalon is responsible for maintaining an activated cerebral cortex and its blood supply is peculiarly open to insult from any significant rise in CSF pressure. It is uncommon for this system to be the site of a primary disorder, but it is often affected by systemic disorders.

Functions of reticular activating system

- Arousal
- Balance
- Control of heart and breathing
- Control of conjugate eye movement

Reactions to organic cerebral insult vary between individuals. Whilst not backed by research evidence (Lipowski, 1980), it is clinically observable that some people weather severe physical insults with equanimity and others 'give in' and become confused.

Most confusional states result from the interaction of three main factors:

1. *Unrecognised complications of a primary condition*, such as pneumonia²⁷¹⁰ arising during detoxification from alcohol
2. *Drug therapy and drug interactions*, such as barbiturates in porphyria
3. *The psychological status of the patient* (related to current emotional expectation and past experience)

Predisposing/precipitating factors in delirium (Hogg, 2008)

Older age, male sex

Dementia²⁷¹¹

Sleep deprivation

Severe illness

Admission for fracture, hospital admission,

Dehydration, malnutrition, reduced mobility

Poor vision/hearing

Polypharmacy (including over-the-counter), anticholinergic load, general anaesthesia (vs spinal anaesthesia)

Use of physical restraints²⁷¹², urinary catheter²⁷¹³

Risk factors for postoperative delirium (Fricchione et al, 2008)

Pre-surgery – old age, dementia, smoking, poor functional status, abnormal electrolytes or glucose levels, and albumin of 4 g/dl or less

During surgery – blood loss, fluid infusion requirements, vascular²⁷¹⁴ surgery

Post-surgery – haematocrit > 30%, multiple blood transfusions, abnormal electrolytes or glucose levels, and albumin of 3 g/dl or less

Psychiatrists should resist any tendency of non-psychiatric physicians to view delirium as a primarily psychiatric concern (APA, 2002, p. 47) and should not agree to the transfer of a delirious patient to a psychiatric ward.

Impaired ability to draw a clock-face may be a useful predictor of postoperative delirium.

Delirium must be distinguished from depression, dementia (especially Lewy body), and mania.

²⁷⁰⁹ The RAS bilaterally projects to the thalamus to regulate alertness. Inputs to the RAS from neocortex and limbic system control attention. Acetylcholine is the main RAS neurotransmitter.

²⁷¹⁰ Most people who have dementia of any type will die from bronchopneumonia or from pulmonary embolism.

²⁷¹¹ About one-quarter of older people with delirium have an underlying dementia.

²⁷¹² Other risks associated with restraints are choking, decubitus ulceration, and other consequences of immobilisation.

²⁷¹³ A catheter not only provides a route/nidus for infection, it also reduces mobility.

²⁷¹⁴ E.g. CABG or repair of abdominal aortic aneurysm.

Anything interfering with concentration or perception may precipitate a confusional state, e.g. shadows, dim light, frequent staff changes, inadequate or incorrect drug usage, and admission to hospital. Quite simple things such as constipation, moving shadows, dark corners, poor illumination, dehydration, or urinary retention or infection may precipitate delirium. Drug-induced delirious states may confound the unwary physician. These may aggravate underlying brain damage.

Examples of drugs reported to have caused delirium (incomplete)

ACTH

Antibiotics – e.g. aminoglycosides, gentamicin, isoniazid, metronidazole, sulphonamides, tetracyclines, vancomycin, etc

Anti-epileptics – phenytoin, carbamazepine, vigabatrin, valproate, clonazepam

Antihypertensives – captopril, clonidine, methyldopa, reserpine

Anticholinergics – atropine, benztropine, benzhexol, diphenhydramine, scopolamine, antipsychotics, TCAs, etc

Antiarrhythmics – disopyramide, lidocaine, mexiletine, procainamide, quinidine, etc

Anti-ulcer drugs – cimetidine, ranitidine

Antivirals – acyclovir, interferon, etc

Beta-blockers – propranolol, etc

Central dopamine agonists – amantadine, bromocriptine, L-DOPA, selegiline

Chlorpropamide

Clozapine

Contrast media - metrizamide

Corticosteroids

Digitalis, theophylline

Disulfiram

Diuretics - acetazolamide

Ergotamine

Immunosuppressants – aminogluthethamide, chlorambucil, 5-fluorouracil, tamoxifen, vinblastine, etc

Ketamine

Lithium

MAOIs – phenelzine, procarbazine, etc

Mefloquine

NSAIDs – ibuprofen, indomethacin, etc

Opiate analgesics²⁷¹⁵ – pethidine, pentazocine, etc

Sedative-hypnotics – baclofen, barbiturates, benzodiazepines, Z-drugs

Sympathomimetics – amphetamine, aminophylline, cocaine, ephedrine, phenylephrine, phenylpropanolamine

A history of excessive drinking should always be sought on admission. Industrial poisons like dichlorodiphenyl trichlorethane (DDT) or trichloroethylene (Q.V.) can cause delirium.

The classical understanding of neurotransmitter malfunction in delirium is that DA activity is increased and Ach activity is reduced. DA may act via its regulatory role in Ach release. Cytokines, including interferon, may contribute by increasing blood-brain barrier permeability and influencing neurotransmission. Chronic stress caused by trauma or illness activates the sympathetic nervous system and HPA axis with increase in cytokine and cortisol levels.(see O’Keeffe & Devlin, 1994) Chronic high cortisol levels had deleterious effects on 5-HT1A receptors in the hippocampus that may also contribute to delirium.(Inouye, 2006)

One theory of the perceptual abnormalities of delirium is the escape of dream material into the waking state. Students undergoing sensory deprivation experienced frightening hallucinations similar to those seen in delirium tremens (DTs).

Complications of encephalitis

Prolonged anxiety and depression

Dementia

Personality change

Epilepsy

Behaviour disorder in children

Acute schizophrenia-like psychosis

²⁷¹⁵ Since pethidine can cause delirium and seizures morphine is safer (unless there is renal failure).

Presentations of delirium

Hyperactive ('agitated', 'hyperalert')

Quiet ('lethargic', 'hypoactive', 'hypoalert')

'Mixed' (alternating hyperactivity and hypoactivity²⁷¹⁶)

Mixed delirium is the most common presentation. (Liptzin & Levkoff, 1992) Quiet (hypoactive) cases²⁷¹⁷ of delirium are often overlooked or misdiagnosed as depressed; the patient may drift into sleep during a conversation.

Consciousness is impaired in delirium. The level of consciousness varies over time, often closely related to variations in pain, sedation, or the discernibility of the environment. It may be subtle or profound. The patient has rational periods, especially when spoken to. There may be reduced awareness of the environment, a diminished capacity to attend to specific issues or to shift attention appropriately from one matter to another, and distractibility.

Fear may be marked (and relatives may be distressed). Mood is usually labile. Temporal disorientation is an early feature. Later on there is global disorientation. Confabulation²⁷¹⁸ may occur, as may dysmnnesia. Restlessness usually commences at night (*sundowning*). Insomnia by night, sleep reversal with fitful daytime naps, and agitation are frequently encountered. Violent behaviour should be met with enough attendants to restrain the patient safely. The patient should be spoken to in calm, reassuring tones. The patient's mental life is full, unlike the impoverished cerebration of the demented. Personality or other psychiatric problems may become exaggerated. Hallucinations are usually visual or visual plus auditory. Seizures may cause or complicate delirium.

Double orientation

Person appears to reside in two worlds simultaneously, e.g. recognising a nurse for what she is while at same time believing, wrongly, her to be his daughter

Where appropriate, before prescribing medication one should attempt non-pharmacological interventions such as changing the environment or employing verbal and non-verbal de-escalation. (Young et al, 2010)

Preventing delirium (Young & Inouye, 2007)

Orient the patient

Activate the patient

Good nutrition and hydration

Non-drug management of insomnia and anxiety

Spectacles or hearing aid

Treat pain

Early discharge to home rehabilitation service

Low doses²⁷¹⁹ of high potency antipsychotic drugs like haloperidol may calm the patient – oral doses need to be 1.5 times the IM dose for equal effect. IV haloperidol (usually) cause fewer EPS than when administered by other routes (APA, 2002, p. 36; Fricchione et al, 2008) and it does not interfere with dopamine's effect of increasing blood flow to the kidney. Atypical antipsychotic drugs are increasingly used in the management of delirium: olanzapine, risperidone, and quetiapine cause less EPS than does haloperidol; and quetiapine may cause sedation. The use of antipsychotic drugs should be reassessed if the

²⁷¹⁶ Shifts between overactivity and apathy may occur rapidly.

²⁷¹⁷ 'Dumb rabies' refers to animals or humans with rabies who are listless and immobile instead of raving or 'rabid'.

²⁷¹⁸ There is evidence for confabulation in schizophrenia where it tends to be associated with thought disorder and perhaps with impaired semantic memory. (Lorente-Rovira et al, 2007)

²⁷¹⁹ Excessive dosing is all too common. (Hally & Cooney, 2005) Recommended doses of haloperidol in delirium are 1-2 mg/2-4 hours as required, further dose changes depending on achieving the desired effect. The stabilised patient can be switched to twice-daily dosing or night-time only dosing. Doses can be tapered gradually whilst clinical status is monitored. HIV/AIDS patients should receive very low doses of haloperidol or be prescribed an atypical antipsychotic.

QTc interval extends beyond 450 msec or more than 25% above baseline. Anticholinergic drugs²⁷²⁰ can exacerbate confusion. Chlorpromazine is probably as effective as haloperidol but may adversely affect cognitive status due to its anticholinergic actions. Physostigmine²⁷²¹ can be employed for anticholinergic delirium but it can cause GIT upset, bradycardia, hypotension, cardiac arrhythmias, or seizures. If it is essential to employ a BZD (e.g. to lower the dose of an antipsychotic as when attempting to minimise EPS from IV haloperidol²⁷²²) then low doses of short-acting drugs like lorazepam should be picked. Lorazepam may negatively impact on cognition. Haloperidol on its own is more effective than Lorazepam monotherapy. Mianserin, which is sedative, is often used for delirium in Japan²⁷²³, especially for hyperactive cases and where the symptoms are worse at night. (Someya et al., 2001) Methylphenidate (for hypoactive delirium) and trazodone have also been used to treat delirium. Cholinesterase inhibitors have also been employed, e.g. for delirium on a background of dementia. (Wengel et al., 1998)

ECT has been used successfully to treat delirium due to a wide variety of primary conditions, varying from neuroleptics malignant syndrome to delirium tremens and pernicious anaemia. (Delay & Maillard, 1945; Krystal & Coffey, 1997) Such use should be a rare event.

Apart from alcohol and sedative withdrawal states, BZDs are not primary treatments for delirium. Many delirious patients recover, although there is some evidence that new and permanent cognitive damage may follow delirium. (Bourgeois et al., 2008, p. 304, 317) Possible outcomes of delirium are complete resolution, gradual resolution, or the unearthing or induction of permanent cognitive dysfunction. Resolution of delirium commonly follows some time *after* recovery from the underlying somatic condition, i.e. there is usually a time lag. Mortality is raised commensurate with the severity of the precipitating disorder: 15% die and 4 out of 10 are in institutional care after 6 months.

When patients recover they may need much reassurance and explanation. Pharmacological treatment should continue until there is full resolution of delirium. (Meagher & Leonard)

Mild cognitive impairment²⁷²⁴ (MCI)

MCI illustrates the common absence of clear boundaries in Nature. (Widiger & Mullins-Sweatt, 2007, p. 7) The numbers affected depends on the diagnostic criteria²⁷²⁵ applied. (Busse et al., 2003) There is a variable recall ability of which the patient is aware and for which he may be profuse in his apologies. Names are forgotten, correct words are difficult to bring to mind, items are misplaced, concentration is poor, and complex problems present exceptional challenges. No other cognitive defects are found. Psychiatric symptoms may account for memory complaints²⁷²⁶ (Jorm et al., 2004). Although the risk is real (Jessen et al.,

²⁷²⁰ E.g. chlorpromazine, thioridazine, clozapine, ranitidine, codeine, dipyrindamole, warfarin, isosorbide, theophylline, nifedipine, digoxin, pethidine, fentanyl, diphenhydramine, carbamazepine, and prednisolone. Prolonged pethidine (meperidine) use may lead to accumulation of nor-meperidine (half-life 30 hours) which is toxic and can cause psychosis, anxiety myoclonus, and seizures; also, pethidine is contraindicated in combination with MAOIs.

²⁷²¹ IV physostigmine has a short duration of action. Some clinicians give IV glycopyrrolate, which does not cross blood-brain barrier, beforehand to block peripheral cholinergic effects of physostigmine.

²⁷²² E.g. haloperidol 3 mg and Lorazepam 0.5 mg IV as starting doses.

²⁷²³ Japanese insurance does not cover use of haloperidol.

²⁷²⁴ **Mild cognitive impairment (MCI)**, benign senescent forgetfulness, benign memory loss, ageing-associated (or age-related) cognitive decline, or age-associated memory impairment: a common condition, described by V A Krall in 1958. One definition of MCI is that cognitive problems are greater than what is expected for chronological impairment which means age-inappropriate cognitive impairment rather than 'age-associated memory impairment'. We know that memory becomes less efficient with advancing age but this 'age-appropriate memory decline/impairment' does not interfere *significantly* (where is the cut-off?) with functioning, either socially or in work, and activities of daily living (ADLs) are carried out about as well as before (arthritis, deafness, poor sight, and respiratory and other organ dysfunction and so on being factored in).

²⁷²⁵ One set of criteria for MCI (Petersen et al., 2001) cognitive complaints (most often, but not confined to, poor memory), cognitive screening (e.g. MMSE) gives overall results that lie within the normal range, memory testing results are 1.5 standard deviations below norms for the patient's chronological age, ADLs are carried out reasonably well, and (to avoid satisfying DSM criteria for a dementing disorder) there is insufficient impairment of social/occupational activity.

²⁷²⁶ In a population-based study (Geda et al., 2008) the most distinguishing features between people with people with mild cognitive impairment (MCI) and those with normal cognition were apathy, agitation, anxiety, irritability, and depression. Non-psychotic symptoms affected half of people and a quarter of those with normal cognition. Psychotic symptoms were rare. Older community-dwelling people who feel that they have a greater *purpose in life* have been noted to have reduced risk of progression to MCI and AD and a slower rate of cognitive decline. (Boyle et al., 2010) In older Americans living in the community (Wilson et al., 2010) measured cognitive status every three years; at the start of the study 614 had no cognitive impairment, 395 had MCI, and 149 had AD (mostly mild); the annual decline in cognitive function on follow-up (mean = 5.5 years, SD = 2.5) was lowest in the non-affected group, at least twice as high in the MCI group, and more than fourfold in the AD group; and there was no reliable effect of age, sex, or age.

2010), only close follow up can tell which case progresses to a full dementia. However a thyroid screen is prudent, other tests being dictated by clinical findings²⁷²⁷. Different studies suggest different risks for dementia and current cognitive screening instruments do not allow us to confidently prognosticate about the future progress of MCI in individual cases.(Lonie *et al*, 2009, 2010) As pointed out by Roose and Devanand (1999, p. 5) subjects recruited from newspaper advertisements fair much better than people who approach a professional with cognitive complaints. A 6-year neuropsychological community study of over-75s (Busse *et al*, 2006) found that 60-65% of people with MCI developed clinical dementia during life, most cases doing so within the first 18 months. In contrast, Mitchell and Shiri-Feshki (2009), in a meta-analysis of 41 studies, found a progression rate of only 10% and 5% per year in high- and low-risk groups respectively, and only 20-40% developed dementia after extended follow-up. MCI is basically a diagnosis by exclusion²⁷²⁸ (Ancelin *et al*, 2006) and follow up. According to Small *et al*, (2006) who employed FDDNP-PET, binding of FDDNP²⁷²⁹ is highest in Alzheimer's disease, lower in MCI, and least in normal controls. Tau and Abeta42 levels in CSF were reported as strongly predicting Alzheimer's disease (AD) in patients with MCI.(Hansson *et al*, 2006) Levels and activity of beta-secretase (BACE1) are elevated in the CSF in sporadic AD and in MCI relative controls.(Zhong *et al*, 2007) The same group²⁷³⁰ looked at the CSF of APOE ϵ 4 carriers and non-carriers and found that APOE ϵ 4 was associated with elevations of BACE1 in both AD and MCI. Levels of Abeta (1-42) were decreased in APOE ϵ 4 carriers in MCI but not AD. BACE1 may detect in vivo changes in amyloidogenic processing potentially modified by APOE genotype. The combination of APOE ϵ 4 status and depression in elderly men (women not included in study) may increase the risk for dementia.(Irie *et al*, 2008) Dutch research (van Exel *et al*, 2009) looked at heritable traits in middle age that contribute to (late-onset) AD. More offspring of parents with AD carried APOE ϵ 4 than those lacking a parental history; the former also had higher systolic and diastolic blood pressures and lower ankle brachial indices and they also had higher levels of IL-1 β , IL-1 β to IL-1 α ratio, TNF α , IL-6 and interferon γ . In a meta-analysis of CSF and MRI biomarkers, Schmand *et al* (2010) found that memory impairment was a more accurate predictor of early AD than MRI evidence atrophy of the medial temporal lobe; CSF tau and beta-amyloid were as predictive as memory impairment; but studies of longer duration are needed for CSF markers. Galantamine (Q.V.) is contraindicated in MCI.

Dementia

Both delirium and dementia are clinical statements. Whilst delirium is characterised by clouding of consciousness, dementia (chronic brain syndrome) is typically but not invariably an irreversible deterioration in cortical functioning. One definition is that dementia is an acquired, global disorder with intellectual deterioration, memory impairment and personality disorganisation in the presence of unimpaired consciousness. An alternative definition of dementia is that it is an acquired global impairment of memory, intelligence and personality skills, commonly progressive, and with no impairment of consciousness. Dementia usually develops gradually but it may be noticed for the first time following an exacerbation caused by a change in social circumstances or an intercurrent illness. Six years after Pick described his disease Binswanger²⁷³¹ introduced the concept of 'presenile dementia'. According to Kay and Tasman (2006, p. 365), the cost of care provision for demented people in the US was over \$100 billion each year, amounting to one-tenth of total health care expenditure, and the average annual

²⁷²⁷ An example would be B12 level in chronic alcoholism with liver or peripheral nerve damage.

²⁷²⁸ Depression, dementia, high anticholinergic load, etc.

²⁷²⁹ A molecule that binds to plaques and tangles in vitro.

²⁷³⁰ The group includes Prof Harald Hampel of Trinity College Dublin.

²⁷³¹ The Swiss psychiatrist-neurologist Otto Ludwig Binswanger (1852-1929) was professor of psychology at Jena, a pupil of Meynert and Westphal, and physician to the German philosopher Friedrich Nietzsche.

cost per family was \$18,000 in 1990. Estimated cost of dementia in community setting in the UK (Stewart, 2008) is £14,540, £20,355, and £28,527/person/year for mild, moderate, and severe cases respectively²⁷³². Total cost per inhabitant of Ireland of dementia is €79.(McHugh ea, 2007)

‘Presenile’ simply means less than 65 years of age

About 15% of the population is over 65 (i.e. ‘senile’); 10% of these will have some degree of dementia; about 40% of that 10% will have severe dementia

About 80% of dementers are still at home

A population-based cross-sectional study in Rotterdam (Ott ea, 1995) found an overall prevalence of dementia of 6.3%²⁷³³. AD accounted for 72% and it also accounted for the pronounced increase in dementia with increasing age. All other causes showed less contribution to an association with increasing age. Vascular dementia, Parkinson’s disease-associated dementia and others accounted for 16%, 6% and 5% of cases of dementia²⁷³⁴. A substantially higher prevalence of dementia was found in subjects with a low educational level²⁷³⁵. A study of Bavarian nuns²⁷³⁶ found a strong association of low education and occupational attainment with dementia.(Bickel & Kurz, 2009) It has been suggested that education may improve brain reserve by promoting neuronal branching. Alternatively, early dementia might be ‘hidden’ by superior verbal skills, e.g. high plaque levels on PET scans using [¹¹C]PiB²⁷³⁷ were associated with better cognitive performance in people with higher educational levels.(Roe ea, 2008) An international consensus of experts (Ferri ea, 2005) concluded that there existed 24.3 million people with dementia world-wide; 4.6 million new cases annually; the numbers of cases will double every 20 years; the majority of cases are in the developed world, but the rate of increase may be higher in some developing parts of east and south Asia. The Barberger-Gateau ea (2002) study that showed a protective effect of fish²⁷³⁸ and seafood against developing dementia was contaminated by the finding that higher education was associated with eating such foods. Interestingly, they found no significant association between eating meat and dementia. There is early evidence from a New York prospective study suggesting that involvement in leisure activities may be protective against dementia.(Verghese ea, 2003) Also, an eastern Finnish prospective cohort study (Håkansson ea, 2009) found that people living in a couple relationship at mid-life had a reduced risk of cognitive impairment later in life compared to those who were single, separated, or widowed.

Occupational therapy in the community improves patient functioning and reduces carer burden.(Graff ea, 2006)

Aetiology²⁷³⁹: The World’s human population is getting older, which may explain why so many dementing disorders only received intense medical attention during the last 100 years or so.²⁷⁴⁰ Older intellectually

²⁷³² Annual cost per person in a care home is £31,263. Total UK cost for late-onset dementia is £17.03 bn – includes informal care, lost income, loss of tax revenue, accommodation, and social and health services, but doesn’t include various allowances.

²⁷³³ 0.4% at age 55-59 years up to 43.2% among those at least 95 years old.

²⁷³⁴ Burns and Iliffe (2009a) suggest that Alzheimer’s disease (AD) causes 50% of cases of dementia, vascular cases (VDM) make up 25%, mixed AD/VDM accounts for 25%, Lewy body dementia (LBD) is present in 15%, and all others make up 5%. The astute observer will quickly see that this adds up to 120%! Sachdev (2008, p. 335) offers the following ‘commonly accepted relative frequencies’: AD, 50%; vascular, 15%; mixed AD/vascular, 20%; LBD, 17%; frontal, < 15%; ‘subcortical’ (progressive supranuclear palsy, Huntington’s disease, Parkinson’s disease), 4%; alcohol, 6%; normal pressure hydrocephalus, 5%; trauma/anoxia/infection, 3%; and prion disease, 2%. In truth, there seems to be no consensus.

²⁷³⁵ See *Alzheimer’s and Dementia* 2008 doi:10.1016/j.jalz.2008.01.001 for University of Michigan suggestion that cognitive decline is decreasing in over-70s in the US in association with better education and personal wealth: cognitive impairment fell from 12.2% in the 1993 cohort to 8.7% in the 2002 cohort.

²⁷³⁶ N = 442. Average time in order = 54 years. 104 cases of dementia identified.

²⁷³⁷ 11-labeled Pittsburgh Compound B adheres to beta-amyloid plaques in brain.

²⁷³⁸ Docosahexaenoic and arachidonic acids are important essential fatty acids, required in laege quantities by the developing brain. The human brain is poor at synthesising these and they are chiefly acquired in the diet: fish and seafood, and breast milk (depending on mother’s diet) are good sources.(see Hibbeln ea, 2007)

²⁷³⁹ See Gupta ea (2009) for a discussion of some rare dementing disorders.

²⁷⁴⁰ Between 1900 and 1998 the percentage of the British population aged over 65 years increased from 5 to 17. The number of people with dementia is said to rise in the UK by 61% from 2008 to 2026. The percentage of the Irish population aged at least 65 years was predicted to reach 16.4 in 2026. GPs may feel that early diagnosis serves little purpose (or that they do not have the necessary training) but this needs to be challenged.(Anonymous, 2008a)

disabled people, even when Down's syndrome is excluded, are at increased risk of developing dementia, often developing dementia at a younger age than is usual in the general population. (Strydom ea, 2009) Commonly the mechanism is widespread neuronal 'fall out' (i.e. loss) from the cortex. Rarely is the cause centrencephalic. The percentage of the demented population that consists of potentially reversible causes has varied from 3.8-37% in the work carried out by general medical services.²⁷⁴¹ This figure tends to be lower among psychiatric referrals, 4.7% in one study. The reasons for testing such cases are to find treatable cases and to discover conditions that aggravate an underlying dementia. Any physical illness either within or outside the cranial cavity is a potential cause of dementia. Volatile inhalants can possibly cause dementia in young people.

Abnormal folding of proteins may be crucial in the genesis of dementia of various aetiologies, e.g. a toxic increase in function mutation leading to the development of toxic aggregates (beta-amyloid, huntingtin, alpha-synuclein, superoxide dismutase, etc). (Morimoto, 2006)

Taxonomy of neurodegeneration (Lovestone, 2002, p. 289)

Synucleinopathies – dementia with Lewy bodies, Parkinson's disease, multiple system atrophy

*Tauopathies*²⁷⁴² – progressive supranuclear palsy, frontal lobe dementias

Amyloidopathies – CJD, British familial dementia

Alzheimer's disease can be classified under any of the above three headings

Clinical features²⁷⁴³: The clinical features of dementia in general include poor comprehension, social disability, normal level of consciousness, focal deficits (such as aphasia or hemiplegia), and single or double incontinence. Use of aids by the patient to remember (notepads etc) is common. Admission to a long-stay facility ward is more frequently precipitated by social problems than by medical or psychiatric considerations. However, many demented leave the gas flowing or the hall door open, accuse innocent people of stealing their goods²⁷⁴⁴, fall and injure themselves, cause fires whilst smoking in bed, get lost easily (topographical memory loss), expose themselves, or wander aimlessly. Confusion mounts because of say mild infection, subdural haemorrhage, or injudicious use of hypnotics. Interest and activity are narrowed and decreased, and self-neglect becomes marked. Cerebration is slowed down and literalism and concreteness characterise thinking. The latter is usually investigated by asking for the meaning behind proverbs, such as 'a stitch in time saves nine'. Judgement is impaired. Social taboos are innocently flouted, as when the once-prim lady enters the street in incomplete attire. Recent memory departs before that for remote events. Apathy, mood swings, fatuousness, rambling and repetitive conversation, irrelevant statements, aphasia, and an exaggeration and coarsening of personality traits add to the degradation caused by this syndrome.

*Behavioural and psychological symptoms of dementia (BPSD)*²⁷⁴⁵ have recently become a major focus of attention. Although extremely common (Savva ea, 2009), the components of this category vary enormously between people with the same form of dementia, between different dementias, and in individual cases over time. It is important to seek out underlying causes for 'challenging behaviour', e.g. depression²⁷⁴⁶. Various alternatives to antipsychotic drugs have been suggested for BPSD, e.g. trazodone, combined

²⁷⁴¹ In one study (Renvoize, ea, 1985) the percentages of physical and psychiatric disorders on admission in 150 demented patients were folate deficiency (44.8), B12 deficiency (14.6), anaemia (14.2), chest infection (13.3), urinary tract infection (13.3), cardiac failure (11.3), alcohol and drug abuse (4.0), and depression (4.0). Less common diagnoses were diabetes mellitus, drug intoxication, neoplasms, renal failure, other infections, heart block and, in 0.7%, hypothyroidism.

²⁷⁴² Abnormal phosphorylation of tau may inhibit binding of tau to microtubules resulting in tau aggregation and formation of neurofibrillary tangles.

²⁷⁴³ Since the 1960s the cognitive approach to describing dementia has become more popular than the older one of psychotic syndromes. One of the latter was presbyphrenia (manic-expansive dementia) in which the patient was very excited. In dementia, there may be shrinkage of the milieu (less interests), organic orderliness (rigid, stereotyped routines) and catastrophic reactions (sudden explosion of anger if pushed too far to complete a task – 'sham rage' consists of excessive rage reactions to trivial stimuli in patients with posterior hypothalamic lesions).

²⁷⁴⁴ Is this a true delusion? Partly the person cannot remember where the 'stolen' property was placed and concludes that another person took it. Whilst the belief is held with conviction despite evidence of the belief being untrue, this is mainly because the sufferer does not understand the evidence rather than simply that he/she simply rejects evidence.

²⁷⁴⁵ Apathy, sleep difficulties, anxiety/agitation/irritability, feeling persecuted, depression, misidentification, confabulation, hallucinosis, and wandering are listed by Savva ea. (2009)

²⁷⁴⁶ Depression seems to be more common in vascular and Lewy body dementias than in Alzheimer's disease.

benzodiazepine-chlormethiazole (Byrne *et al.*, 2008, p. 363), aromatherapy²⁷⁴⁷, bright light, and diversion techniques. In the opinion of Treolar *et al.* (2010), if a demented patient is obviously distressed and no treatable cause can be found the clinician should discuss the risks and benefits of antipsychotic drug use with carers and relatives and when there is agreement a trial of such medication is ethical. This author agrees.

Causes of rapidly progressive dementia

Subdural haematoma

Vasculitis

CNS lymphoma

Brain neoplasia (primary or secondary)

CJD²⁷⁴⁸

Non-convulsive epileptic status

Various causes of meningitis and encephalitis, e.g. tuberculosis, mycoses, herpetic infection, carcinomatosis and paraneoplasia

Alzheimer's disease is rarely rapidly progressive

Some cases of multi-infarct dementia can progress rapidly

Xie *et al.* (2008) followed up dementia patients in England and Wales. These were drawn from primary care population registers. Estimated median survival time from dementia onset was 4.1 years for men and 4.6 years for women. The older one was at onset the fewer years one survived. Disability also shortened survival time.

Subcortical dementia²⁷⁴⁹ (SCD): This represents an attempt to split the dementias into cortical and subcortical types (and indeed, mixed types, e.g. vascular). Subcortical dementia is caused by a disorder of subcortical structures such as the striatum or brainstem nuclei. The differential diagnosis includes Parkinson's disease, idiopathic basal ganglia calcification, spinocerebellar degenerations, progressive supranuclear palsy, Huntington's disease, Wilson's disease, thalamic degeneration or tumour²⁷⁵⁰, infarction of the basal ganglia and thalamus, granulomatous and post-encephalitic involvement of the basal ganglia and thalamus, and parathyroid dysfunction.

Clinical features

Acquired intellectual impairment

Forgetfulness and slowing of mental processes as the primary abnormality

Intellectual deterioration characterised by difficulty in manipulating acquired knowledge

Personality and affective changes that include apathy and depression

Functions of language, calculation and learning remain intact

Proponents of the division insist that these features contrast sharply with the manifestations of cortical dysfunction in AD and its analogues where aphasia, amnesia and agnosia are salient features and intellectual impairment is paramount. Turner *et al.* (2002) point out that there is some evidence that frontal executive dysfunction and memory deficit profile, as well as neuropathological findings, may overlap in SCD and cortical dementia.

Patients with AD do not show improved memory performance when provided with multiple choice options or clues, where those with dementia of depression or subcortical dementia may show improvement.

'White matter dementia' (Filley, 2003)

²⁷⁴⁷ Aromatherapy (e.g. lavender) can be applied to the skin or by inhalation. The oils used contain terpenes (hydrocarbons from plants such as conifers) that are lipid soluble and freely enter the brain.

²⁷⁴⁸ Replication of normal protein that has assumed an abnormal configuration (prion) so that it becomes infectious or, in the case of new variant CJD, transmission of bovine spongiform encephalopathy.

²⁷⁴⁹ The first description of this heterogeneous group of disorders with a common preferential involvement of subcortical grey matter structures was by Kinnier Wilson in 1912.

²⁷⁵⁰ **Tumours of the thalamus** may lead to a severe, rapidly developing dementia, with or without personality change or neurological signs (e.g. abnormal pupillary reflexes).

Proposed term covering cognitive disorders secondary to wide range of disorders

Causes: MS, toluene poisoning, SLE, B12 deficiency, Binswanger disease, trauma, gliomatosis cerebri,²⁷⁵¹ normal pressure hydrocephalus, AIDS dementia complex, etc

Main group features are inability to sustain attention, poor memory retrieval, visuospatial deficits, frontal lobe dysfunction, psychiatric problems, with preservation of language, procedural memory,²⁷⁵² and extrapyramidal function

Alzheimer's disease²⁷⁵³ (AD)

AD affects relatives four times more often than unrelated persons and more women²⁷⁵⁴ than men, although 35% have no family history of AD. It can arise as early as the late forties. The duration is said to be about five years before death following diagnosis.²⁷⁵⁵ There is a steady downhill course although cognitive decline may be accelerated by delirium.(Fong ea, 2009) The core DSM-IV features are memory impairment (impaired learning of new information or recall of previously learned information) and one or more of aphasia, apraxia, agnosia, and disturbed executive function.

Gene-environment interaction²⁷⁵⁶ provides the most likely pathogenic model for AD. AD is found significantly more often in Down's syndrome and Down's syndrome births are more prevalent in families containing cases of presenile AD.(Murphy & Wetter, 2002) The gene encoding beta-amyloid, a prominent component of neuritic (senile) plaques, is near the AD disease locus on chromosome 21.

Early onset AD has been linked to 21 q21 in c. 10% of such families (APP or amyloid precursor protein²⁷⁵⁷; APP gene = β -protein²⁷⁵⁸ or A4-amyloid gene), 14 q24 in most such families (PS1 or presenilin 1), and 1 q31-42 (PS2 or presenilin 2²⁷⁵⁹) – presenilins are secretases involved in beta-amyloid protein production. Early-onset cases show faster cognitive decline than do late-onset cases, and van der Vlies ea (2009) found that a more aggressive course is associated with absence of APOE ϵ 4.

Late onset AD has been linked to 19 q13 (APOE ϵ 4 or apolipoprotein E type ϵ 4 - increases risk but is not essential²⁷⁶⁰) and possibly 12p (White Americans with FAD of late onset; effect of locus occurs mainly if lower loading for ApoE ϵ 4).²⁷⁶¹

²⁷⁵¹ **Gliomatosis cerebri:** In this rare disorder neoplastic cells spread out diffusely through the brain after starting in white matter, including corpus callosum. Cerebral cortex and basal and other nuclei become involved eventually. Other rare malignant causes of dementia are **malignant angioendotheliosis** (variable degree of vascular occlusion by cancer cells) and **lymphomatosis cerebri** (most cases of CNS lymphoma present as single or multiple mass lesions but the diffuse form can present with dementia).

²⁷⁵² **Procedural memory** is memory for non-conscious motor sequences. It is less inclined to be compromised in the brain injured than is memory for information based on language or vision. **Declarative memory** (DM) is more vulnerable in such cases. DM includes *episodic* (recollection of events) and *semantic* (memory for facts) memory.

²⁷⁵³ Alois Alzheimer described his condition in 1906 in a 51-year old female. This common disorder, from which the actress Rita Hayworth died, originally thought to be a rare presenile dementia. The website of Alzheimer's Disease International is at <http://www.alz.co.uk>. The senile form of AD was formerly known 'senile dementia' and is still often referred to as 'senile dementia of the Alzheimer type' (SDAT). See Burns and Iliffe (2009b) for a recent review.

²⁷⁵⁴ Cumulative risk at age 65 years for developing AD at age 95 years is more than twice as high in females compared to males.(Leon ea, 1998)

²⁷⁵⁵ Although this author noticed the first sign of it in his father (getting lost on a familiar route) 13 years before death, although there were hints prior to this (e.g. narrowing of interests).

²⁷⁵⁶ Loneliness is associated with lower cognition at baseline and increased risk of later dementia in later life.(Wilson ea, 2007) Which is the cart, and which is the horse? A high cortisol level plus APOE- ϵ 4 allele status worsens cognitive function in population-based older people and the more of such alleles there are the worse the worse is cognitive function.(Lee ea, 2008)

²⁷⁵⁷ APP is a ubiquitous membrane protein with a large extracellular and domain and a shorter intracellular carboxy terminus. The first mutation found in the APP gene ('London mutation': V717I) was discovered in a kindred whose AD was confirmed at autopsy. A number of other mutations were discovered since but they only account for one in twenty early-onset cases. Duplication of the APP gene in early-onset AD was reported in 2006.

²⁷⁵⁸ Amyloid β -protein (A β) is a central component of neuritic plaques. It is derived from β -APP after beta- and alpha-secretase cleavage.

²⁷⁵⁹ Mutations in presenilin 2 are most frequent in the relatively (genetically) isolated USA-resident Volga Germans.

²⁷⁶⁰ **APOE**, a plasma lipoprotein (gene on chromosome 19), is synthesised by astrocytes and is the most important CNS carrier of cholesterol. A study in the US (Caselli ea, 2009) found that age-related memory decline diverged from that of non-carriers before age 60 years, despite continued normal cognitive status.

The cholesterol ester transfer protein (**CETP** – gene at 16q21) helps regulate cholesterol particle size. Substitution of valine for isoleucine in CETP is associated with lower CETP serum concentration and activity and with increases in HDL. Sanders ea (2010) found preliminary evidence that CETP valine (instead of isoleucine) homozygosity is associated with slower memory decline and incident dementia and AD.

SORL 1 (neuronal sortilin-related receptor) is a neuronal apolipoprotein E receptor and mutation of the gene (on chromosome 11) for this receptor is a marker for late-onset AD (Rogaeva ea, 2007): reduced expression of SORL 1 is found in AD brain and this situation is associated increased amounts of beta-amyloid in laboratory tests.

APP, PS1, and PS2 mutations lead to excess of the pathogenic long-chain amyloid beta protein (A β 42). Also, PS1 protein (gamma secretase) is important in producing A β 42 protein.

Work done in Belfast (Carson ea, 2007) suggests that a haplotype of the alpha-7 nicotinic ACh receptor gene (CHRNA7) may reduce the risk of developing AD. This was independent of APOE status.

The *amyloid cascade hypothesis* states that A β 42²⁷⁶² is a crucial element in the early stages of AD.²⁷⁶³ (Hardy & Selkoe, 2002; Citron, 2004)

In typical clinical practice most cases of AD appear to be sporadic, less than half of cases having a family history²⁷⁶⁴. Bell (2004, p. 68) states that about 10% of cases of AD are familial. Familial AD (FAD) with clear autosomal dominant transmission may make up less than 1% of all cases of AD. Jayadev ea (2008) retrospectively studied adults where both of their parents had suffered from AD and found them to be at increased risk for AD. The risk²⁷⁶⁵ increased with age and was only partly explained by APOE ϵ 4 status. Twin studies²⁷⁶⁶ in late-onset AD suggested a heritability of 0.6-0.7. (Bergem ea, 1997) In the Swedish Twin Registry (Gatz ea, 2006) it was estimated that AD had a heritability of 58%. Seshadri ea, (2002) in an 8-year follow-up Boston study, found that plasma homocysteine levels to be associated with an increased risk for developing AD²⁷⁶⁷. This finding was independent of other risk factors, including apolipoprotein E genotype and B vitamin levels. However, homocysteine levels were performed in non-fasting subjects and not all subjects had their B vitamin levels measured. Prospective studies of vitamin B supplements are required. Folate, which decreases homocysteine levels, might reduce the risk for AD. (Durga ea, 2007; Luchsinger ea, 2007)

Inflammation occurs in AD. Microglia are activated with increased expression of cell surface antigens. They are ineffective in attempts to removing plaques in AD which might be due to partial microglial activation or to the slow process of the disease causing these cells to become 'used to' their presence. Cytokine levels have been described as increased by some authors but not by others. There is the suggestion that apoptosis suppresses the synthesis of pro-inflammatory molecules by microglia. (e.g. Di Simone ea, 2003)

It has been suggested that cognitive impairment may not occur until at least 50 ml of brain tissue has been affected²⁷⁶⁸. Larson (1993) listed risk factors for AD as old age and a family history of AD. To these may be added head injury²⁷⁶⁹ (increased A β deposition in plaques), Down's syndrome, and specific chromosomal mutations (apo E4, for example). Obesity may be a risk factor for dementia, (Gustafson ea, 2003; Whitmer ea, 2005), possibly with a vascular basis.²⁷⁷⁰ However, a common allele of the obesity-related FTO gene may play a role. (Hoa ea, 2010) Kenya ea (2009), in a follow-up study of elderly males and females (N = 3,054) enrolled in a health study, found that obesity was associated with cognitive decline

²⁷⁶¹ All presenilin mutations distort APP processing by promoting secretion of the longer form of A β peptide.

²⁷⁶² A 42-amino acid peptide and proteolytic product of a large transmembrane A β precursor protein.

²⁷⁶³ The A β 42 N-terminus is released by beta-secretase converting enzyme (BACE). BACE and its homologue BACE2 are transmembrane aspartic proteases. The C-terminus of A β 42 is released by an intramembrane gamma-secretase cleavage of the A β precursor protein by a complex consisting of presenilin, nicastrin, APH anterior pharynx defective 1, and presenilin enhancer 2. BACE may prove to be a therapeutic target, using reticulon. Reticulon, a member of a family of receptor-associated proteins, appears to sequester BASE and regulate its activity. Trials are also ongoing of A β 42-brain clearance by immune and non-immune mechanisms. (Selkoe, 2001)

²⁷⁶⁴ However, relatives may die too early to develop AD or cases may not be recognised as such.

²⁷⁶⁵ The risk was 31% and 41.8% in those over 60 and 70 respectively, but 79% of the subjects were still younger than 70 years.

²⁷⁶⁶ Higher pairwise concordance in MZ than in DZ twins.

²⁷⁶⁷ A 5 μ mol increase in homocysteine plasma level increased the risk for AD 40%.

²⁷⁶⁸ However, Snowdon ea (1996) found low density of ideas at age 18 years to be strongly correlated with post-mortem AD pathology among nuns.

²⁷⁶⁹ Mehta ea (1999) could not confirm head injury as a risk factor in a large cohort study, which suggests that the reported association in case-control studies might have been due to recall bias or selective mortality.

²⁷⁷⁰ **Vascular problems in AD:** Purandare ea, (2006) based on a case-control study, suggest that spontaneous cerebral emboli may be important in the pathogenesis of both Alzheimer's and vascular dementias. Helzner ea (2009) found that a higher pre-diagnosis total cholesterol and low-density lipoprotein concentrations and a history of diabetes were associated with faster cognitive decline in patients with incident AD.

in men and not in women. Proposed protective factors (Burns & Murphy, 1996) are education, smoking²⁷⁷¹, moderate drinking²⁷⁷² (controversial), NSAIDs, and oestrogens²⁷⁷³. The P300 is a large, positive delayed wave on the EEG which occurs 300 milliseconds after a stimulus. The latency of the P300 is significantly longer and the amplitude significantly smaller in the AD than in comparison subjects. A pathological delay occurs 20 years earlier in Down's syndrome than in controls. The P3 of the olfactory event-related potential (OERP) shows longer latencies in AD²⁷⁷⁴ than in age/gender-matched controls and may be a better discriminator for AD than the auditory event-related potential. Possession of the ApoE ϵ 4 allele also increases the latencies of the OERP, but by less than that associated with AD. (Murphy & Wetter, 2002) Odour identification, odour threshold, and odour recognition memory are abnormal in Down's syndrome; OERP P3 latencies increase in Down's syndrome with increasing severity of dementia. Also, there are increased P3 delays in visual and auditory event-related potentials in Down's syndrome. In SDAT, both PET and SPET studies show a characteristic reduction in the posterior temporoparietal regions that can be temporarily reversed with physostigmine, a cholinergic agonist. Beacher *et al.* (2009) compared Down's syndrome patients with and without AD using volumetric MRI. Those with AD had significantly smaller hippocampi and caudate nuclei and right amygdala and putamen.

Schupf (2002) reviewed factors promoting dementia in Down's syndrome. Apolipoprotein E ϵ 4 allele, oestrogen deficiency and high levels of A β 1-42 peptide are associated with earlier onset of dementia. Atypical karyotypes and apolipoprotein E ϵ 2 allele are associated with lower mortality and lessened risk of dementia.

The notion that AD results from exposure to electromagnetic fields²⁷⁷⁵ has not been adequately researched. Researchers should study exposure directly rather than infer exposure on the basis of occupation (e.g. electrician). This has been done in a controlled experiment (Landgrebe *et al.*, 2008) using transcranial magnetic stimulation (rTMS) to the prefrontal cortex. 40% of the hypersensitive group and 60% of matched controls could feel no sensation when given sham stimulation. The authors found 'significant cognitive and neurobiological alterations pointing to a genuine individual vulnerability of electromagnetic hypersensitive patients'. Interestingly, Cotelli *et al.* (2010) found that rTMS (20 Hz, 25 minute sessions, 5 days/week for 4 weeks) applied to the prefrontal of moderate AD patients (N = 5) improved correct answers on a comprehension test from 66% to over 77% compared to similarly affected subjects (N = 5) given a 'sham' (dummy for 2 weeks, rTMS for next 2 weeks) treatment. Other cognitive abilities and memory were unchanged. These results are preliminary.

Braak²⁷⁷⁶ staging of Alzheimer-type pathology

Stages 1 + 2: entorhinal

Stages 3 + 4: limbic

Stages 5 + 6: neocortical

The neuropathology is complex²⁷⁷⁷. There is loss of cortical neurones²⁷⁷⁸ with wide sulci and shrunken, narrow gyri. Argyrophilic senile (neuritic) plaques with amyloid in their cores (the more plaques the deeper the dementia) are also found. One description of these plaques was that they begin as a cluster of abnormal neurites (dystrophic axonal or dendritic terminals) without amyloid cores and progress into a mature or

²⁷⁷¹ Long-term tobacco use reduces A β deposition. (e.g. Court *et al.*, 2005) The effect of smoking has been reported to increase and to decrease risk for AD. One possible reason for a false protective report would be the early death of smokers, i.e. smokers are less likely to figure in AD cohorts. Fratiglioni *et al.* (2008, p. 395) suggest that smoking is a risk factor for dementia. Passive smokers may suffer cognitive impairment. (Llewellyn *et al.*, 2009)

²⁷⁷² Heavy drinking may be a risk factor for dementia in late life, particularly in conjunction with the APOE ϵ 4 allele. (Antilla *et al.*, 2004)

²⁷⁷³ Removal of guinea pig ovaries leads to excess beta-amyloid in brain.

²⁷⁷⁴ Unlike other sensory cortices, there is involvement of the primary olfactory cortex and the peripheral olfactory cortex in AD and these are associated with olfactory deficits in excess of those expected in old age.

²⁷⁷⁵ The modern citizen is exposed to electromagnetic fields arising from the presence of electric equipment, including mobile phones. Many non-specific symptoms have been blamed on such exposure, e.g. skin and GIT problems, poor concentration, sleep difficulties, and tiredness.

²⁷⁷⁶ After Frankfurt anatomists Heiko and Eva Braak. See Braak and Braak. (1991) According to Nagy *et al.* (1999 –the Braak group) dementia symptoms develop during stages 3 and 4.

²⁷⁷⁷ The large community-based study of Esiri *et al.* (2001) found that most non-demented people's brains have some features of AD or cerebrovascular disease.

²⁷⁷⁸ Especially in the hippocampus, neocortex, locus ceruleus, and nucleus basalis.

classical plaque, with central amyloid surrounded by numerous neurites and some astrocytic processes and microglia. Diffuse plaques are deposits of beta-amyloid without a surround of degenerating nerve cells whilst neuritic plaques have a core of beta-amyloid surrounded by dystrophic neurites whilst the whole is surrounded by activated microglia and reactive astrocytes.

Amyloid plaque

Studies of neurotransmitters during the 1980s suggested that the primary lesion is cortical and that the pathology may originate with plaque formation in the hippocampus/amygdala, although other studies suggest that the pathology may commence in subcortical structures such as the basal nucleus. Neuritic plaques are largely found outside cells, whereas the tangles are found inside cells – the number of tangles, but not of plaques, correlate (subject to great inter-individual variability²⁷⁷⁹) with clinical degree and duration of dementia (however, soluble beta amyloid more strongly correlated with severity of dementia than do plaque counts). There are neurofibrillary tangles (helically paired twisted filaments: intraneuronal bundles of phosphorylated tau proteins) in the neuronal perikarya (occasionally in neurites) and in pyramidal neurones of the hippocampus, entorhinal cortex and neocortex, nucleus basalis of Meynert, and periaqueductal grey matter²⁷⁸⁰.

Neurofibrillary tangle

Alzheimer tangles contain a fragment of tau²⁷⁸¹, a protein normally associated with the microtubules that are responsible for rapid axonal transport in the healthy brain. Also described is granulovacuolar degeneration of Simchowicz²⁷⁸² and congophilic angiopathy²⁷⁸³.

Chronology of selected AD research (from 1990)

1990. 3 pairs of elderly MZ twins discordant for AD.

National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) criteria predict probable and possible AD with sensitivities of 88% and 78% respectively – criteria checked against histology. (Definite AD requires both clinical and pathological data.)

AD cases show depression less often as the illness advances whereas multi-infarct dementia cases can be depressed at any stage.

Early in AD, an amyloid A4 protein, derived from a large precursor protein coded on chromosome 21, is deposited in parenchymal plaques and in cerebral vessels. Cerebral cortex and sub-cortical nuclei are most affected. Cell damage causes neurotransmitter loss, the most consistent damage being to cholinergic neurones connecting sub-cortical nuclei to cerebral cortex. Postsynaptic muscarinic cholinergic receptors are usually intact. Ascending noradrenergic and serotonergic pathways are also damaged, especially in younger patients.

65% of carers of dementia sufferers experienced significant stress. Most at risk were females and younger carers. Stress in carers was associated with high levels of physical disability but not with degree of cognitive impairment.

In primary dementia, population of locus coeruleus neurones most extensively reduced in depressed patients, and such patients have a much greater reduction in noradrenaline levels than do non-depressed patients.

²⁷⁷⁹ E.g. it is quite possible for a mildly cognitively impaired person to have a very high tangle count at post-mortem and, for early cases, *vice versa*.

²⁷⁸⁰ They are rarely, if ever, seen in Purkinje's cells or in lower motor neurones.

²⁷⁸¹ 60, 64 and 68 kDa

²⁷⁸² Small, clear, intraneuronal cytoplasmic vacuolation, each vacuole containing one argyrophilic granule.

²⁷⁸³ Amyloid infiltration of blood vessel walls and adjacent perivascular neuropil (aka **neuropil**, i.e. axons + dendrites collectively).

Huntington patients more aggressive and apathetic than AD cases, and irritability related more to premonitory poor temper control in Huntington patients than in AD cases. (Study using scales)

1991. Variation in age of onset in cases of early onset FAD is produced by interfamily variations, but within families it tends to be constant.

In early onset AD smoking was associated with a reduced risk of AD and at least a 4-year delay in onset of AD.

The risk of dementia in first-degree relatives is about the same whether the dementia is due to AD or not.

Prognosis in dementia over 4 years not predicted by scores on parietal tests, but high scores for global cognitive impairment predicted early demise.

Using isoelectric focusing, an abnormal band found in acetylcholinesterase in CSF of AD patients.

Putative linkage reported of late-onset AD to chromosome 19.

1992. β -Amyloid is neurotoxic but animal studies equivocal.

Patients with FAD have a faster course of illness and stronger family history of psychiatric disorders v patients with non-familial AD – these may reflect genetic or environmental differences between the 2 groups.

FAD seems to transmit as an autosomal dominant trait. Mutations of the gene coding for APP have been identified. β -Amyloid protein (normally produced in soluble form, but present in insoluble form in AD) is cleaved from APP.

Discovery of second gene FAD on chromosome 14: AD likely to be aetiologically heterogeneous.

1993. Retrospective Scottish study finds female sex positively associated with development of AD before age 65 years.

Replication reported of early onset FAD gene on chromosome 14q.

It is probably not β -amyloid production per se that is neurotoxic, but rather the aggregation of insoluble β -amyloid.

SPECT using Tc^{99m} -HMPAO: AD showed reduced uptake in all regions, especially in temporal (important for memory) and posterior parietal areas, duration of illness correlating with reduced uptake in most brain regions.

1994. AD is fourth major cause of death in developed world.

Morphological brain damage may promote psychotic phenomena, e.g. depression, hallucinations, paranoid delusions, and delusional misidentification.

Mothers of Down's syndrome probands are at increased risk for non-stroke dementia.

AD disease associated with neuronal loss in CA1 region of hippocampus, an area relatively preserved in normal ageing.

Familial contribution to risk for 'primary progressive dementia' decreases with increasing age and is very low or non-existent by latter half of ninth decade.

Earlier onset of AD may be related to the presence of more language and praxis impairment, and greater depression during the illness.

1995. Against the idea that AD equates with old age is its absence in a 118 year old French woman.

Transgenic mice produced that express high concentrations of human amyloid precursor protein and progressively develop many, but not all, of the pathological hallmarks of AD.

Gene responsible for many cases of presenile FAD on 14q cloned and mutations characterised.

A number of mutations in S182 gene on chromosome 14 and another in a homologous STM-2, on chromosome 2, may cause early-onset FAD.

Meta-analysis suggests that the very old may be less prone to develop AD than are the old i.e. the rate of increase falls off.

Patients with AD plus psychosis had relative (to right side) hypoperfusion of left frontal lobe (not so with AD only).

Scottish study suggested that increased paternal age increased the risk for presenile AD in male offspring only.

Early CT volumetric changes may help to distinguish early, mild AD from normal ageing.

β -Amyloid in peripheral blood vessels damages endothelial cells by producing superoxide radicals. This process can be blocked by superoxide dismutase (which mops up superoxide radicals). It remains to be proved that this occurs centrally.

No link found between cognitive dysfunction in the elderly and antihypertensive therapy.

15-year follow-up of 70 year olds found that hypertension was associated with increased risk for AD and/or multi-infarct dementia, but blood pressure tends to fall before onset of dementia.

APOE ϵ 4 allele may have a dose effect that increases risk and brings the disorder forward in time.

1997. 83% of family members accompanying patients with AD to memory clinic did not want patient told diagnosis – but 71% would want to be told if they had AD!

Pairwise and probandwise concordance for AD among MZ and DZ twins were 78% plus 39% and 83% plus 46% respectively. No significant difference in rate of apolipoprotein E ϵ 4 allele between twin pairs concordant and discordant for AD. Estimated heritability was about 0.6.

APOE ϵ 4 allele is a risk factor for AD but no support found for a strong association between APOE ϵ 4 dosage and the rate of cognitive decline. Also, the APOE ϵ 4 allele did not predict age of onset.

Controlled study using PET plus radiolabelled acetylcholine analogue found decreased acetylcholinesterase activity in AD brain, especially in temporal (31% decrease) and parietal (38% decrease) areas.

1998. Age-specific prevalence rate of AD in Down's syndrome reached 40% in the 50-59 year age group.

Late onset AD is a common familial disease involving several genes and environmental factors.

1999. Depressive symptoms may be early manifestations rather than predictors of AD.

Corticotrophin releasing factor immunoreactivity reduced in mild and severe dementia but somatostatin-like immunoreactivity reduced in severe cases only.

2000. Significant excess of APOE ϵ 4 in demented v non-demented Down's patients.

Both magnitude and extent of brain activation (MRI during memory testing) in regions affected by AD (including left hippocampal, parietal and prefrontal) were greater among cases with ϵ 4 allele than in those with ϵ 3 allele. During periods of recall, carriers of ϵ 4 allele had greater average increase in hippocampal signal intensity and greater mean number of activated brain regions than did ϵ 3 allele carriers.

Deficits in olfactory identification detected by University of Pennsylvania Smell Identification Test may have clinical utility as an early marker for AD.

Dutch study of centenarians assessed 15 of 17 people over 100 (in one area) and found all were demented, 12 having greater than mild dementia.

- 2001.** Microglial activation occurs early in course of AD.
PET revealed parietal/temporal/prefrontal deficits in glucose metabolism in cognitively intact APOE ϵ 4-positive individuals.
- 2002.** Homocysteine may have an aetiological role.
Trials of a vaccine (AN1792) being developed by ELAN (Ireland)/Wyeth suspended after 12 volunteers became ill (aseptic meningoencephalitis); autopsy on one case showed less brain amyloid than expected.
When predicting AD in patients with mild cognitive impairment, CSF-CBF index (tau levels \div regional cerebral blood flow in posterior cingulate cortex on SPECT; using cut-off value of 296) gave sensitivity of 88.5% and specificity of 90%.
- 2003.** Workers assessed and followed up 1435 Swedish non-demented people aged 75-95 years for three years and found that only 18% of future dementia cases could be identified.
Feeding tubes do not increase survival rates in dementia and can have significant adverse effects.
- 2004.** Study of diagnostic accuracy of CSF concentrations of tau proteins phosphorylated at 3 pathologically important epitopes²⁷⁸⁴ (p-tau) – AD, other dementias, and normals – in terms of sensitivity and specificity, these proteins ‘come closest to fulfilling the criteria of a biological marker of AD’.
Cache County (Utah) Study: estimated 100-year lifetime incidence of AD at 72% (28% would never develop AD). 1 or 2 APOE ϵ 4 alleles accelerated onset of AD but did not determine if one got AD.
Both high and no alcohol intake in middle life led to increase in mild cognitive impairment, and, less certainly, to dementia – this has been interpreted as a U-shaped relationship but it could also be spurious.
- 2005.** Vitamin E does not prevent progression from mild cognitive impairment to AD. Whilst donepezil lowers the rate of such progression in the first 12 months of treatment, the rate of progression catches up later.
AD pathology is more likely to be clinically expressed as dementia in females than in men.
If tau production is turned off in transgenic mice that over-express mutant tau the mice demonstrate improved cognition despite continued neurofibrillary tangle accumulation.
Apparent decline in incidence of AD reported in some studies in oldest-old may be an artefact of poor response rates, survival effects, and the populations sampled.
Uncontrolled hypertension in middle age increases risk for dementia in old age but hypotension in the elderly is related to the development of dementia.
- 2006.** In later-myelinating regions, severity and rate of myelin breakdown in healthy older people are associated with ApoE status.
A lifetime history of depression in AD cases in nursing homes was associated with increased AD-associated neuropathological changes in hippocampus and more rapid cognitive decline.
Depression early in AD increases expression of AD-related pathology in hippocampus.
Donepezil improves cognition and preserves function in severe AD in nursing homes.
Donepezil was of no benefit in chronic schizophrenia regarding cognition or negative symptoms.
Mild cognitive impairment plus other cognitive domain deficits (espc. in verbal memory and psychomotor speed/executive function) constitute a higher risk for AD than pure amnesic problems.
Heritability of AD in Sweden estimated at 58%.
- 2007.** Whole brain atrophy rates may be greater in cognitively normal ϵ 4 homozygous late middle-aged people than in comparable individuals with no or one copy of apolipoprotein E (APOE) ϵ 4 allele.
Inconclusive results with trapirosate, a vaccine that binds to beta-amyloid protein.
- 2008.** Mild cognitive impairment as a predictor of AD is only good for subjects 70-85 years of age, not for younger people.
Depressed homebound elderly had lower plasma A β 42 levels and a higher A β 40:A β 42 ratio than controls.
12.7%, 78.8%, and 4.2% of patients attending a Cork memory clinic had mild cognitive impairment, dementia, and depression without dementia respectively.
Although immunisation with A β 42 led to clearance of amyloid plaque in AD this did not stop progression of neurodegeneration.
115 year-old Belgian woman had good cognitive function during life and negligible neurodegenerative brain changes at post-mortem.
Prevalence of DSM-IV dementia in people aged at least 65 years at 11 sites varied from 0.3% in rural India to 6.3% in Cuba but the criteria may underestimate true prevalence, particularly in the most under-developed regions where there may be problems in defining and ascertaining decline in cognitive function and its consequences.
In transgenic AD model mice valproic acid decreased A β production by inhibiting glycogen synthase kinase-3 β (GSK-3)-mediated gamma-secretase cleavage of APP; valproic acid significantly reduced neuritic plaque formation and improved memory deficits; early use of valproic acid is important to alleviate memory deficits.
- 2009.** Association between pathological features of AD and dementia is stronger in younger old people than in older old persons.
Older people with extensive age-related white matter changes on MRI are at high risk of functional decline over the following 3 years.
The stronger was muscle strength at the start of this study of community-dwelling older people the lower was the risk of developing AD during follow up; the mechanism is unknown (possible mitochondrial damage leading to poor muscle strength and cognitive function, or CNS damage from stroke that reveals subclinical AD, etc).
- 2010.** Carers of community-dwelling people with dementia attending a Dublin service had high levels of met and unmet needs.

Damage to, or loss of cholinergic fibres leads to depletion of enzymes involved in ACh metabolism. Most of the cholinergic loss in AD is presynaptic²⁷⁸⁵. The apparent preservation of receptors is part of the rationale for replacement therapy. Noradrenergic, dopaminergic and serotonergic systems are also impaired. These neurotransmitters are largely made in subcortical structures, such as the nucleus of Meynert and locus ceruleus. Older cases have a mainly cholinergic deficit whereas younger cases have not

²⁷⁸⁴ Epitope = antigenic determinant.

²⁷⁸⁵ Up to 50% of total cortical synapses are lost in AD – synaptophysin immunoreactivity in frontal and parietal cortices and hippocampus correlates with severity of dementia.

only a more widespread and severe cholinergic loss but they also have greater impairment of other neurotransmitter systems. Amongst the enzymes depleted is choline acetyltransferase. Choline replacement has been disappointing. GABA and the catecholamines may also be affected. The balance between transmitters may be more important than the absolute level of any single substance. The brain of the normal resting adult has a respiratory rate of about 3.3 ml. O₂/100g/min. In dementia this falls to about 2.7 ml, about the same as in myxoedema. The reduction is pathological and is not explicable on age grounds alone. Leonard (2003, p. 352) emphasises the fact that not all neuropathologically verified cases of AD have reduced levels of choline acetyltransferase and others have normal numbers of cholinergic cells in the nucleus basalis of Meynert. He also points out that there is gross loss of basal forebrain cholinergic neurones in olivopontocerebellar atrophy with no clinical dementia. (Cf. multiple system atrophy) It is possible that AD may result from abnormal membrane phospholipid metabolism regulation, leading to rigid membranes. Large decreases in brain N-acetylaspartate in cerebral gray and white matter have been found in AD using proton MRS. (Huang *et al*, 2001) However, the specificity of such findings to one type of dementia is not high.

Studies conducted during the 1980s found that clinico-pathological agreement on diagnosis approached 90%, an increase from 70% of some years previously. However, there is probably a wide disparity in what is meant, clinically, by AD. Some workers proposed a continuum model between senile dementia of the Alzheimer type (SDAT) and normal ageing. However, using PET scanning to measure cerebral metabolism of glucose, and neuropsychological tests, Grady *et al* (1987) found no support for the existence of different subgroups of AD based on age at onset, or for a faster rate of cognitive decline in younger patients. Aluminium injected into the brains of animals can produce neurofibrillary tangles, but there are ultrastructural differences between aluminium-induced and Alzheimer tangles. It is potentially possible that a genetic defect might facilitate the entry of aluminium into the brain. There is often much more aluminium in food or in medicaments than in water! There is a higher level of aluminium in the water on Guam (see below) but these people get amyotrophic lateral sclerosis, and the water there is also low in calcium and magnesium. Dialysis dementia (high brain aluminium levels, no plaques or tangles) occurs unless the aluminium level has been reduced by purification procedures. Aluminium is used as a coagulant to remove particulate matter containing toxic pollutants in water.

The entorhinal cortex²⁷⁸⁶ is linked with the hippocampal formation, providing the latter with its major cortical input. The cells of origin of the perforated pathway are destroyed in AD and a marked decrease in glutamate (a putative neurotransmitter in its terminal zone) occurs. Identification of odours is impaired early in AD, but acuity of odour detection is impaired only later in the evolution of the disease.

Down's syndrome²⁷⁸⁷ is more likely to occur in families with AD than in families without such a history. In patients with trisomy 21, the 50% increase in all of chromosome 21's genes results in both an increase in the quantity of β -amyloid protein and an acceleration of the deposition of β -amyloid protein in the brain. The presence of excess β -amyloid protein (A β) within and without the neurone may convert a physiological function into a pathological one by inhibiting axonal protein transport using the same transport machinery as amyloid precursor protein (APP), thereby leading to synaptic dysfunction and death.

Oxidative damage may be important in both vascular dementia and AD. There are many antioxidants in the diet, including vitamins C and E. Those antioxidants may act synergistically as free radical scavengers and it is suggested that vitamin E may protect muscarinic receptors. Levels of the free radical defensive enzyme superoxide dismutase are reduced by 25-30% in the frontal cortex and hippocampus. (Lethem & Orrell, 1997) Trisomy 21, as stated above, is associated with an increased risk for early onset AD and is associated with increased superoxide dismutase activity (because the gene is on chromosome 21 of which the patients has 3 copies). Superoxide dismutase converts the superoxide free radical to H₂O₂ that is then converted to H₂O by other enzymes. In the presence of certain metal ions like iron the H₂O₂ can be converted to the extremely toxic hydroxyl free radical. The excess of superoxide dismutase in Down's syndrome may cause excess production of the hydroxy radical. One piece of good advice is to eat a healthy diet, including fruit and vegetables. (Lethem & Orrell, 1997) A meta-analytic study (Sofi *et al*, 2008) suggests that adherence to a Mediterranean diet is significantly associated with reduced mortality overall and from cardiovascular and malignant causes, Parkinson's disease, and AD. However, there are many Mediterranean diets and the

²⁷⁸⁶ Islands of cells in layer II of the entorhinal cortex degenerate very early in AD, thus disconnecting neocortex and hippocampus.

²⁷⁸⁷ Even though dementia occurs earlier in Down's syndrome than in the general population it is still rare before age 50 years, despite neuropathological changes being present for about the preceding decade.

study is limited to some degree by adjustment for potential confounders in the studies employed in the meta-analysis.

Alzheimer patients with depression are more cognitively impaired and more disabled than are their non-depressed fellows.

Dementia-Parkinsonism complex of Guam

Guam, New Guinea, and Honshu

Features of motor neurone disease, Parkinson's disease, or AD, or combinations of these

Affected areas share low concentrations of calcium and magnesium in soil and drinking water as well as high concentrations of aluminium and iron, but working in an aluminium factory is not associated with an excess risk for AD

May be some interaction between an environmental insult and aging process because migrants from these areas have developed the condition years later

Plant poison has been suggested - seeds of the cycad containing an analogue of alanine

Retrogenesis

As AD develops, developmental acquisitions are progressively lost in reverse order to their acquirement during development

Person eventually unable talk, walk, etc, and expresses reflexes, like palmar grasp, that were suppressed in earlier life

It is said that AD may have a long history of neuropathological change that precedes clinical symptoms, (Goldman *et al.*, 2001) including hippocampal atrophy on MRI. (De Leon *et al.*, 1997) However, close prospective observation (of, say, close relatives) suggests that there may be hints of incipient dementia during this 'prodrome', e.g. giving up pastimes such as walking or doing crosswords, or irritability when asked to do chores or become involved with grandchildren's play. Eventually the postman may bring the patient home in a distressed state after the latter becomes lost on a familiar route. High intelligence and the supports provided by others may mask early changes. Loss of support, as through death of a partner, can lead to a crisis. Early onset AD (say, < 60 years) is more likely to manifest changes in comportment (e.g. disinhibition²⁷⁸⁸), abnormal gait, and extrapyramidal disturbances.

Clinical features of Alzheimer's disease divided into four arbitrary stages

Stage I: Memory and concentration are poor. Fatigue and anxiety increase. The person is restless and experiences fleeting depression²⁷⁸⁹. Premorbid personality characteristics are exaggerated. Antisocial acts or statements occur that are out of character. There may be nominal dysphasia at times, changed handwriting, and perseveration. Medication may compound disability, e.g. confusion from anticholinergic drugs.

Stage II: Work performance deteriorates and the patient may live in squalid surroundings. Dysarthria, reduced vocabulary, poor grammatical construction, logoclonia (reiterating parts of words), echolalia, misspelling and duplication of parts of words, reduced reading ability, reduced ability to comprehend the speech of others, urinary incontinence, epilepsy (5-10%), dyspraxia and agnosia may be noted. The patient may become easily lost. Recent and remote memory is poor. Misidentification occurs (mirror sign, or talking to photographs), as do depression, delusions and hallucinations, especially visual. There are behaviour problems, emotional lability, catastrophic reactions, motor restlessness, phases of inertia, muscular rigidity, and gait apraxia.

Stage III: Gross impairment of all intellectual functions, severe neurological disability (+/- hemiparesis, rigidity, and wide-based unsteady gait), double incontinence, fatuousness, euphoria, jargon dysphasia, emaciation, limb contractures, and inability to recognise anyone including the self.

²⁷⁸⁸ Sexual disinhibition might respond to SSRIs (Stewart & Shin, 1997) or medroxyprogesterone. (Rabins, 1998)

²⁷⁸⁹ There is no direct correlation between stage of AD and depression. (Thomas, 2008, p. 430) Depression is usually of brief duration in demented people and may respond to simple measures such day centre attendance and spending more time with the patient; only severe, prolonged depression requires medication. Depression is a common prodrome of AD and may be a risk factor for AD, perhaps acting via cortisol/HPA axis activation or via vascular pathology.

Stage IV: Death.

Weight loss can be severe in AD, even greater than with cancer.(Thomas, 2008, p. 431)
Effective treatment focuses on the patient-caregiver unit, not on the patient alone. It is essential that the family and the patient know enough to initiate proceedings to cover financial, health-care and other matters before competence is lost.

Management of AD

Step 1 – non-pharmacological, e.g. behavioural

Step 2 – if 1 fails and behavioural problems persist – cholinesterase inhibitors

Step 3 – if 2 fails and behavioural problems persist - low dose atypical antipsychotics

Physical exercise is inversely associated with the risk of dementia.(Hamer & Chida, 2009) Is this a true prophylactic action or are people with subtle cognitive decline less likely to exercise and so compromise their cardiovascular status?

Treatments have been aimed at replacing neurotransmitters, stimulating intact receptors, and alleviating disturbed behaviour symptomatically.²⁷⁹⁰ Anticonvulsant treatment for aggressive behaviour has been disappointing.(Thomas, 2008, p. 430) It has been tentatively (Martyn, 2003) claimed that NSAIDs like ibuprofen may delay the onset of AD, an effect not found for aspirin²⁷⁹¹ (although Etminanan ea, 2003 found a reduced risk for AD of 13% with aspirin compared to 30% with NSAIDs), acetaminophen,(Stewart ea, 1997) or hydroxychloroquine²⁷⁹². Longer use of NSAIDs appear more protective against AD than shorter use.(Etminanan ea, 2003) Although small clinical trials have suggested a role for oestrogen treatment, a larger trial found no benefit after one year.(Mulnard ea, 2000) Health-seeking behaviour and socioeconomic status of women receiving oestrogens must be controlled for in such research. However, there is some evidence that women who lack the APOE ε4 allele may benefit from oestrogen treatment whereas ε4 negative women may not benefit; the same study suggests that oestrogen may exert its beneficial effects by reducing carotid atherosclerosis.(Yaffe ea, 2000) Nevertheless, there is also evidence suggesting that oestrogen/HRT may be a risk factor for AD rather than protecting against it.(Shumaker ea, 2004; Simard & Sampson, 2008, p. 234) Also, oestrogens have their own adverse effects.

The *anticholinesterases* showed some consistent promise.(see box) They are indicated for ‘mild to moderate’ dementia²⁷⁹³. Most cases experience little in the way of side-effects (mainly GIT and responsive to antiemetics) and such events tend to occur early as doses are titrated. If the patient deteriorates cognitively the anticholinesterase may be slowly withdrawn to see what benefit was being derived from its prescription; if the latter is worthwhile the medication may be continued. Byrne ea (2008, p. 362) suggest that prescription of anticholinesterase drugs should be maintained as long as MMSE scores remain above 12 points and where overall, functional and behavioural status suggests a useful drug effect. Interestingly, these drugs may maintain their effects for some weeks after discontinuation²⁷⁹⁴. The ethical/moral question has been raised as to whether they inappropriately prolong life.²⁷⁹⁵ Apathy may respond to

²⁷⁹⁰ The list of proposed drug treatments includes vasodilators (e.g. isoxsuprine, cyclandelate, dihydroergotoxine, and mixtures of ergot alkaloids like hydergine), precursors of Ach (e.g. choline and lecithin – lecithin is phosphatidyl choline), stimulators of Ach release (e.g. piracetam), inhibitors of Ach hydrolysis (e.g. physostigmine, THA), neuropeptides (e.g. vasopressin and its papaverine analogues – given intranasally), and so-called brain metabolism enhancers (e.g. pyritinol, pentifylline). The selective muscarinic agonist xanomeline may reduce shouting and psychotic phenomena.(Bodick ea, 1997) ‘Disruptive vocalization’ is sometimes due to depression.(Dwyer & Byrne, 2000)

²⁷⁹¹ Aspirin is a COX-1 inhibitor that inhibits platelet aggregation.

²⁷⁹² Hydroxychloroquine may cause anxiety, nightmares, a confusional state, aggression, depression, and mania.

²⁷⁹³ MMSE score 10-24 and duration < 6 months.

²⁷⁹⁴ This raises the question why this is so? Is it persistence of drug in CNS or is it due to muscarinic receptor stimulation causing non-amyloidogenic processing of amyloid precursor protein. Anticholinesterases may slow hippocampal atrophy.

²⁷⁹⁵ Their value in routine clinical practice and foretelling which patients benefit have also been challenged.(Anonymous, 1998; Anonymous, 2000a) A tendency to avoid telling patients that they are suffering from dementia may work against such drugs receiving a trial in such cases.(Wild & Petit, 2002) Knapp (2003) suggests that cholinesterase inhibitors save money spent on institutional care but shifts the economic burden onto family carers (who will have to care for the patient for longer). In 2006 NICE in the UK restricted use of anticholinesterases for AD who have moderate disease (not early or late), a decision challenged by the pharmaceutical industry and the UK Alzheimer’s Society (donepezil is advertised as suitable for all degrees of AD in the US). According to Dyer (2007), prescribers, whilst keeping controversial 2006 NICE guidelines in mind, are not prohibited from

anticholinesterases (Thomas, 2008, p. 430) as may agitation, anxiety, delusions, and hallucinations. (Trinh ea, 2003) Cholinesterase inhibitors have been used²⁷⁹⁶ to treat AD, vascular dementia, delirium, traumatic brain injury, frontotemporal dementia, Korsakoff's syndrome, Huntington's disease, and mild cognitive impairment. (Overshott & Burns, 2005)

Anticholinesterases for 'mild to moderate' Alzheimer's disease

Caution is required with succinylcholine type muscle relaxants (e.g. during ECT) as the relaxant effect (i.e. paralysis) may be prolonged as a result of plasma pseudocholinesterase inhibition: stop acetylcholinesterase inhibitors before procedures requiring use of succinylcholine. Cholinesterase inhibitors increase gastric acid secretion with the risk of bleeding (esp. if there is peptic ulcer or the patient is taking anti-inflammatory medication). They may exacerbate weight loss, COPD²⁷⁹⁷ or asthma, obstruct urinary outflow, increase seizure risk, and cause heart block and sinus bradycardia²⁷⁹⁸ (esp. in cases of supraventricular conduction delay) with the possibility of fainting or falls. There is a theoretical possibility of toxicity from cocaine or cocaine-like local anaesthetics. Butylcholinesterase degrades aspirin, mivacurium and cocaine-like local anaesthetics. Over time, acetylcholinesterase levels fall relative to butylcholinesterase in AD.

(a) *Terahydroaminoacridine*: There has been some evidence for improved cognitive function using the centrally active anticholinesterase THA (terahydroaminoacridine or Cognex, an acridine) but this have fallen from favour because of its hepatic toxicity²⁷⁹⁹ and because not all studies have found it to be effective. THA can cause troublesome cholinergic side effects (e.g. GIT upset and hypotension).

(b) *Donepezil hydrochloride* (Aricept, Arippez, Donesyn, Donecept, Dozept), a piperidine derivative has been said to delay the progress of AD, although a study of community-based 'mild to moderate' cases of AD failed to support this claim. (AD2000 Collaborative Group, 2004; Schneider, 2004) There is some evidence that the rate of progression from mild cognitive impairment to AD may be slowed during the first year by donepezil, but this effect wears off. (Petersen ea, 2005) It is tolerated better and is much less toxic than THA. Donepezil is excreted in the urine and metabolised to multiple metabolites by the cytochrome P450 system. It has a plasma half-life of c 70 hours. It can cause mild and transient nausea, diarrhoea, vomiting, fatigue, insomnia, headache, coryza-like symptoms, dizziness/syncope, bradycardia, heart block, muscle cramps (minor increase in muscle CK), abdominal disturbance, anorexia, hallucinations, agitation²⁸⁰⁰ and aggression. (Anonymous, 1998) The last three neuropsychiatric symptoms tend to resolve if the drug is stopped or the dose is reduced. (Anonymous, 2003a) Other associated problems include enhancement of succinylcholine-like muscle relaxants, vagotonic effects (e.g. bradycardia – may be problematic in sick sinus syndrome or other supraventricular cardiac conduction disorders like sinoatrial or A-V block), urinary retention, and (like AD) seizures. Caution is required in asthmatics or obstructive lung cases. Breakdown of donepezil is inhibited by ketoconazole and quinidine and probably by itraconazole, erythromycin and fluoxetine. There may also be reduced plasma levels of donepezil in the presence of enzyme inducers like rifampicin, phenytoin, carbamazepine and alcohol.

(c) *Rivastigmine* (Exelon²⁸⁰¹), a carbamate, is another acetylcholinesterase inhibitor. Upward dose titration should be slower if there is renal or hepatic dysfunction and the drug should be avoided in the case of

prescribing for 'mild' cases. However, Bayer (2007) points out that the 3 acetylcholinesterase inhibitors in question (donepezil, galantamine, and rivastigmine) were recommended by NICE (following a High Court case) for cases 'of moderate severity only' (MMSE scores 10-20); MMSE and other relevant review should be conducted every 6 months; and the drug should be continued while MMSE score is 'above 10 points'. Naturally, interpretation of the MMSE must take heed of factors such as IQ and linguistics. In 2008 (Dyer, 2008) the appeal court held that NICE put the pharmaceutical industry at a disadvantage by not revealing how it came to its conclusions.

²⁷⁹⁶ With various levels of evidence for efficacy. A few cases may show marked deterioration when these drugs are stopped.

²⁷⁹⁷ Muscle weakness due to cholinesterase inhibitors can compromise breathing in susceptible individuals.

²⁷⁹⁸ The incidence of cardiovascular events with these agents is low and serious events are rare. (Rowland ea, 2007) Vigilance is required and intervention depends on the degree of slowing of pulse, clinical effects like syncope, and specialist opinion on the cause (e.g. one might use the drug if the problem was not due to the drug or a pacemaker is fitted).

²⁷⁹⁹ Autoimmune granulomatous hepatitis.

²⁸⁰⁰ Howard ea (2007) donepezil does not reduce agitation in AD.

²⁸⁰¹ Exelon is available as Hard Capsules (1.5 mg, 3 mg, 4.5 mg, and 6 mg) and in two transdermal patch strengths: 4.6 mg/24 hrs (contains 9 mg rivastigmine, released at 4.6 mg/24 hrs) and 9.5 mg/24 hrs (contains 18 mg rivastigmine, released at 9.5 mg/24 hrs). Only ONE patch to be applied daily: remove yesterday's patch first! Overdose (> 1 patch) may cause nausea, vomiting, hypertension, hallucinations, bradycardia, and syncope. Do not use same site during any 14-day period to avoid irritation. Start with 4.6 mg/day patch and (if tolerated and if required) increase to 9.5 mg/day patch after at least FOUR WEEKS has elapsed.

severe hepatic impairment. There may be associated weight loss²⁸⁰². Problems include nausea, vomiting, cholinomimesis²⁸⁰³, increased gastric acid secretion, and worsening of urinary obstruction or seizure disorders. Care should be taken in asthmatic patients or those with obstructive lung disease. Rivastigmine may increase the effects of succinylcholine-type muscle relaxants. It should not be given with cholinomimetic drugs and it may interfere with the action of anticholinergic drugs. It can cause asthenia, anorexia, dizziness, and tiredness. Other side effects include abdominal pain, agitation, (Ballard et al, 2005) confusion, depression, diarrhoea, dyspepsia, headache, insomnia, sweating, malaise, tremor, and an increased likelihood of upper respiratory tract and urinary infection. Rare associations are angina, GIT bleeding, and syncope. Massive overdose warrants atropine administration. Return to baseline enzyme levels takes 9 hours. Emre et al (2004) used rivastigmine for mild to moderate dementia associated with Parkinson's disease and found a moderate improvement in dementia but with increased rates of nausea, vomiting, and tremor compared to placebo-treated cases. Peak rivastigmine plasma level is reached in 60 minutes, only 40% is plasma protein bound, it readily crosses the blood-brain barrier, the plasma half-life is one hour only, unchanged drug is not found in the urine²⁸⁰⁴, the drug does not accumulate, old age does not influence bioavailability, and there is no change in C_{max} and AUC in severe renal impairment. Rivastigmine is almost totally independent of the hepatic cytochrome P450 system.

(d) *Metrifonate* was a non-hepatotoxic organophosphate antischistosomal drug marketed as an acetylcholinesterase inhibitor for 'mild to moderate' AD. It is its metabolite 2,2-dichlorovinyl dimethylphosphate²⁸⁰⁵ that is the enzyme inhibitor. It was withdrawn because it caused myasthenia and respiratory muscle weakness. (De Deyn, 2002)

(e) *Galantamine*²⁸⁰⁶ (Reminyl; Reminyl XL contains prolonged release galantamine), reversibly and competitively inhibits acetylcholinesterase and enhances the response of nicotine receptors to Ach. It appears to be well tolerated and has been shown reduce both behavioural disturbance in patients and distress in carers. (Cummings et al, 2004) Galantamine does not help people with mild cognitive impairment and it may be associated with an increased mortality rate in such cases. Therefore its use is strictly confined to 'mild to severe' dementia of the Alzheimer type. Lower doses are indicated if there is moderate hepatic impairment. Avoid drug in presence of severe renal/liver impairment. Precautions: cerebrovascular disease, GIT obstructive disorders/surgery, seizures, severe asthma/COPD, urinary obstruction/bladder surgery, allergy to E110, and galactose intolerance. Interactions: other cholinomimetics, beta-blockers, digoxin, anaesthetics, CYP2D6 or DYP3A4 inhibitors. Avoid in pregnancy/lactation. Side effects: nausea, vomiting, diarrhoea, abdominal discomfort, headache, dizziness, somnolence, weight loss, confusion, falls, injury, insomnia, rhinitis, and UTI. Less common are tremor, fainting, and severe bradycardia. Atropine is given for severe overdose.

Memantine (Ebixa [Nemanda in US]), a weak non-competitive NMDA receptor antagonist²⁸⁰⁷, is indicated for 'moderate to severe' AD²⁸⁰⁸. (Foster, 2003, p. 1059) It may protect the brain against excess glutamate and to improve activities of daily living, memory, thought processes, and global function. (Reisberg et al, 2003) These effects may be less than robust. (Anonymous, 2003b) Memantine is mainly excreted unchanged by the kidneys. Hydrochlorothiazide may alter memantine excretion. A raised urine pH may increase memantine plasma levels. Memantine should be avoided with severe renal impairment and caution should be exercised in cases of epilepsy. Other NMDA antagonists²⁸⁰⁹ should not be taken concomitantly with memantine but it can be combined with cholinesterase inhibitors. Memantine may exaggerate the effects of L-DOPA, dopaminergic agonists, and anticholinergic drugs. Effects of barbiturates and antipsychotic drugs may be diminished. Uncommonly, memantine may cause hallucinations, confusion,

²⁸⁰² Weigh patient at intervals.

²⁸⁰³ Causing difficulties in the case of sick sinus syndrome or heart block.

²⁸⁰⁴ The decarbamylated metabolite is found in urine.

²⁸⁰⁵ DDVP or dichlorvos – produced by hydrolysis.

²⁸⁰⁶ A tertiary amine, phenanthrene derivative (from bulbs and flowers of snowdrops); tablets or oral solution (4 mg/ml) – 4 mg b.i.d. four at least 4 weeks, then 8 mg b.i.d. for at least 4 weeks, and finally the maintenance dose of 12 mg b.i.d.

²⁸⁰⁷ The drug dissociates rapidly from receptor if the receptor is physiologically activated, but blocks receptor when it is activated continually and moderately. It has been in use in German neurology since the 1980s.

²⁸⁰⁸ MMSE score 5-15. NICE recommended that memantine only be used as part of well-designed clinical studies, but it can be continued if the patient responds, i.e. NICE did not recommend memantine as a treatment. (Bayer, 2007)

²⁸⁰⁹ E.g. amantadine, ketamine, dextromethorphan.

dizziness, headache, or tiredness, and, less often, hypertonic muscles, vomiting, cystitis, and increased sexual drive. It comes as a tablet (10 mg) and as a solution. The starting dose is 5 mg (half a tablet) per day; each week the daily dose is increased by 5 mg; and the recommended maintenance dose is 20 mg per day²⁸¹⁰.

Combined memantine added to donepezil may produce increased gains in terms of global outcome, activities of daily living, behaviour, and cognition.(Tariot ea, 2004) Memantine improves behavioural symptoms in moderate to severe AD, especially agitation and aggression.(Gauthier ea, 2005)

*Angiotensin receptor blockers*²⁸¹¹ (Li ea, 2010) might have a role in reducing the risk for dementia or in delaying nursing home entry, although research in this area is at an early stage and not without methodological problems.

Methylthioninium chloride (Rember), a blue dye used in laboratory experiments, targets clumps of Tau in the brain and is being tested in the treatment of AD wherein it demonstrated a tendency to slow disease progress.

Dimebon is a non-selective antihistamine and has been shown in Russia to improve cognition in AD.(Doody ea, 2008) It was well tolerated, the main side effects being dry mouth and low mood.

Phytoneuropsychotropics (herbal products) include ginkgo biloba and huperzine-A.²⁸¹² Huperzine-A has been employed for centuries in China. It seems to have acetylcholinesterase activity but with little effect on butylcholinesterase. There is some evidence of efficacy when used alone or in combination with ginkgo biloba. However, DeKosky ea (2008) assigned 3,069 community volunteers aged at least 75 years with either normal cognition or mild cognitive impairment to either placebo or ginkgo biloba 120 mg twice daily and followed them up for a median of 6.1 years and found no reduction in either overall dementia or AD rates. Whilst the vinca alkaloid vinpocetine improves learning and memory in animals it does not benefit dementia sufferers.

The common sage (*Salvia officinalis*²⁸¹³) might be helpful for agitation.(Akhondzadeh ea, 2003)

New treatment concepts include selective inhibition or modulation of beta- and gamma-secretase activity.

A number of secretases are involved in beta-amyloid peptide (40-42 amino acids) production from amyloid precursor protein. Normally, APP is cleaved by beta-secretase and then by alpha-secretase with no A β accumulation. However, in AD it appears that γ -secretase (rather than alpha-secretase) cleaves much of APP leading to a 42-amino acid important in accumulation of amyloid. R-flurbiprofen, a gamma-secretase modulator, leads to shorter amino acids that do not lead to A β accumulation.

Hypercholesterolaemia accelerates amyloid pathology and reduced cholesterol intake slows plaque development in transgenic mouse models, a finding that may have some application in humans²⁸¹⁴. Statins²⁸¹⁵, by reducing cholesterol, have been suggested as having some therapeutic role. However, because more educated people may be more likely to take such drugs, the effects of education have to be controlled for in research. Also, Zandi ea (2005) found no support for a preventive role for statins. Nerve growth factor²⁸¹⁶, a neurotrophin, and deprenyl, a MAO-B inhibitor, have long been suggested as possible neuroprotective agents. Ampakines, the subject of research, attach to AMPA receptors and normalise glutamate activity; they also increase nerve growth factor (NGF) production. Gene therapy, implanting

²⁸¹⁰ This may be given once-daily.

²⁸¹¹ These are antihypertensives and not the same as ACE inhibitors.

²⁸¹² None of these are first line treatments. *Ginkgo biloba*, from the leaves of the maidenhair tree, was used in Chinese medicine for millennia; concerns have been raised over a tendency to cause bleeding. It can also cause GIT upset and headache.

²⁸¹³ A small evergreen shrub used as a food flavour. *Salvia* (sage) is Latin for 'to heal'. The 'essential oil' contains cineole, borneol and thujone and the leaf contains many chemicals such as oleic and tannic acids. The shrub has been touted as a treatment for many ills.

²⁸¹⁴ Amyloid deposition in blood vessel walls in AD is often harmless but not always so. There may be thrombosis of leptomeningeal or cortical vessels leading to many small infarcts. There may be ischaemic changes in the white matter. Bleeding of various degrees may occur into brain or subarachnoid space. Unlike in hypertension, which tends to affect the basal ganglia, the bleeding in AD tends to be peripherally placed.

²⁸¹⁵ Statins (e.g. simvastatin) have been associated with sleep problems, memory difficulties, depressed mood, sexual dysfunction, and interstitial lung disease.

²⁸¹⁶ Genetically modified fibroblasts that produce have been transplanted into brain NGF with some positive effect on cognition.(Tuszynski ea, 2005)

modified cells into the AD brain where they produce NGF, is in its early stages of development. The possibility of immunising people against AD requires further research.

Lithium inhibits glycogen synthase kinase-3 (involved in APP metabolism and tau phosphorylation). There is evidence for an increased risk for dementia in people with affective disorders (e.g. Thompson *et al.*, 2005) and some evidence that lithium may reduce this risk (see Nunes *et al.*, 2007; Kessing *et al.*, 2008).

Do not use antipsychotics as a convenient replacement for good care, to satisfy the needs of a care home over the clinical requirements of patients. Staffing levels in such settings are often poor²⁸¹⁷. The *Omnibus Budget Reconciliation Act* of 1987 (aka OBRA 87) in the USA placed restrictions on such prescribing with inconsistent results (Denning & Milne, 2008, p. 362). Schneider *et al.* (2005) conducted a meta-analysis of the literature and found that atypical antipsychotic use was associated with a small increase in mortality in elderly demented compared to placebo. Most studies were of short duration, they were more often unpublished, and they were usually funded by the pharmaceutical industry. Schneider *et al.* (2006) found adverse effects of atypical antipsychotic drugs for treatment of psychosis, aggression, or agitation in Alzheimer patients outweighed any therapeutic advantages. Sultzer *et al.* (2008) used antipsychotic drugs for psychosis or agitated/aggressive behaviour in outpatients with Alzheimer's disease: the drugs were useful for certain symptoms (e.g. anger, aggression, paranoid thinking) but did nothing for functional status, care requirements, or quality of life. Conventional antipsychotic drugs may carry similar risks for mortality when used in demented subjects (Kales *et al.*, 2007). The decision to prescribe antipsychotic drugs to demented patients should ideally follow failure of other approaches, consultation, and monitoring (Anonymous, 2007c; O'Brien, 2008). APA Practice Guidelines (2007) suggest caution in their use at the lowest effective dosage, education of patients and families about potential risks and benefits (especially mortality risk), and choice of particular drug based on side effect profile and individual patient characteristics. The effects of antipsychotic drugs on weight and cholesterol cannot be ignored in AD patients (Zheng *et al.*, 2009). Haw *et al.* (2009) found that all British old age psychiatrists (only 31% response rate) still used antipsychotic symptoms for behavioural and psychological symptoms of dementia (BPSD) and were not particularly impressed by NICE guidelines on the subject! Burns and Iliffe (2009a) suggest using trazodone²⁸¹⁸, clomethiazole, and SSRIs²⁸¹⁹ for agitation in dementia.

ECT (Sutor & Rasmussen, 2008) has been used safely and effectively for agitation in AD.

Women have been at the forefront in starting up self-help national organisations (O'Shea, 1992). Reality orientation therapy should be individualised and non-confrontational. Otherwise it may lead to anger, frustration, and depression (Simard & Sampson, 2008, p. 237).

Lewy body dementia (LBD)²⁸²⁰

Lewy bodies are inclusion bodies containing abnormally phosphorylated neurofilament proteins aggregated with ubiquitin²⁸²¹ and alpha-synuclein. They can be of various shapes and even be outside the cell. In the substantia nigra they are brightly eosinophilic (pink) with hyaline core and paler halo; in cortex they are faintly eosinophilic and have no core. They were considered confined to idiopathic Parkinson's disease (paralysis agitans) until recent years.²⁸²²

'Pure' LBD (with no AD pathology), although reported (Gurd *et al.*, 2000), is rare. McKeith (2002) and Rapoport *et al.* (2008, p. 251) admit that the boundary between LBD and Parkinson's disease with

²⁸¹⁷ There is no point in educating care home staff if the lessons do not become part of the culture of the facility; staff turnover alone will cause atrophy of skills unless managers are involved in training (Denning & Milne, 2008, p. 364).

²⁸¹⁸ Trazodone is suggested as being useful in the control of screaming.

²⁸¹⁹ Paroxetine is more anticholinergic than other SSRIs.

²⁸²⁰ This is also known as dementia with Lewy bodies (DLB), dementia of the Lewy body type, diffuse Lewy body disease, and cortical Lewy body disease. The general term LBD includes 'common form LBD' (or 'Lewy body variant' = Lewy bodies + AD pathology) and 'pure form LBD' (or 'diffuse LBD' = Lewy bodies minus AD pathology). Friedrich Heinrich Levy (1885-1950) discovered these bodies in the brains of Parkinson's disease patients in 1912 when with Alzheimer at Kraepelin's Royal Psychiatric Clinic in Munich. When he moved to the US he changed his name to Frederic Lewy.

²⁸²¹ Ubiquitin is a protein that targets other proteins for degradation by the proteasome.

²⁸²² Based on postmortem work (Lewy bodies in cerebral cortex and substantia nigra, may have senile plaques but no tangles, widespread reduction in level of choline acetyltransferase in neocortex, and some reduction in DA levels in caudate nucleus), it is often stated that LBD cases (11-25%: Wilcock, 2003) may constitute the second or third commonest cause of dementia [after AD (52%) and vascular dementia], although some, but not all, authors wonder about its nosological status and wonder if it is a variant of AD (Carter & Levy, 1995; Miller, 1997; Nixon & Albert, 1999; Foster *et al.*, 2003, p. 1052). Others point out that AD and LBD frequently or usually coexist (Foster, 2003, p. 1061; Falk *et al.*, 2004, p. 139) and Wise and Rundell (2005, p. 50) point out that the relative frequency of LBD versus vascular dementia depends on the author one is quoting! Bennett *et al.* (2006) prospectively reported that 7-14% of non-demented/non-cognitively impaired people who died had Lewy body pathology.

dementia/psychosis remains indistinct. Indeed, there is generally some overlap in the distribution of Lewy bodies between LBD and paralysis agitans, (Olichney *et al.*, 1995; Foster, 2003, p. 1051) some Lewy bodies being present in the cortex in idiopathic Parkinson's disease and many patients with LBD meet the pathology criteria for AD, (Cras, 2002; Lovestone, 2002, p. 289) such as Consortium to Establish a Registry for Alzheimer's Disease (CERAD) criteria. Lewy bodies contain ubiquitin and alpha-synuclein²⁸²³ and antibodies to these proteins can be used in postmortem tissue as a method of detecting these bodies. The dose of alpha-synuclein (number of genes) may play a role in the aetiology of dementia. Lewy bodies in autonomic ganglia may be associated with postural hypotension. Lewy neurites are diffusely aggregated neurofilament proteins found particularly in the CA2-3 region of the hippocampus in LBD. In Parkinson's disease up to 70% of cells are lost from the substantia nigra before symptoms manifest themselves. In LBD up to 40% of the same cells are lost, which may explain the vulnerability of such cases to EPS when given neuroleptic medication. Functional neuroimaging (PET, SPECT) early in the course of LBD may show reduced occipito-temporal cortical activity, with much wider involvement later²⁸²⁴. There may be an excess of males. (Weiner *et al.*, 1996)

Dementia with Lewy bodies neuropathology

Lewy bodies

Lewy neuritis

Neuritic (senile) plaques

Neurofibrillary tangles

Regional neuronal loss²⁸²⁵

Microvacuolation (spongiform)

Loss of synapses

Note: LBD is more or less indistinguishable pathologically from Parkinson's disease-associated dementia (PDD) but PDD responds to L-DOPA from the start and there is delayed onset of dementia (>12 months) whereas Parkinsonism develops late in LBD and, in almost one-third of cases, may not develop at all

Clinical features of LBD include marked fluctuations in cognitive impairment, amnesia, apraxia, aphasia, EPS, falls (orthostatic hypotension), clouding of consciousness, visual and auditory hallucinations²⁸²⁶, paranoid delusions²⁸²⁷, and hypersensitivity to the adverse effects of neuroleptic drugs, including atypicals. The excess psychotic symptoms may relate to reduced DA turnover and metabolism that is reflected in lower CSF HVA levels. Olfaction is impaired. Cognitive decline has correlated with both neuroleptic usage and with persecutory ideas! (McShane *et al.*, 1997) Vivid dreams are often reported in DLB and REM-sleep behaviour disorder is common in DLB and may long precede it. (Ericksen & Tsuang, 2007, p. 477) Anticholinergic drugs may precipitate life-threatening delirium. (Miller, 1997)

The course followed by LBD varies between patients but is more rapid than with AD and death occurs about six years following diagnosis.

The psychopathology of LBD (delusions and hallucinations) may be ameliorated by the anticholinesterase rivastigmine. (McKeith *et al.*, 2000) Poor light (e.g. evening) and patterned furnishings may exacerbate hallucinations and attention should be aimed at remedying such matters. L-deprenyl has been suggested for Parkinsonism but it may precipitate hallucinations. Antidepressants with orthostatic propensities are best avoided. Atypical antipsychotic drugs may cause as many problems as typical agents, although olanzapine, quetiapine, aripiprazole or clozapine may be useful. (e.g. Fernandez *et al.*, 2003) BZDs have been suggested for behavioural problems and restless or wandering behaviour may respond to beta-blockers or L-DOPA. The following box presents further research details.

²⁸²³ With disorders such as multiple system atrophy and Parkinson's disease, LBD is included in the family of α -synucleinopathies.

²⁸²⁴ There may be sparing of the primary sensorimotor cortex.

²⁸²⁵ Nucleus basalis of Meynert and brain stem are commonly affected.

²⁸²⁶ Insight into the pathological nature of hallucinations may be preserved for long periods. Visual hallucinations, present in at least 60% of cases, may relate to a reduction in ACh (greater than in Parkinson's disease with dementia) and relative sparing of 5-HT. (Perry *et al.*, 1990) Visual hallucinations may respond to cholinesterase inhibitors. The usual visual hallucinations are of people or animals that may disappear when the patient stares at the image. Other visual hallucinations may be of smoke, fire, or water lying on a surface. Also, the patient may see (illusions) things such as a face in detailed objects like a bush.

²⁸²⁷ Delusions may stem from up-regulated postsynaptic muscarinic receptors.

Summarised research on Lewy body dementia (LBD)

1912. The German neuropathologist Friedrich Heinrich Lewy (1885-1950), while working with Alzheimer, described spherical neuronal inclusions.

1986. Parkinson's disease patients with overt dementia are no more often depressed than in those without dementia.

1990. Anergia, motor retardation, and early awakening may be equally severe in Parkinson's disease patients with and without depression.

1997. LBD may resemble AD except for better recall and worse praxis in the former.

A mutation of the gene for α -synuclein on chromosome 4 is associated with rare, autosomal dominant, early-onset Parkinson's disease.

1999. Olanzapine had little advantage over conventional agents.

Non-significant neurone loss in cortical areas affected by Lewy bodies (perhaps synaptic dysfunction is operative?)

2000. Apathy, anxiety, delusions and hallucinations reduced more in LBD than in controls by rivastigmine, better if dose titrated for individual.

Olanzapine used for BPSD and psychosis in dementia was safe (somnolence and gait disturbance reported) and effective at 5-10 mg/day, but 15 mg/day was ineffective and associated with significant peripheral anticholinergic effects.

2001. Occipital hypometabolism is seen in LBD both with and without co-existing AD pathology.

Frequency of co-occurring AD and LBD pathological stigmata is greater than that due to chance.

2003. Substantial relief of depression from ECT in a series of 7 cases.

2004. Olanzapine indication in dementia terminated because of reports of increased mortality and stroke in that group.

2008. ¹²³I-FP-CIT SPECT²⁸²⁸ improves diagnostic accuracy of LBD – if scan is abnormal in a possible case of LBD it favours a diagnosis of that disorder.

Vascular dementias²⁸²⁹

Vascular contributions to dementia are easier to identify today because of FLAIR²⁸³⁰ and other MRI techniques. Fresh infarcts can be identified with diffusion-weighted MRI. The occipito-frontal power ratio is higher in dementia due to a vascular cause than in cases of AD. Also, EEG coherence will be decreased between areas disconnected²⁸³¹ by vascular lesions. Larson (1993) listed the risk factors for vascular dementia as old age, high blood pressure, smoking, diabetes mellitus²⁸³², cardiac disorders, atrial fibrillation, and extracranial arterial disease. To these can be added male sex. A twin study from Norway

²⁸²⁸ [¹²³I]-2-β-carbomethoxy-3β-(4-iodophenyl)-N-(3-fluoropropyl)nortropane.

²⁸²⁹ Vascular dementia is reportedly more common in AD in Japan, among Blacks and in at least one unselected elderly Swedish group. (Skoog et al, 1993) AD may be becoming more common in Japan, and more so in Japanese-Americans in Seattle. (Homma, 2000) Fratiglioni et al (2008, p. 392) are critical of reports of an excess of vascular dementia in East Asia. Stewart (2002) is sceptical about the usefulness of vascular dementia as a diagnostic category because it involves a high degree of subjective judgement, because it subsumes many different disorders, and because it overlaps with AD. Again, Stewart (2008) lists problems with the diagnosis as (a) stepwise vs gradual course poorly predicts pathology; (b) post-stroke dementia may occur gradually, often without further infarction; (c) risk factors for stroke may also be risk factors for AD; (d) dementia from cerebrovascular disease is usually associated with Alzheimer pathology; (e) research diagnostic criteria poorly predict pathology; (f) poor inter-rater reliability of clinical diagnostic criteria for vascular dementia; (g) operational definitions of dementia tend to ignore the common non-memory deficits (e.g. executive) found in vascular cases. A systematic review and meta-analysis (DeBette & Markus, 2010) concluded that white matter hyperintensities (*leucoariosis*) on brain MRI were associated with increased risk of CVA, cognitive decline, dementia, and demise. There was much heterogeneity in the way such lesions were measured and analysed and some studies were omitted because of use of different scales that viewed white matter hyperintensities as continuous variables.

The **Hachinski ischaemic index** (HII) was introduced in the 1970s. The higher the score the more likely dementia is due to cerebrovascular disease. Scores (in brackets) are given for abrupt onset (2), stepwise deterioration (1), fluctuating course (2), nocturnal confusion (1), relative preservation of personality (1), depression (1), somatic complaints (1), emotional incontinence (1), history of hypertension (1) or strokes (2), evidence of associated atherosclerosis (1), and focal neurological symptoms (2) or signs (2). A score of < 4: probable AD; 4-7: probable mixed AD and multi-infarct dementia (MID); > 7: probable MID. The HII was derived from patients who were relatively young and mildly impaired. The Index does not take account of imaging findings and are of diminished applicability in cases of insidious onset. For these reasons is used less today than heretofore.

The **NINDS-AIREN** (National Institute of Neurological Disorders and Stroke – *Association Internationale pour la Recherche et L'Enseignement en Neurosciences*) criteria of 1993 avoid (highly specific but of low sensitivity) avoid trying to define mixed AD-vascular dementia. *Probable vascular dementia* = early onset of abnormal gait (magnetic, *marche à petit pas*, apraxic-ataxic, or parkinsonian), unsteady/prone to falling, early onset of urinary incontinence, pseudobulbar palsy (dysphagia, dysarthria, emotional incontinence), changes in mood and personality, and psychomotor retardation, perseveration, and difficulty shifting/maintain sets.

Definite vascular dementia = clinical criteria for probable case, biopsy/autopsy histology favours cerebrovascular disease, plaques/tangles do not exceed what would be expected at patient's age, and no other cause of dementia.

²⁸³⁰ Fluid-attenuated inversion recovery sequences.

²⁸³¹ Disruption of cortico-cortical and cortico-subcortical fibres.

²⁸³² There is some evidence that diabetes mellitus, especially type II, increases the risk of vascular dementia (and, to a lesser extent Alzheimer's disease). No association between decline in cognitive function and frequency of severe hypoglycaemia has been found, but high mean glycated haemoglobin concentration and a moderate decline in motor speed and psychomotor deficiency has been reported. There are many possible mechanisms involved (ranging from genes to hypertension and vascular pathology). (Strachan et al, 2008)

suggested that heredity may be far less important in the genesis of vascular dementia than in AD.(Bergem ea, 1997) Vascular dementia is an umbrella term covering all dementias due to vascular disease, multi-infarct cases being but one example. There is no specific treatment. Blood pressure should be controlled²⁸³³, low dose aspirin might help²⁸³⁴, and there may be a role for surgical correction of carotid artery stenosis. Depression seems to be more common in vascular dementia than in AD.(Allen & Burns, 1995) Antidepressants, especially SSRIs, can be used to treat or prevent post-stroke depression and they may improve cerebral recovery and improve long-term survival. Antidepressants may be augmented with calcium channel blockers, such as the centrally active nimodipine, in post-stroke depression. *Multi-infarct dementia*²⁸³⁵ tends to vary in severity over time. Each new lesion adds to the total cognitive disability. The patient often retains insight. Irritability and depression²⁸³⁶ are commonly encountered. The mortality rate is lower than for AD. Epilepsy (20%), hypertension, transient ischaemic attacks (TIA²⁸³⁷), and renal, ophthalmic or cardiac disease may complicate the picture. It is more common in males. Atheroma of some degree is common within the cerebral circulation in the senium. However, extreme degrees of atherosclerosis in the postmortem specimen are quite compatible with clinically normal cognitive functioning.

Pathology in vascular dementia

Lenticulostriate branches of middle cerebral artery most often affected

Vasculature progressively narrows, bloats, twists, and becomes yellow and rigid

Supple vessels give way to corrugated drainpipes

Brain parenchyma may be normal, cystic, infarcted, necrotic, or scarred

Dementia is due to cerebral softening from multiple small infarctions²⁸³⁸ of brain tissue - it is not the cerebral arteriosclerosis *per se* that causes dementia

Middle cerebral artery most often involved

Followed by **posterior** artery supplying areas important for memory, e.g. the hippocampus

Anterior cerebral artery least often affected

According to some authorities (Korczyn, 2002) pure Alzheimer and vascular dementias are rare and mixed pathology has been underestimated

Strategic infarct

An infarct that, because of its position (e.g. hippocampus), causes dysfunction out of proportion to its size

E.g. Severe memory problems due to bilateral paramedian thalamic or fornical infarction; severe problems with comprehension following left supramarginal or angular gyrus infarction

Acute stroke can be treated with IV tissue plasminogen activator (within 3 hours) or aspirin (within 2 days) and decompression surgery. Preventive measures for stroke include anti-platelet, anti-hypertensive and anti-coagulant medications, cholesterol reduction, and endarterectomy.(Donnan ea, 2008)

²⁸³³ However, blood pressure may fall with the onset of dementia, prompting a review of antihypertensive treatment.(e.g. Pettiti ea, 2005)

²⁸³⁴ Kang ea (2007) found that low dose aspirin failed to improve cognition in healthy older females. Price ea (2008) found low dose aspirin not to affect cognitive function in middle aged to elderly people at moderately increased cardiovascular risk. Methodological issues remain a problem.(Whalley & Mowat, 2007) Simard and Sampson (2008, p. 236) point out that results of studies of NSAIDs are 'widely' contradictory and there are 'serious concerns about tolerability'. However, aspirin does prevent major vascular events.(Eikelboom & O'Donnell, 2008)

²⁸³⁵ Vladimir Hachinski and colleagues proposed the term *multi-infarct dementia* in 1974.

²⁸³⁶ Depression may be obstinately persistent.

²⁸³⁷ **TIA**s were defined as acute phenomena (focal cerebral or monocular deficits, the latter being due to ischaemia of the retina) that resolve within 24 hours. We know that any such attack lasting more than 4 hours can cause infarction and thrombolytic therapy should be given with the first 3 hours. A more modern definition is one that limits the event to 1 hour with no evidence (on diffusion-weighted MRI) of infarction. TIAs are not benign because they are associated with increased short-term morbidity and mortality. *Crescendo TIAs* consist of > 3 TIAs in a 3 day period during which the attacks become more severe and increase in frequency and duration.

²⁸³⁸ **Lacunar infarcts** are small punctuate lesions (< 1.5 cm in diameter) that often affect deep white matter, basal ganglia and brainstem: many such lacunae (or fewer large strokes) can cause multi-infarct dementia. The patient may have a history of CVAs or MIs. High blood pressure is a major predisposing factor. The presence of lacunes plus depression in the elderly is associated with significant reduction in life expectancy.(Lavretsky ea, 2010)

*Binswanger's disease*²⁸³⁹

Rare variant of cerebrovascular disease of controversial nosological status

Starts in middle to old age

Periventricular and deep white matter bear brunt of pathology

Atherosclerotic changes occur in local nutrient arteries leading to many small white matter infarctions, the cortex being spared

CT scan shows periventricular lucency

MRI scan shows areas of decreased and increased signal intensity on T1- and T2-weighted images respectively (Such lesions must be distinguished from the smoother periventricular caps and rims and from 'unidentified bright objects' or UBOs, which are normal variants)

Clinical picture includes progressive dementia with generalised slowing of intellectual processes, memory impairment, and disorientation, and (but not in all cases) neurological signs

May also get depression, euphoria, irritability and anxiety

Anti-phospholipid antibody syndrome (Hughes' syndrome) (D'Cruz ea, 2007; Cohen ea, 2010)

Described in 1983

Recurrent arterial and venous (including renal vein/renal infarction) thromboses

Kidney – above plus thrombotic microangiopathy, antiphospholipid syndrome nephropathy

Heart valve disease, coronary artery disease, pulmonary embolism

Recurrent early miscarriage/intrauterine fetal death²⁸⁴⁰; early/severe pre-eclampsia

May experience TIAs, CVAs and multi-infarct-like dementia

Migraine

Skin - livedo reticularis, Raynaud's phenomenon

Overlaps with SLE

*CADASIL*²⁸⁴¹

Prevalence of 1/50,000

Familial disorder associated with autosomal dominant (variable penetrance) gene at 19p13²⁸⁴²

Mutation in Notch 3 gene²⁸⁴³

Phenotype varies, even within a family

Walls of small and medium penetrating arteries thickened and fibrotic²⁸⁴⁴

A white matter ischaemic disease

60-70% decrease in cortical choline acetyltransferase

Parieto-occipital and dorso-frontal axonal damage

Immuno-staining of skin biopsy may assist in diagnosis: granular osmophilic material

Arteriolar smooth muscle shows GOM (glomerular osmophilic material) on electron microscopy

Adults²⁸⁴⁵ with no vascular risk factors develop vascular dementia and pseudobulbar palsy (dysphagia, dysarthria, and emotional incontinence)

Youngsters may develop migraine and depression with TIA and CVA in 20s and 30s, and dementia in their 50s

May present with psychosis, mania, or depression

Duration about 10 years

Address stroke risk factors²⁸⁴⁶

²⁸³⁹ Subcortical arteriosclerotic (or vascular) encephalopathy: It is an extreme form of 'small vessel disease' (diffuse and widespread), itself a cause of subcortical dementia. The effects of small vessel disease may be added to those of lacunar infarcts.

²⁸⁴⁰ 27% of women with at least 2 spontaneous miscarriages have antiphospholipid syndrome.

²⁸⁴¹ Cerebral dominant arteriopathy with subcortical infarcts and leucoencephalopathy, formerly hereditary multi-infarct dementia.

²⁸⁴² Related to another chromosome 19 gene, this time for familial hemiplegic migraine.

²⁸⁴³ Notch 3 at 19p13.1 encodes a transmembrane receptor with an important function in vascular smooth muscle signalling pathways. There are 33 exons. Distribution of gene mutations varies between countries.

²⁸⁴⁴ The problem lies in the basal smooth muscle cells.

²⁸⁴⁵ Mean age of onset = 35-40, age range 20-70. (Taylor & Doody, 2008)

SSRIs for depression

*Fabry's disease*²⁸⁴⁷

Painful neuropathy and progressive involvement of cardio- and cerebro-vascular systems and kidneys

*HERNS*²⁸⁴⁸

Autosomal dominant disorder with basement membrane involvement

Anton's syndrome (cortical blindness)

Inability to perceive visual stimuli (cannot see) because of bilateral cortical damage²⁸⁴⁹ with normal eyes and pupils²⁸⁵⁰ Patients **deny blindness**, confabulate, and describe vividly what is 'seen'

Often already have cognitive impairment, visual loss, and mainly nondominant hemisphere damage

Rarely, despite cortical blindness, visual stimuli may evoke responses (**blindsight**) which may be due to subcortical/brainstem processing of perceptions – direct projections from the lateral geniculate nucleus to the extrastriate cortex may contribute to blindsight (Schmid et al, 2010)

Aetiology includes Alzheimer's disease, vascular lesions, Creutzfeldt-Jakob disease, lissencephaly, and carbon monoxide poisoning

Normal pressure hydrocephalus²⁸⁵¹

The essential features are normal CSF pressure²⁸⁵² and communicating hydrocephalus²⁸⁵³. Stretching of nerve fibres appears to be important in the production of clinical manifestations. Memory problems develop over many weeks, there is psychomotor retardation, and the first signs are often gait apraxia (e.g. 'magnetic' gait: unable to lift feet in order to commence walking) and urinary incontinence. Headache is uncommon. Pyramidal or other long tract signs may dominate the clinical picture whereas other cases may present as a cerebellar syndrome with, e.g., intention tremor. Other cases are simply demented. Combined pictures may occur.²⁸⁵⁴ Air-encephalography and isotope-encephalography were commonly used to assist diagnosis. The air or isotope concentrated in the dilated ventricles and failed to reach the convexity of the hemispheres. CT is used today and shows symmetrically enlarged ventricles²⁸⁵⁵ without significant cerebral atrophy, i.e. dilatation of ventricles is out of proportion to widening of sulci. SPECT shows a reduced cerebral blood flow, especially (unlike AD) in the anterior brain.

Sometimes there is a history of meningitis, subarachnoid haemorrhage, and intracranial (posterior fossa) surgery or head injury. Other associations include distortion of the third ventricle by the basilar artery in hypertensives, aqueduct stenosis, and tumours of the posterior fossa.

A shunt²⁸⁵⁶ (better outlook if periods of raised CSF pressure can be demonstrated) that runs from a cerebral ventricle to the right atrium or to the peritoneum may benefit a proportion of cases²⁸⁵⁷, gait difficulties

²⁸⁴⁶ Antiplatelet therapy (aspirin, dipyridamole), antihypertensives, statins (even with normal cholesterol levels), treatment for diabetes, decrease weight, stop smoking, exercise, moderate alcohol intake, and treat any co-morbid problems such as valvular disease. (Taylor & Doody, 2008)

²⁸⁴⁷ X-linked recessive lysosomal storage disorder: deficiency of alpha-galactosidase A with accumulation of globotriaosylceramide intracellularly: mainly middle-aged men but female carriers at risk of stroke.

²⁸⁴⁸ Hereditary endotheliopathy with retinopathy, nephropathy and stroke – generalised vasculopathy in Chinese Americans.

²⁸⁴⁹ E.g. due to occlusion of the posterior cerebral arteries, multiple sclerosis, or head trauma.

²⁸⁵⁰ Extensive damage to occipital lobes may cause cortical blindness. Unlike in peripheral causes of blindness, the fundi are normal and pupillary light reflexes are preserved.

²⁸⁵¹ *Hakim-Adams syndrome*: Raymond Adams and co-workers described this in 1965. Opinion has varied over the years on its frequency, some modern authorities suggesting that it is a very rare cause of dementia. (Foster, 2003, p. 1054)

²⁸⁵² In fact, intermittently raised pressure (B waves), especially at night, are found when continuously monitored.

²⁸⁵³ There is no block in ventricles but there is a block in the subarachnoid space. CSF gets out of the ventricles but cannot flow up over the hemispheric surfaces.

²⁸⁵⁴ Vascular dementia, it should be noted, is a more common cause of subcortical dementia, gait disturbance, and urinary incontinence, than is normal pressure hydrocephalus.

²⁸⁵⁵ *Evan's ratio* = greatest width of frontal horns of lateral ventricles/maximum internal width of skull. A ratio of > 0.3 suggests significant ventriculomegaly. In cases in which such ventriculomegaly is associated with severe cortical atrophy or widespread cerebrovascular disease the ventriculomegaly may just be due to loss of brain tissue rather than normal pressure hydrocephalus.

²⁸⁵⁶ Various further investigations will be performed prior to proceeding to shunting: assessing cognition before and after removing CSF, slow prolonged removal of CSF by lumbar catheter, 24-hour intracranial pressure monitoring, and saline infusion into

responding best; the milder the dementia the better the chance of an improvement. With use of adjustable valves with subcutaneous magnetically controlled mechanisms to allow manipulation of CSF drainage by the clinician the patient must avoid magnets, including MRI scanners.

Neurosyphilis²⁸⁵⁸

The advent of HIV has led to a resurgence of neurosyphilis. (French, 2007) There are three classic types of neurosyphilis: asymptomatic with CSF changes only, meningovascular involving the leptomeninges and blood supply, and parenchymatous with degeneration of neurones and axons. The last type includes general paresis (GPI, dementia paralytica), tabes dorsalis (locomotor ataxia), and taboparesis. There has been a shift away from parenchymatous to meningovascular syphilis over time. Atypical and attenuated presentations are now much more likely. Both GPI and meningovascular syphilis²⁸⁵⁹ may lead to dementia. Affective or personality change is common and may precede intellectual deficits. The disorder may present as a social indiscretion. Three males are affected for every female and there is a wide variation in the age of onset but the mean is around 40 years. Congenital GPI can affect the young child and GPI can start in the very old. The period between infection and onset of GPI is usually of the order of 10-15 years with wide variation²⁸⁶⁰. The following forms²⁸⁶¹ have been described: grandiose (expansive), simple dementing, depressive, taboparetic, manic, schizophrenia-like ('paraphrenic'), neurasthenic, acute brain reaction, Korsakoff-like, epileptic, miscellaneous neurological presentations, Lissauer's²⁸⁶², and juvenile. GPI is the only type of syphilis wherein *T. pallidum* can be visualised in the brain.

It is important to obtain the patient's cooperation in contact tracing and the family may need to be tested. *Treponema pallidum* cannot be cultured *in vitro* but it may be seen with dark ground microscopy. Enzyme immunoassay detects IgM and IgA antibodies. If this is positive it should be confirmed using the TPHA/TPPA and VDRL/RPR tests.²⁸⁶³ In cases of suspected neurosyphilis the CSF may need to be tested. IV aqueous benzylpenicillin 18-24 million units daily for 1-2 weeks is the recommended treatment for neurosyphilis. 2 gram of ceftriaxone given parenterally for the same period may be used if the patient is allergic to penicillin. ECT may exacerbate focal neurological signs.

Pellagra²⁸⁶⁴

subarachnoid space through a lumbar needle with continuous CSF pressure monitoring and calculation of CSF absorption. All such tests have their own problems and deficiencies.

²⁸⁵⁷ About 40%.

²⁸⁵⁸ Theories of the **origin of syphilis** vary from the Crusaders to Spanish adventures in the New World to a worldwide (including Europe) mutation at the close of the 15th century. Fracastoro gave the name syphilis to this disease in 1530. August von Wasserman introduced his blood test (WR) in 1906. The first clear accounts of general paralysis of the insane (general paresis, GPI), which causes an insidious dementia, date from 19th century Paris; it spread from there to other parts of the world; and GPI may have arisen because of a mutation in *Treponema pallidum*. (See Hare, 1998, ch. 3) Syphilis was a leading cause of insanity at the end of the nineteenth century. (Strathern, 2005, p. 332) Its more famous victims may have included Oscar Wilde, Nietzsche, Gauguin, and John Keats. Congenital syphilis featured in the Norwegian playwright Henrik Johan Ibsen's (1828-1906) *Ghosts* (an attack on Victorian hypocrisy) in 1881. It has been suggested that *T. pallidum* underwent mutation in order to cause GPI. Fournier of Paris showed a statistical relationship between syphilis, paresis and tabes in 1894. Schaudinn of Berlin identified the causative organism in material from a genital lesion in 1905. Noguchi and Moore demonstrated *T. pallidum* in the brain of GPI patients in 1913. There was a resurgence of syphilis in Dublin and other European cities from 2000, with a peak in Irish notifications of 300 cases in 2002. The **Argyll Robertson pupil** is small, stays the same size, is unchanged by light/shade, contracts on convergence, and dilates when the patient ceases to attempt convergence. Pupil response to light is lost although accommodation to near objects is normal. Douglas Argyll Robertson (1837-1909) was born in Edinburgh and was a pupil of Remak, Romberg and von Graefe; he experimented with physostigmine in the early 1860s and observed his eponymous pupil in 1869. (Timoney & Breathnach, 2010) Elderly diabetics may have small and irregular pupils with a sluggish light reflex or even the full Argyll Robertson pupil, so-called *pseudo-tabes*.

²⁸⁵⁹ Meningovascular syphilis may present as subacute meningitis with papilloedema and cranial nerve involvement; chronic expansion of a gumma; or, if there is involvement of the cord meninges, paraparesis.

²⁸⁶⁰ About half that time applies for meningovascular syphilis. The pupils are unequal, irregular, and eccentric. There may be loss of iris pigment. Diabetes (**pseudo-tabes**) is a commoner cause today than is neurosyphilis. The lesion is probably pretectal (midbrain).

²⁸⁶¹ The relative preponderance of different clinical presentations may have changed over time. (Hare, 1998, ch. 3)

²⁸⁶² Hemiparesis, aphasia and other evidence of focal brain damage.

²⁸⁶³ *T. pallidum* haemagglutination or particle agglutination assay (TPHA/TPPA); Venereal Disease Research Laboratory and rapid plasma reagin (VDRL/RPR) tests.

²⁸⁶⁴ *Mal de la Rosa*, described by the Spanish physician Gaspar Casal (1679-1759) in 1735, is due to nicotinic acid (vitamin B3) deficiency. Goldberg detected its more specific dietary origin in 1915 and in 1937 niacin was shown to be the deficient chemical. Niacin is found in a number of foods. Removal of bran eliminates niacin from cereals although foods in developed areas are often fortified with the vitamin. Eggs and cheese contain tryptophan. Humans can make niacin from tryptophan. Deficiency of vitamin B6 and riboflavin can give rise to pellagra because the enzymes involved in converting tryptophan to niacin (kynureninase and kynurenine hydroxylase) are dependent on these vitamins. Pellagra rarely accompanies malabsorption states. Other associations are

Pellagra, due to deficiency of nicotinic acid (niacin) or its precursor (tryptophan) is found in maize-eating areas, alcoholics, and refugees. The clinical features are dermatitis (symmetrical, affecting sun-exposed areas²⁸⁶⁵), diarrhoea (or constipation), delirium, dementia, depression, dysmnnesia, and neurasthenia, together with angular stomatitis, wasting, increased reflexes, clonus, positive Babinski sign, and peripheral neuropathy. Mild cases may be depressed, apathetic and even thought disordered. Frank psychosis may occur in severe cases. The application of epidemiological principles to the cause and treatment of pellagra provided a convincing demonstration of the public-health approach to mental illness. There is also an acute form of pellagra with delirium, rigidity and no rash.

Huntington's disease²⁸⁶⁶ (HD; O'Shea, 1997, 2003; O'Shea & Falvey, 1991)

This is inherited as a single dominant genetic trait (IT-15 gene at chromosome 4p 16.3; Gusella et al, 1983) and has a mean age of onset of 40 years (range 2-90²⁸⁶⁷) and affects the sexes equally. The actual gene was discovered by MacDonald and co-workers. (Huntington's Disease Collaborative Research Group, 1993) It may have a low genetic mutation rate²⁸⁶⁸; it is thought that an unaffected father has an unstable CAG repeat sequence (cytosine-adenine-guanine) that undergoes expansion. People with HD express a 350 kDa huntingtin²⁸⁶⁹ protein containing the polyglutamine sequence translated from the (CAG)_n repeat. It has been suggested that mutant huntingtin protein may open excess channels in mitochondrial membranes with resultant loss of calcium leading to reduction in the electrical gradients needed to drive ATP synthesis. In a worm model, the length of the mutant polyglutamate repeat and the expression of proteins in the insulin-signalling pathway (that regulates life span) determine cellular toxicity of mutant huntingtin. (Morley et al, 2002) In animals, damage to mitochondria from 3-nitropropionic acid leads to a Huntington-like disorder; excitotoxic effects of NMDA may be an important additional factor in this model. (Perez-De la Cruz & Santamaria, 2007)

The earlier the onset of HD in the offspring of an affected father the greater the enlargement of the trinucleotide repeat sequence (CAG trinucleotide expansion – longest in juvenile cases) in the abnormal gene. There is degeneration of cells in the caudate nucleus²⁸⁷⁰, putamen and cerebral cortex.

Head of caudate indenting ventricle (coronal section)

The number of neurones in the striatum are diminished, especially the small to medium-sized spiny neurones. The spiny neurones are relatively spared. Changes in the dendrites of spiny neurones are more extensive in the caudate than in the putamen. Neuronal intranuclear inclusions containing huntingtin and ubiquitin develop in humans and transgenic mouse models of HD. (Maat-Schieman et al, 2007) GABA deficiency with a relative excess of dopamine has been confirmed. Enkephalin deficiency is also reported. The EEG shows changes only late in the course of HD. The clinical features depend to some extent on the age of onset: young adults – rigidity (*Westphal variant*), middle years – chorea, and old age – cerebellar signs. Features include personality problems, schizophrenia-like psychosis, depression²⁸⁷¹, suicide (3-20 times the rate of the population at large), chorea, facial grimacing, dysarthria, often an explosive speech, a shuffling or dancing gait, cessation of abnormal movements in sleep, weight loss despite a good appetite,

Hartnup's disease (inborn failure to absorb tryptophan and urinary tryptophan loss), isoniazid treatment (B6 deficiency), and phaeochromocytoma and carcinoid syndrome (tryptophan is used to form amines instead of nicotinamide in the latter two disorders).

²⁸⁶⁵ Backs of the hands and neck (Casal's necklace) but also skin around anus and vulva.

²⁸⁶⁶ HD was described by George Sumner Huntington (1851-1916) of Long Island in 1872, although John Elliotson of London (1791-1868) may have predated him. (Elliotson, 1832/3) It was previously known as 'the magrums'.

²⁸⁶⁷ Massive expansion of the triplet repeat can cause the disorder to manifest in infancy. (Seneca et al, 2004)

²⁸⁶⁸ The exact rate varies with different authors, from rare to 10%.

²⁸⁶⁹ Huntingtin is found in all human and mammalian cells, with highest concentrations in brain and testis. It appears to have excitotoxic potential.

²⁸⁷⁰ CT shows atrophy of the caudate head. Resultant dilatation of lateral ventricles gives a 'butterfly' appearance.

²⁸⁷¹ About 3 in 1,000 people diagnosed with major depression were reported to have CAG trinucleotide expansion. (Perlis et al, 2010)

and dementia. Authors differ in their findings of psychiatric problems among close relatives of Huntington patients, interpreting their results as indicating heredity or shared environment (or both) accordingly. The so-called 'milkmaids sign' is a method of exaggerating the chorea by grasping the examiner's fingers (and squeezing them) in the same way as one tests for power.²⁸⁷² The chorea may also be exaggerated by getting the patient to stretch out his hands in front of him. Memory disturbance is only moderate. Attention, problem-solving, and arithmetical skills are more prominently affected. (Goldstein *et al.*, 2002) The patients is apathetic and distractible and judgement is often poor. The patient often remains aware of intellectual dysfunction. Common complaints are of being confused, slowed up, and difficulties with remembering. Language is preserved. Focal cortical deficits are absent. Treatment is symptomatic. Antipsychotic drugs and tetrabenazine may decrease chorea but should only be used if really necessary because of unwanted side-effects. Injection of foetal striatal cells into the caudate nucleus and putamen has led to improvement in some cases. However, numbers were small and follow up was short. Excessive activation of glutamate-gated ion channels kills neurones via oxidative stress and may have a role in the pathogenesis of HD (*cf.* above), and α -tocopherol²⁸⁷³ may have a protective role in reducing early motor decline. Coenzyme Q10, effective in transgenic mouse HD, is being tested. (Walker, 2007) The differential diagnosis is mainly from tardive dyskinesia and AD.

Frontotemporal dementias (FTD)²⁸⁷⁴

According to Snowden *et al.* (2002) FTD may account for up to one fifth of cases of presenile dementia cases. Farrell (2007) gives the prevalence of FTD as 15/10,000, second after AD as a cause of *presenile* degenerative dementia. The frontal and temporal lobes are principally involved. There may be a positive family history in up to half of these cases. The microtubule-associated protein tau (MAPT) gene on chromosome 17q21 may have a role in some (but not all) familial cases of frontotemporal dementia²⁸⁷⁵. FTD can be divided into FTD-tau and FTD-U, clinically similar but pathologically different. In FTD-tau there is abnormal hyperphosphorylation of tau with widespread tau deposition in neurones; FTD-U shows widespread ubiquitin immunopositivity with lentiform neuronal nuclear inclusions. (Farrell, 2007) Null mutations²⁸⁷⁶ causing reduced transcription of progranulin²⁸⁷⁷ may be responsible for some cases of FTD. Defective serotonergic activity is commonly reported in FTD but the cholinergic system is spared. The EEG is classically normal in FTD and seizures are rare²⁸⁷⁸. HMPAO-SPECT may demonstrate diminished blood flow or metabolic activity in the anterior part of the brain despite relatively normal CT or MRI scans.

There are pronounced changes in affect and personal and social conduct: 'The salient clinical characteristic is a profound alteration in character and social conduct, occurring in the context of relative preservation of instrumental functions of perception, spatial skills, praxis and memory'. (Snowden *et al.*, 2002)²⁸⁷⁹ The patient appears indifferent. Both FTD and AD are associated with executive dysfunction and confabulation, confabulation being more common in FTD. Loss of function in the left anterior temporal lobe in people with frontotemporal dementia may increase artistic and musical skills! Motor problems may appear long before dementia. Weight gain due to overeating gives way to weight loss due to apathy. Dysphagia is common. Dysautonomia may lead to hypotension, cold extremities and other problems. Death may be sudden either for unknown reasons or because of autonomic dysfunction or (due to hyperorality) choking. Young people may be diagnosed as having 'schizophrenia' or 'schizoaffective disorder' years before a diagnosis of FTD is made. (Velakoulis *et al.*, 2009)

²⁸⁷² The patient's fingers move as if mimicking what one does when milking cattle.

²⁸⁷³ This (vitamin E) reduces oxyradical-induced membrane damage.

²⁸⁷⁴ Baldwin (1993) argued that there are a group of lobar or localised dementias that may be more common than is generally recognised and that are not due to other causes, such as AD, Pick's disease (others, such as Dermaut & Van Broeckhoven [2002] include Pick's disease among the frontotemporal dementias which makes epidemiological interpretation difficult), or CJD. Hodges (2001) states that there are 3 distinct types of FTD: frontal variant FTD, semantic dementia, and progressive non-fluent aphasia (primary progressive aphasia).

²⁸⁷⁵ The mutations alter binding of microtubules to tau or lead to production of one isoform of tau rather than another. There are 6 known tau isoforms.

²⁸⁷⁶ Stop mutations and intronic mutations in splice donor sites and in the initiation codon.

²⁸⁷⁷ The progranulin gene is 1.7 Mb from the tau gene. Progranulin is involved in development, repair, inflammation (it is increased in activated microglia in AD and a number of other neurodegenerative disorders), and tumour formation.

²⁸⁷⁸ qEEG may show differences between AD and FTD and some chromosome 17 mutations may lead to early seizures.

²⁸⁷⁹ If the picture is one of loss of executive functions and problems with speech and memory is minimally affected then it is likely that the frontal lobe is mainly affected.

*PEMA syndrome*Palilalia²⁸⁸⁰

Echolalia

Mutism (late)

Amimia²⁸⁸¹

Typical of FTD

Rare in AD

*Other associations with FTD*Amyotrophic lateral sclerosis (ALS)²⁸⁸²

Progressive supranuclear palsy

Parkinsonism (PD)²⁸⁸³Dementia due to fragile X-associated tremor/ataxia syndrome (FXTAS)²⁸⁸⁴Cortico-basal ganglionic degeneration²⁸⁸⁵

Pasquier ea (2003) suggest trying trazodone for behavioural disturbance. Cholinesterase inhibitors may worsen behaviour. There is a suggestion that FTD is associated with hypersensitivity to antipsychotic drugs.(Pasquier ea, 2008, p. 469)

Pick's disease²⁸⁸⁶

This uncommon disorder usually manifests around 50–60 years of age. It is characterised by bands of 60 and 64 kDa phosphorylated tau. Gray and Cummings (1999) suggest that Pick's disease accounts for about one-fifth of cases of frontal lobe dementias. An incompletely penetrant autosomal dominant inheritance has been suggested. Two women are affected for every man. A majority will die within 4 to 6 years. A Pick's brain may be as light as 1,000 gm. Atrophic changes occur chiefly in the frontal and temporal lobes²⁸⁸⁷. The gyri show a characteristic brownish 'knife blade (or knife edge) atrophy'²⁸⁸⁸. Gliosis occurs in the white matter under cortical grey matter. Cell loss occurs and other cells may be ballooned. Pick bodies are within neurones and can displace the nucleus. Symptoms vary but include personality change (emotional blunting, egocentricity, mild euphoria, and fleeting anger), aphasia, echolalia, palilalia, perseveration, mutism and incontinence. Memory loss is relatively late. Catastrophic reactions to failure are absent. Kluver-Bucy elements (hypersexuality, placidity, and hyperorality) are not uncommon. Patients can find their way about, dress, cook (although repetitiously) and sew (with reduced dexterity). Wasting is less marked than in AD. Many cases are diagnosed at postmortem examination although CT, MRI and brain biopsies have increased the numbers diagnosed during life. In a Minnesota autopsy series (Heston and Mastri, 1982) Pick's disease accounted for about 5% of cases regarded as progressive dementia in life, and AD accounted for about 70%. Differences in cholinergic markers and somatostatin, which distinguish AD, are not present in Pick's disease.

Reflecting the confusion surrounding nosology of the dementias, Foster (2003, p. 1050) states that Pick's disease is not hereditary and that previously reported cases of familial Pick's do not have Pick bodies and are due to a tau mutation, and should be classified as frontotemporal dementia with Parkinsonism linked to chromosome 17.

²⁸⁸⁰ Stereotypy of speech: repeating one's own words.

²⁸⁸¹ Inability to express oneself by using signs or gestures.

²⁸⁸² The FTD-ALS and FTD-PD were linked to the tau locus on chromosome 17.(see *Wilhelmsen- [Tim] Lynch syndrome* [of Dublin]: Lynch ea, 1994; Wilhelmsen ea, 1994)

²⁸⁸³ Rigidity is very common. Hemiparesis may occur with asymmetrical cases.

²⁸⁸⁴ **FXTAS:** Grandfathers of cases of fragile X syndrome have frontal, subcortical, and motor manifestations: executive dysfunction, psychomotor slowing, amnesia, tremor, ataxia, and rigidity. Cortical and cerebellar atrophy are generalised. There is increased signal intensity in the middle cerebellar peduncles on neuroimaging. The FMR1 gene (Xq27.3) is altered. This condition resembles Parkinson's disease plus dementia. Cognition and neurological status progressively deteriorate.(Jacquemont ea, 2003)

²⁸⁸⁵ Loss of neurones in basal ganglia and fronto-parietal cortex., with atrophy of latter on MRI. Intracellular accumulated tau protein.

²⁸⁸⁶ Described by Arnold Pick of Prague in 1892.

²⁸⁸⁷ Unlike parieto-temporal changes in AD.

²⁸⁸⁸ Ulegyria.

Progressive subcortical gliosis

Rare dementia described as 'Pick disease type II' by Neumann in 1949. Most cases start insidiously in their 40s or 50s. Age of onset is not affected whether cases are familial or sporadic and the sexes appear to be affected equally. Although it resembles Pick's it has a distinct neuropathology. Tau gene mutation has been reported. There is genetic linkage to 17q21-22. Progress: personality/emotional change; reduced judgement and insight; problematic social behaviour; delusions, paranoia, auditory/visual hallucinations, and depression - decline in memory and speech output and word-finding difficulties (some have verbal stereotypes, acholalia, or Kluver-Bucy syndrome) - late cases are densely demented, akinetic/mute, incontinent, dysphagic, and have extrapyramidal signs.

Primary progressive aphasia²⁸⁸⁹ (PPA)

PPA is the presenting picture in about one-tenth of dementias. There is often an initial word-finding difficulty (dysnomia) with relative (to AD) preservation of memory and non-verbal cognition. Typically, the case progresses from dysnomia to non-fluent aphasia with anomia. The disorder may progress extremely slowly. AD is often the end result. However, a severe form of motor neurone disease can also develop. An alternative end point is corticobasilar degeneration. Alien hand syndrome has been reported, although this has been disputed²⁸⁹⁰. Atrophy predominates in the left temporal lobe. SPECT reveals greatly reduced tracer uptake in left frontal, temporal and parietal areas.

Semantic dementia (temporal variant of FTD)

This is a very rare condition. As a result of bilateral atrophy of middle and inferior temporal gyri²⁸⁹¹, these patients have fluent speech with semantic errors and poor comprehension and naming²⁸⁹². There is associative agnosia with impaired identification of sounds, odours, place, objects, etc. The patient's interests narrow, often becoming extremely focused on one activity. There may be loss of awareness of danger. Interestingly, and unlike AD, older memories may be affected more than newer ones²⁸⁹³. SPECT shows reduced bilateral (often left more than right) tracer uptake in the temporal region.

Creutzfeldt-Jakob disease (CJD)

Creutzfeldt-Jakob²⁸⁹⁴ disease is a rare condition that ends fatally within two years, with most cases dying well before a year is past. (O'Shea, 2001a,b) Treatment is non-specific. The incidence of CJD is about 0.5 cases/ million of the population/ year, with a higher incidence in parts of Slovakia and in Libyan-born Israelis.²⁸⁹⁵ The latter high-risk groups might inherit the disorder rather than become infected through their diet. Contact between cases is most unlikely.

Transmissible spongiform encephalopathies (Puoti et al, 1999)

Heterogeneous group of animal and human conditions

Neurodegenerative

Cellular prion²⁸⁹⁶ protein converted into disease-specific species

These altered isoforms account for neuropathology and transmissibility

²⁸⁸⁹ Pure progressive aphemia, progressive aphasia sans dementia, progressive non-fluent aphasia. Described by Mesulam in 1982. (Mesulam, 2003)

²⁸⁹⁰ Simple grasping movements are undisputed.

²⁸⁹¹ Semantic dementia is associated with involvement of the **left** temporal lobe; dysfunction of the right temporal lobe is associated with prosopagnosia.

²⁸⁹² Patient may give a broad superordinate response, e.g. 'clothes' when shown a hat.

²⁸⁹³ This may be due to relative hippocampal sparing.

²⁸⁹⁴ This is sometimes written as Jacob. Hans-Gerhard Creutzfeldt and Alfons Jakob described this condition independently of one another.

²⁸⁹⁵ A total of 23 cases of CJD in all its forms were reported in *Ireland* during the period 1996-September 2002. Sporadic cases reached a high of 6 in 1998. There was one case only of variant CJD (vCJD), in 1999, and one case of iatrogenic CJD, in 2001. Included in the total is one case of fatal familial insomnia, reported in 1997. Between 1999 and 2004 there were a total of 19 cases of definite sporadic CJD (plus 6 possible cases), 2 cases of vCJD, and the one cases of iatrogenic CJD mentioned above. Incidence rates of all types of CJD varied during that period from 0.5 (1999) to 2.01 (2004) per million. The incidence of CJD in the *EU* in 1994 varied from 0.53/million person years (mpy) in Italy to 1.04/mpy in the Netherlands, with the UK figure being 0.93/mpy.

²⁸⁹⁶ Carleton Gajdusek (1923-2008) was awarded Nobel Prize in 1976 for discovering what he called a slow virus, now known as a prion.

There is no particular association between any occupation and CJD, including farming, and no proven association with the national incidence of BSE. However, the rarity of CJD and the long incubation period of 2 to 30 years or more may put the peak incidence of sporadic disease in the 70-79-year-old age group and so be easily missed. The mean age of onset is 65 years for the sporadic type and 29 years for the variant type, with mean duration of illness being 4 and 14 months respectively.

Prion²⁸⁹⁷ protein is a membrane glycoprotein present in most organs, including neurones. The human PrP gene²⁸⁹⁸ (PRNP) is a single-copy gene located on the short arm of chromosome 20²⁸⁹⁹. Prion proteins move cyclically from the cell membrane into the cytoplasm where they are digested by lysosomal enzymes. Pathological prion proteins also move into the cell but resist degradation, instead aggregating to form prions. Normal cellular prion protein is present chiefly in α -helical conformation. Pathological prion protein is mainly in a β -sheet conformation.

There are inherited²⁹⁰⁰, iatrogenic²⁹⁰¹, and sporadic²⁹⁰² forms.

Accumulation of this abnormal protein is central to the pathogenesis of the spongiform encephalopathies. Small virus-like particles were observed in hamster brains deliberately infected with scrapie and these can be isolated from CJD brains and identified electronmicroscopically. Histology of CJD shows astrocytosis, loss of neurones, and a spongiform²⁹⁰³ encephalopathy. Cortex, deep nuclei and cerebellum are involved. Amyloid plaques are seen in only 5% of cases. A role for apolipoprotein E has been suggested.

Related disorders: The 'subacute spongiform encephalopathies' are possibly caused by the same or related prions. In animals they cause scrapie²⁹⁰⁴, spongiform encephalopathy in cats, chronic wasting disease in elk and deer, transmissible encephalopathy in mink, bovine spongiform encephalopathy (BSE), and many others. In man they cause kuru²⁹⁰⁵, Gerstmann-Straussler-Scheinker²⁹⁰⁶ syndrome (GSS) and CJD. In all of these conditions one can find fine meshed vacuolation, astrocytic proliferation, fibrillary gliosis, delayed loss of neurones, minimal demyelination, and a propensity to attack the cerebral cortex, basal ganglia and cerebellum. Amyloid plaques are also found. The scrapie agent is sub-microscopic. GSS has a more insidious course than CJD; there is less vacuolation and many amyloid plaques.

Virology: CJD agent, a 'slow virus'²⁹⁰⁷, contains only protein, i.e. a prion. One theory is that the host's cell already contains the DNA sequence necessary to produce a peptide that in turn infects the host. Prions are thought to be about the same size as viroids²⁹⁰⁸.

Transmission: Spongiform encephalopathies can be experimentally transmitted to a range of species not showing a natural tendency to develop these conditions. BSE (mad cow disease) sets cattle wild, mad and falling. BSE is thought to be due to feeding cattle with meat and bonemeal derived from sheep offal, with transmission of the scrapie agent. (Alternative theories include transmission of human prion to cattle that were then imported from India, origin other species, iatrogenic, PRNP gene mutation²⁹⁰⁹, various host factors, organophosphate pesticide exposure, high manganese or low copper levels in soil, and *Acinetobacter* bacteria in cattle feed: Colchester & Colchester, 2005.) This practice has been outlawed. It

²⁸⁹⁷ 'Subvirus' or proteinaceous infectious agent (term coined by Stanley Ben Prusiner of California, b. 1942, neurologist and biochemist, Nobel Prize in Medicine 1997) – contains no genetic material. The abbreviations employed in the literature for various forms of prion protein are at least confusing: PrP^c for normal prion protein; PrP^{sc} for all pathological forms of the protein, sc standing for scrapie; ΔPrP for inherited cases; and PrP^{cjd} for sporadic cases.

²⁸⁹⁸ Protease-resistant prion protein.

²⁸⁹⁹ PrP means protease-resistant prion protein.

²⁹⁰⁰ Due to one of many mutations in the PRNP gene: 5-15% of cases.

²⁹⁰¹ See later – foreign prion protein might act as a template that causes conformational change in normal prion protein from α -helix to β -sheet: rarest form.

²⁹⁰² ? age-related spontaneous mutation or some earlier environmental event: 85% of cases.

²⁹⁰³ Vacuolation of neuropil. The vacuoles consist of swollen axons and dendrites.

²⁹⁰⁴ Affecting sheep and goats; sheep 'scrapes' its wool against wooden fences.

²⁹⁰⁵ 'Trembling disease' of Fore Tribe, New Guinea. Kuru plaques have surrounding spikes.

²⁹⁰⁶ **Gerstmann-Straussler-Scheinker syndrome:** Rare (1-10/million population) familial disorder affecting those with a specific autosomal dominant defect in chromosome 20, i.e. mutations in PRNP gene. It usually presents in fourth/fifth decade with progressive ataxia, dysarthria, extrapyramidal signs, and dementia and lasts about 7 years. Pathologically it looks like a combination of AD (except that plaques mainly contain PrP) and spongiform changes with gliosis.

²⁹⁰⁷ A very long incubation period and a profound resistance to inactivating agents. In fact, prions are not viruses.

²⁹⁰⁸ Smallest life form: naked RNA with no protein coat; cause plant diseases.

²⁹⁰⁹ PRNP polymorphisms may act as susceptibility or protective factors for human prion diseases such as CJD and kuru. (Mead et al, 2009)

has been postulated that mink may become affected in the same way. Domestic cats have been infected with BSE from eating cat food that use cattle offal.

CJD transmission may occur via injected brain tissue²⁹¹⁰, infected in-dwelling cerebral electrodes, pituitary extracts, (cadaveric) human growth hormone²⁹¹¹, and corneal or tympanic transplants, and, possibly, wild animals. Up to 15% of cases have a family history of the condition and a dominant inheritance pattern. It is possible that an uncommon prion genotype confers susceptibility to infection with exogenous prion, although the nature of the prion protein-gene interaction is unknown.

Kuru may have been spread by cuts and by mucous membranes during ritual ceremonies with affected corpses²⁹¹². Prion diseases can be familial or sporadic. Familial spongiform encephalopathy is associated with mutations in the normal (harmless) prion protein (PrPc) gene, the latter coding for a normal cell surface protein²⁹¹³. This protein accumulates in CJD and GSS and is deposited in plaques as amyloid (prion amyloid is different to Alzheimer amyloid). In prion disease it is this protein that becomes resistant, as PrPsc (scrapie prion protein), to proteolysis and is itself infectious.

Fatal familial insomnia (FFI) is a rare, untreatable prion-induced spongiform encephalopathy²⁹¹⁴ characterised by progressive insomnia, dysautonomia, and motor signs. Chronic hypertension without the expected fall in blood pressure during sleep, elevated cortisol and catecholamine levels, and disturbed rhythms of melatonin, prolactin, and somatotrophin may be found. FFI is a PRNP mutation disorder (chromosome 20): **D178N mutation** causes the disorder when codon 129 codes for **methionine**. When the same codon codes for **valine** the result is CJD. Patients usually die within a year. The thalamic nuclei undergo atrophy. Protease-resistant PrP can be demonstrated, albeit weakly, by immunoblotting.

Clinical features: CJD typically comes on during the sixth or seventh decades with memory loss, or, less commonly with changes in behaviour or higher cortical deficits such as dysphasia or dyslexia. Over several weeks there follow frank dementia, visual (cortical blindness) or co-ordination problems, rigidity and involuntary movements, particularly myoclonic jerks, the latter often occurring in synchrony with periodic electroencephalogram (EEG) periodic sharp and slow wave complexes (on a low voltage background). Signs of pyramidal and cerebellar damage may be elicited. Death usually occurs within 6 months.

Knight (1989) described three types of clinical picture in CJD: subacute lasting less than 6 months²⁹¹⁵; chronic form²⁹¹⁶; and an amyotrophic type.²⁹¹⁷

Phlebotomists should wear gloves when taking blood from demented patients as a precautionary measure. All suspected live cases should be reported to the Department of Neurology at St Vincent's Hospital, Elm Park, and all deceased suspected cases must have a post mortem examination at Beaumont Hospital.

Clinical diagnosis of CJD is usually reliable and accurate in the presence of dementia, myoclonus and periodic triphasic EEG discharges at 1-2 Hz, and the absence of both the latter two parts of the triad count against a diagnosis of sporadic CJD. However, the same EEG changes are found in hepatic encephalopathy, lithium intoxication, uraemia, and some rarer disorders (e.g. SSPE). Also, these triphasic EEG discharges are probably (sources differ) not found in vCJD.²⁹¹⁸ Lithium intoxication also causes myoclonus, but this and the EEG changes are reversible. Otto et al reported raised serum S100, a brain specific protein mainly found in glia that may be a marker for activated astroglia, in CJD. These levels were higher than those found in other diseases and showed 77.8% sensitivity and 81.1% specificity for CJD. S100 levels rise in serum after head trauma but decline quickly due to renal elimination. (Otto et al, 1998) PrP immunohistochemistry, using appropriate pre-treatments, will be positive in the great majority of cases.

²⁹¹⁰ E.g. human brain biopsy homogenate put into monkey brains.

²⁹¹¹ Used in USA for dwarfism from 1959 to 1985. Recombinant HGH used now instead.

²⁹¹² Cannibalism began in 1910, followed some time later by the earliest cases of kuru. (MacCormack, 2004)

²⁹¹³ **PrPc prion protein**, which contains many alpha-helices, is plentiful in nerve cells and seems to have a number of functions (neuroprotective, copper metabolism, and oxidative balance). PrPc may change to PrPsc, a beta-pleated peptide like the Aβ of AD, tends to form insoluble aggregates. Beta-pleated PrPsc is almost protease resistant and *can promote further PrPsc formation from PrPc*. It may be that when prion protein moves from the endoplasmic reticulum to cell membrane or cytosol that it is capable of damaging nerve cells. (Aguzzi & Polymenidou, 2004)

²⁹¹⁴ Mild spongiform changes in some cases.

²⁹¹⁵ Especially dementia, mutism, akinesia, hypertonia, myoclonus, normal CT scan, increased protein in cerebrospinal fluid (CSF) or a normal CSF, and periodic discharges in the EEG - non-specific slowing goes on to generalised periodic biphasic or triphasic complexes.

²⁹¹⁶ 8% of cases, usually lasts more than 2 years, similar to subacute form but lasts longer.

²⁹¹⁷ 5% of cases, usually lasts a few years, similar to a combination of motor neurone disease and dementia.

²⁹¹⁸ Triphasic waves are found (eventually) in most sporadic cases, in some inherited and iatrogenic cases.

Protease-resistant PrP, found in all known prion diseases, can be shown by immunoblotting of brain homogenates. Plasminogen binds to the pathological prion protein whilst ignoring its normal counterpart. The currently recommended approach to diagnosing sporadic CJD in the laboratory is to look for the 14-3-3 protein in the CSF by Western blot immunodetection. (Will ea, 2000) This is found in a majority of cases. It may also be present in vCJD and in about 10% of cases of MS (Martinez-Yelamos ea, 2001) and a few cases of fatal familial insomnia but is not found in Gerstmann-Straussler-Scheinker syndrome. False positives can occur with recent CVA, herpes simplex encephalitis, and paraneoplastic cerebellar degeneration and limbic encephalitis.

MRI may show 'cortical ribboning' on diffusion-weighted imaging. (Poser ea, 1999)

*Variant CJD*²⁹¹⁹ (vCJD): Will ea (1996) reported a variant syndrome in young British adults and adolescents that many have speculated might be due to eating beef.

vCJD

Starts with psychiatric and sensory symptoms

Neurological deficits, such as dementia and ataxia, are delayed

EEG is atypical

Patient exhibits anxiety, depression, behavioural problems, ataxia and dementia

The incidence of vCJD is higher in the north than in the south of Britain, (Cousens ea, 2001) with the largest cluster being in part of Leicestershire. (Dobson, 2001) The latter phenomenon may relate to a n outdated butchery practice that allowed infected brain tissue contact with meat.

First 14 cases of vCJD in UK (Zeidler ea, 1997a)

10 examined when alive

8 of 14 were female

Mean onset at 29 years (range: 16-48)

Median duration of 14 months (range: 9-35)

Early psychiatric symptoms in all, especially depression

8 had early, persistent, often painful sensory symptoms

All had neurological signs, including ataxia and involuntary movements e.g. chorea and myoclonus

Most had terminal akinetic mutism

EEG mostly abnormal but absence of CJD periodic complexes

CT normal or non-specifically abnormal

2 cases had high thalamic MRI signal

Diagnosis was neuropathological

Psychiatric symptoms in vCJD (Zeidler ea, 1997b)

Common and include:

Depression (main diagnosis)

First rank symptoms (minority)

Transient delusions

Auditory or visual hallucinations

Large aggregates of prion protein are seen in cerebellum and basal ganglia. The hallmark on brain biopsy is the presence of dense eosinophilic amyloid plaques, staining positive with anti-PrP antibody, with a pale periphery surrounded by a zone of spongiform change. These are similar to lesions found in animal brain after intracerebral inoculation with BSE cattle brain homogenate. When vCJD was transmitted to mice they

²⁹¹⁹ **Will-Ironside syndrome** or **(new) variant CJD**. Brown (2001) goes further and insists that BSE is the cause of vCJD, that scrapie from sheep caused BSE in bovines by crossing the species barrier, and that changes in rendering of livestock carcasses allowed infectivity to survive and contaminate meat and bone meal in livestock feed, amplifying infection to epidemic proportions. The same author holds that the export of contaminated meat and bone meal and live cattle incubating BSE spread the disease outside Britain; and that BSE caused vCJD through adulteration of cooked meat products with mechanically recovered meat contaminated by compressed spinal cord and paraspinal ganglia.

showed BSE-like change. vCJD may be diagnosed by tonsil biopsy²⁹²⁰ but brain biopsy remains mandatory in order to outrule treatable disorders like vasculitis or Whipple's disease. Zeidler *et al* (2000) reported bilateral increased pulvinar (posterior thalamus) signal on T2-weighted MRI – the 'pulvinar sign'²⁹²¹ to have 78% sensitivity and 100% specificity for vCJD. The specificity of the 'pulvinar sign' is not as strong as this report suggests, although it is a welcome addition to invasive tonsil biopsy. FLAIR sequences may reveal the 'hockey-stick sign' (hyperintense pulvinar and dorsomedial thalamic nuclei). (Zeidler *et al*, 2000) Other findings included medial thalamic and periaqueductal grey matter high signal, and a notable absence of cerebral atrophy.

As far as host susceptibility to vCJD is concerned, all cases have the same normal allelic variant (MM) at codon 129 of the gene for cellular prion protein, (Will *et al*, 2000) i.e. all patients with vCJD reported so far (and most cases with sporadic CJD) are homozygous for amino acid methionine at position 129, whilst heterozygosity at this position appears protective.²⁹²² Because 38% of the UK population carry the high risk amino acid methionine 129 and since so few people seem to develop cCJD, other factors must be involved, e.g. a lower incidence of HLA DQ7 was thought to confer susceptibility but replication studies failed to confirm this. HLA molecules present antigenic peptides to the immune system.

The current method of diagnosis of vCJD rests on tonsil biopsy. Zanusso *et al* (2003) have found PrP^{sc} in olfactory cilia and the central olfactory pathway, but not in respiratory mucosa, in deceased cases of sporadic CJD, which may offer a new route for biopsy. The future may see the availability of a test using erythroid-differentiation-related factor (EDRF) which starts to fall early in the disease and falls further with disease progression. EDRF and prion protein co-localise and EDRF transcripts are easily measured in blood by northern blotting. Selective affinity resins are being developed to remove endogenous transmissible spongiform encephalopathies present in blood. (Gregori *et al*, 2006; Turner, 2006)

In conclusion, CJD has rapidly changed from being seen as a rare, esoteric disorder to occupying centre stage in medical thinking. This elevation was caused by the BSE crisis initially and later by reports of both iatrogenic and variant forms of the disease.

Aspects of CJD

Hans-Gerhard Creutzfeldt (1885-1964) and Alfons Maria Jakob (1884-1931) described the condition in 1920 and 1921 respectively, the latter naming it 'spastic pseudosclerosis'.

1950s: extraction of hormones from cadaveric pituitary glands

1985: UK, US, and other countries halt distribution of growth hormone after 3 deaths.

1986: first cases of BSE.

1970s: CJD transmitted via corneal transplants, depth electrodes, and neurosurgical instruments.

1990: Feline spongiform encephalopathy cases in UK; ban on specified animal offal in pet food.

UK deaths secondary to use of cadaveric pituitary gland [growth hormone (GH) or gonadotrophins] (by then replaced by genetically engineered growth hormone).

1993: Kuru cases reported despite abandonment of cannibalism in 1950s.

Illegal surgical use of cadaveric materials in some countries is a potential source of CJD; athletes using human growth hormone may be at risk.

1995: vCJD in UK.

1997: CJD transmission via cadaveric dura mater grafts.

1997: controversial, preliminary evidence concerning CJD transmission via blood and blood products.

1998: 6 young adults treated with human GH receive compensation for distress of being at risk of CJD.

Suggestion that vCJD is due to changes in rendering process of sheep carcasses, causing scrapie in cattle, or to a novel strain of scrapie or BSE resistant to rendering?

1999: first case of vCJD in Republic of Ireland.

ROI: CJD a notifiable disease: Irish National CJD Surveillance Centre resides at St Vincent's (clinical – 01-8092643) and Beaumont (neuropathology – 01-2094412) Hospitals, Dublin²⁹²³.

2000: BSE transmission to rodents and sheep by blood; small number of UK children develop vCJD.

2001: UK government to use disposable tonsillectomy equipment, Ireland may follow.

2001: A case of iatrogenic CJD notified in Ireland.

2002: Male dies of vCJD in Canada; probably contracted in Britain.

2002 (May): 128 cases of vCJD in UK, France and Ireland.

2002: vCJD case diagnosed in Italy (see October *Lancet*).

²⁹²⁰ By demonstrating characteristic PrP immunostaining and PrP^{sc} on western blot. Tonsil biopsy allows early and pre-symptomatic diagnosis. (Wroe *et al*, 2006)

²⁹²¹ 'Pulvinar sign' – this is also found in, e.g., paraneoplastic limbic encephalitis and Wernicke-Korsakoff syndrome. This sign – bilateral thalamic hyperintensity in T2 proton-weighted images – is due to gliosis.

²⁹²² See Partenen (2003) for review.

²⁹²³ UK Surveillance Unit is based in Edinburgh, Scotland.

2003: Swiss scientists find abnormal prions in spleen and skeletal muscle in sporadic CJD.
 2003: UK patient dies of vCJD who may have acquired it from a blood transfusion: the donor gave the blood in 1996 and died of vCJD in 1999.
 2003: Ireland reported to have an incidence of 0.75 cases of CJD/million/year, not dissimilar to neighbouring European countries. 26 cases of CJD (incl. vCJD) were recorded in Ireland 1996-2003.
 2005: BSE reported in a goat in France in January.
 2006: Irish coroner remarks on two fatal and one living cases of vCJD with addresses within 5 miles of one another.
 2006: First Japanese case of vCJD in 50 year old man who was in UK in 1990 and showed mental symptoms from 2001, akinetic mutism in 2003, and died of pneumonia in 2004.
 2006: Findings from appendix (homozygous **valine** genotype in tissue that harboured prion proteins) raises the spectre that ongoing iatrogenic transmission may sustain the spread of vCJD.
 2006: Eleven cases of kuru identified from July 1996-June 2004, all in South Fore and born before cannibalism ceased.
 2008: Seven doctors and pharmacists on trial in France over death of at least 110 people who developed CJD after being given tainted human growth hormone in childhood²⁹²⁴.

(Idiopathic) Parkinson's disease²⁹²⁵

Lifetime risk for Parkinson's disease is around 1 in 50, increasing in the presence of affected relatives. DA-containing cell bodies in the *pars compacta* of the substantia nigra undergo degeneration. Hyaline material (Lewy bodies) is present in nigral cells. There is a reduction in neurone numbers in the locus coeruleus with loss of cortical noradrenaline occurring secondarily. Parkinson's disease with dementia is associated with greater atrophy of the hippocampus than is the case with Parkinson's disease without dementia; there is also less cortical atrophy than that found in AD; and there is cell loss in the nucleus basalis of Meynert. There is less cortical acetylcholine loss than in AD. Loss of raphe cells leads to 5-HT depletion, possibly explaining the excess of depression²⁹²⁶ and anxiety in these cases. Hentschel and Förstl (2008, p. 185) see Parkinson's disease and AD as extremes of a pathological spectrum with the Lewy body variant of AD occupying an intermediate position.

Parkinson's disease

↓ DA output from substantia nigra to globus pallidus – ↓ inhibitory action on subthalamic nucleus (STN) -
 ↑ activity of STN - ↑ cortical inhibition - bradykinesia²⁹²⁷

Cognitive impairment has been reported in from 20-40% (8-80%) of cases but most sufferers probably have some level cognitive impairment (bradyphrenia, impaired visuospatial ability, poor attention shifting, and executive problems). It may be that sufficient longevity will always be associated with dementia. (Aarsland et al, 2003) Dementia may be caused by a co-existing disorder, most often, AD²⁹²⁸, or by Lewy body degeneration in the nucleus basalis and cerebral cortex. Demented cases and non-demented cases show marked and modest cortical choline acetyltransferase deficiency respectively.

40% of cases are said to suffer from depression, although not all studies an excess of major depression over that found in age- and sex-matched physically disabled persons. There is a large element of anxiety and relatively little self-blame. Depression is more likely with reduced CSF 5-HIAA, a history of depression, or significant functional disability. Depression in Parkinson's disease may be due to involvement of frontal dopaminergic projections. PET studies suggest that reduced cerebral blood flow in the medial prefrontal cortex may be common to primary depression and depression in Parkinson's disease. The depression responds to antidepressant drugs²⁹²⁹ and ECT. ECT may also improve physical function in Parkinson's disease. Indeed, some patients benefit from maintenance ECT. (e.g. Shulman, 2003) Neuroleptics can

²⁹²⁴ Some donor cadavers had neurological, dementing, or infectious disorders and gland were pooled. (King, 2008)

²⁹²⁵ This was described by James Parkinson of Hoxton in London in 1817. Parkinson described a patient who made his servant walk ahead of him so that he could be stopped when his slow gait would suddenly accelerate! Famous patients with this disorder include Pope John Paul II, Kenneth Moore, Muhammad Ali, Michael J Fox, Dame Anna Neagle, Janet Reno, and AJP Taylor.

²⁹²⁶ As with clinical Parkinson's disease, depression is a frequent problem in community-dwelling elders with parkinsonism, even in the absence of functional disability. (Braam et al, 2009)

²⁹²⁷ Anticholinergic drugs reduce tremor and rigidity but do not reduce bradykinesia.

Freezing: The bradykinetic or akinetic patient may freeze on intentionally trying to move. Such patients may use 'sensory tricks' (e.g. listening to stirring music or stepping over a crack) to overcome this. Freezing should not be mistaken as being 'psychogenic'.

²⁹²⁸ If the dementing patient develops early cortical symptoms (e.g. dysphasia) co-existing AD is suggested.

²⁹²⁹ TCAs can cause significant side effects, and nortriptyline may be the first choice; SSRIs can cause EPS and, if combined with selegiline [L-deprenyl], a serotonin syndrome. Dietary precautions are required for higher (9 or more mg) but not lower (6 mg) doses of selegiline, a selective, irreversible MAO-B inhibitor.

unmask latent Parkinson's disease. Amoxapine should be avoided in depressed Parkinson's disease patients because of its DA blocking actions.

Akathisia may precede use of medication in patients with Parkinson's disease.

Visual hallucinations may occur in Parkinson's disease patients even before they receive any medication.

Patients may have insight into the nature of these experiences at first but most will eventually react to them as if they were true perceptions when the disease becomes more established. Opinion about their pathogenesis is divided between dopamine dysfunction within the visual system and disrupted circuitry subserving regulation of REM sleep. (Wilson & Nutt, 2008, p. 88) All drugs used to treat this disorder can cause (especially at night) visual hallucinations and worsen cognitive function. Greater Lewy body load and cell loss in the amygdala increases the likelihood of developing hallucinations on exposure to levodopa. (Harding et al., 2002)

There are a few reports of mania²⁹³⁰, most likely due to medications such as levodopa. Most patients tolerate levodopa for years without developing psychosis. Psychosis in Parkinson's disease²⁹³¹ should be managed by reviewing any possible aetiological role of medication and failing any success there one might try low dose quetiapine, sulpiride or risperidone²⁹³². Low dose clozapine has been shown to work. A BZD is often all that is necessary for brief psychotic episodes²⁹³³. Nortriptyline or clonazepam may be used for panic attacks.

Pathological gambling may be induced by dopamine agonist therapy. (Wong & Steiger, 2007) Hypersexual behaviour and compulsive shopping may also occur in such circumstances. Treatment-induced stereotypies ('punding'²⁹³⁴) may take up much of the patient's time, e.g. purposeless putting together and taking apart of machines.

Reduced striatal uptake of dopamine in 'sporadic' Parkinson's disease patients *and* their asymptomatic co-twins has been demonstrated with PET. (Piccini et al., 1999) Mutations of genes encoding for alpha-synuclein and parkin have been identified in familial cases. In fact, a number of genes (PARK-1, PARK-2, etc) have been reported to be associated with Parkinson's disease but they collectively account for only a small proportion of cases. Parkinson's disease may be associated with mutations in the gene encoding glucocerebrosidase²⁹³⁵. (Sidransky et al., 2009) The pesticide rotenone causes a Parkinsonian syndrome in rodents. MPTP (methyl-phenyl-tetrahydropyridine), which resembles paraquat, caused severe Parkinsonism in drug abusers. Familial fatal Parkinsonism is a rare condition, therapeutically unresponsive condition, presenting in the fifth decade with severe depression and with death from respiratory failure 4-6 years later. Fahr's disease²⁹³⁶ (familial idiopathic calcification of the basal ganglia) is an uncommon disorder with progressive dementia, convulsions, and rigidity and sometimes a schizophrenia-like illness and Parkinsonism; cases may be sporadic or autosomal dominant and in one family linkage was found to a locus on chromosome 14.

Thioridazine was a favourite neuroleptic in Parkinson's disease when one was required, but this neuroleptic has become unpopular because of associated QTc concerns. Clozapine and quetiapine are preferred today.

Never combine MAOIs with L-DOPA.

Glabella tap test (Myerson's sign): The examiner taps the glabella just above the nasal root from behind the patient and counts the number of blinks. More than 3 blinks are the usual criterion for 'abnormality'. The sign is more often positive in Parkinson's disease than in drug-induced Parkinsonism. However it (> 3 blinks) can also be found in very anxious people and as a release phenomenon (primitive reflex) in association with dementia.

Surgery for Parkinson's disease may involve pallidotomy, thalamotomy, and thalamic stimulation. Lesions in ventral intermediate thalamic nucleus mainly relieves tremor. If the tremor is bilateral then thalamotomy

²⁹³⁰ A few patients increase the dose of their medication in order to induce euphoria.

²⁹³¹ Psychosis affects 7-14% of non-demented cases. Those with hallucinations tend to retain insight as in Charles Bonnet syndrome. (Carson et al., 2007, p. 343)

²⁹³² Doses in the range 0.75-1.5 mg/day risperidone were been recommended for dementia cases (Jeste et al. 2000) but there appears to be an increased risk of strokes.

²⁹³³ High-dose diazepam has been associated with Parkinsonism. (Kellett & Chadwick, 2004, p. 326)

²⁹³⁴ Punding was originally applied to the stereotypies found in association with chronic amphetamine abuse.

²⁹³⁵ Glucocerebrosidase deficiency causes Gaucher's disease. Sufferers from the latter disorder can develop Parkinsonism and their relatives (who may be heterozygotes) have an increased risk for Parkinson's disease.

²⁹³⁶ Fahr disease is not the same as Fahr syndrome. The latter refers to basal ganglia calcification secondary to hormonal (e.g. hypoparathyroidism) or metabolic disorders (e.g. disorders of phosphate-calcium metabolism).

must be bilateral. Bilateral thalamotomy may interfere with gait and speech. Pallidotomy reduces tremor, rigidity, and bradykinesia contralaterally. It also is effective for medication-related dyskinesia. Bilateral pallidotomy may cause speech and cognitive problems. Brain stimulation, usually bilateral for better results, may also lead to slurring of speech. However, thalamic stimulation may occasionally yield dramatic improvements. Autologous adrenal medullary tissue transplantation has given less than hoped for results and may be complicated in the post-surgical period by psychosis, confusion and affective change. Fetal dopaminergic cell transplantation has excited ethical debate.

Acquired Immune Deficiency Syndrome (AIDS)

Of 33 million people living with HIV/AIDS worldwide in 2008²⁹³⁷, 67% live in Africa. Two million people succumbed to AIDS in 2007 and 24 million died from the disease during 1980-2007.(Bongaarts ea, 2010) HIV is involved in a titanic struggle in the body²⁹³⁸, eventually exhausting the immune system. CD4 T-helper lymphocytes are the preferred target of the HIV virus, the virus using the CD4 molecule as receptor²⁹³⁹. Viral reverse transcriptase is the intracellular catalyst for the conversion of viral RNA to DNA, the latter becoming incorporated into host chromosomes. Cellular activation leads to copying of this DNA leading on, with the assistance of protease, to HIV particles. HIV invades the CNS early on in the course of infection, entering via macrophages. These and microglia are mainly responsible for replication of HIV in the CNS. *HIV does enter CNS neurones*. It possibly causes neuronal damage via microglial neurotoxin production. It has been suggested that quinolinic acid, possibly derived from HIV-infected monocytes and a selective activator of NMDA receptors, may play a role in the development of AIDS dementia.(Duka, 2002)

The breakdown by type of case is shown in the table.²⁹⁴⁰ HIV/AIDS is not a notifiable disease in Ireland. There is not one laboratory responsible for collating confirmed results and the practice of using initials

²⁹³⁷ The figure for 1988 was 5 million.

²⁹³⁸ A mutation in the gene for the **Duffy antigen receptor chemokines** (DARC) occurs only in people of African descent. It prevents expression of DARC on red blood cells thereby eliminating the site where *Plasmodium vivax* attaches to the cell (useful in malarial areas) but it increases the risk of HIV infection by about 40%. Male **circumcision** has been said to reduce the risk of acquiring HIV (Siegfried ea, 2009) through vaginal intercourse (at least from women to men), although not all research agrees (Wawer ea, 2009) - the foreskin's (the latter acting to retain HIV-containing secretions) Langerhans cells are particularly vulnerable to HIV infection.(Roehr, 2007; Bailey ea, 2007; Gray ea, 2007; Katz & Wright, 2008) Unhygienic circumcision may increase risk of HIV in Africa (Moszynski, 2007) and surgical procedures are not popular.(Katz & Wright, 2008) It seems that **condom** use is still necessary after male circumcision if HIV spread is to be controlled.(Wawer ea, 2009)

²⁹³⁹ CD4 receptors are common in brain tissue. 80% of circulating lymphocytes are T cells (expressing CD antigens 1-5, 7 and 8) which mediate cellular immunity. The two main types are CD4+ helper cells and CD8+ suppressor cells. **HIV** contains 2 molecules of single-stranded RNA. Reverse transcriptase polymerase converts viral RNA into DNA. Protease is also present in the virus. The core protein (p24, surrounding the 'nucleus') level can be employed in monitoring the disease. Outside this is the matrix protein (p17). The outer envelope glycoprotein (p120) binds to molecules on the surface of CD4 cells - this interaction, together with the chemokine co-receptors CCR5 and CXCR4, is responsible for the entry of virus into the host cell. A transmembrane protein (gp41) is important for infectivity and cell fusion.

²⁹⁴⁰ Up to December 1993 there were 355,936 cases of AIDS in the USA and the American public health service spent more on AIDS research in 1992/3 than on heart disease.(Tanne, 1993) By the end of 1999 there were 113,167 cases of HIV, 299,944 cases of AIDS, and 430,441 cumulative deaths from AIDS in the USA.(Centers for Disease Control and Prevention, 1999) An estimated total of 42 million persons worldwide lived with HIV/AIDS up to the end of 2002 (e.g. 570,000 in Western Europe, 1.2 million in Eastern Europe/Central Asia, and 980,000 in North America) with the greatest concentration in Sub-Saharan Africa (29.4 million). As of December 2003, over a million people in the US were infected with HIV. The largest affected group were Blacks at 47% of the total. 45% of cases were MSM, followed by injecting drug users.(Roehr, 2005)

Of 941 HIV⁺ cases reported in Edinburgh up to September 1992, 55% were associated with injecting drug misuse. The number of HIV cases in the UK was 41,700 in 2001 and 49,500 in 2002, an increased proportion deriving the infection abroad; gay and bisexual men accounted for 80% of the new HIV cases in 2002 that were likely to have been acquired abroad; there was a parallel increase in gonorrhoea and syphilis in gay people; there was also an increase in HIV in the heterosexual population (147 in 1998 and 275 in 2002 were most likely acquired in the UK).(Reviewing the Focus: HIV and Other Sexually Transmitted Infections in the United Kingdom in 2002) Mathers ea (2008) estimated that almost 16 million worldwide inject drugs and that 3 million of these might be HIV positive. 124 cases of AIDS were reported in Ireland between 1982 and 1989, rising from 2 during the first year to 50 during the last year. The number of cases had risen to 207 by July 1991 (with 1,101 HIV-positive cases and 85 deaths). The rate of infection was noted to be rising most rapidly among heterosexuals in 1992. By the end of June 1998 there had been 647 cases of AIDS (> 40% in IV drug users, about a third of cases were homosexual/bisexual, and 12.5% were heterosexuals), almost 2,000 HIV-positive cases and 328 deaths. During the whole of 1998 and 1999 there were 136 and 151 HIV-positive cases and 3 and 41 new AIDS cases and 4 and 17 deaths respectively, the total number of AIDS cases reaching 691 by the end of 1999. Over 80% of those deaths in 1999 were in males and most deaths were in the 25-35 year age bracket. According to an annual Durex survey (Anonymous, 2000b) two-thirds of 17-20 year old in Ireland have had unprotected sex.

rather than names of patients on specimens may lead to confusion in totals of cases. The majority of affected children now survive into adulthood.(Hermoine Lyall, 2002)

HIV/AIDS statistics for Republic of Ireland (RoI)

Note: figures and classification vary with source.

(a) Numbers of patients with AIDS in the RoI up to 2005*

	Total to end 1991**	Up to 30/6/94 cases (deaths#)	1999 (‘HIV’)	2001*** (‘HIV’)	2004^ (‘HIV’)	2005 (‘HIV’)
Heterosexuals	24	45 (21)	59	82 (59.4%)	178	159
<u>Men having sex with men (MSM)</u>				32 (23.2%)		
<u>Homosexuals/bisexuals (H/B)</u>	94	136 (67)	40		62	
H/B plus IV drug abuse	7	8 (06)				
IV drug abusers	100	177 (86)	69	11 (8.0%)		
Haemophiliacs	20	28 (20)				
Transfusion recipient				1 (0.7%)		
Mothers-to-child					3	
Babies born to IV drug abusers	8	8 (06)				
Undetermined	5	5 (03)				
Mothers	?	1 (00)				
Children			23	5 (3.6%)		
Prisoners			13			
Undetermined				7 (5.1%)		

*Undoubtedly there is cross-infection between the classes of patients listed here, e.g. IV users to heterosexual partners. The first needlestick-related case in Ireland was reported in 1995. The first case of HIV from needlestick in Britain’s NHS was reported in 1984, and a small number of deaths have since occurred.(Anonymous, 2003c)

**Kelly, 1994. #51% mortality rate.

***Last half of 2001 only (Source: National Disease Surveillance Centre). This gives a total of 138 newly diagnosed HIV cases for the third and fourth quarters of 2001. However, elsewhere the same group gives a figure of 299 new cases, down 9 cases on the year 2000! 75% of new HIV cases in 2001 were 20-40 years of age. Two of the children were born to HIV mothers and the transfusion recipient received the transfusion abroad.

Up to 31/3/97 the number of HIV+ cases came to 1,753, the number of AIDS cases totalled 593, and 308 deaths were recorded.

^356 HIV positive cases in 2004, a decrease of 57 from 2003. There were 41 AIDS cases in 2004 (fell from about 75 in 1994 to a low about 11 in 2000, and rising thereafter to over 40 in 2004).(Source: CSO health statistics).

(b) HIV cases in RoI 2006 onwards*

2006 – 337 reported new diagnoses (RNDs)

2007 – 362²⁹⁴¹ RNDs**

2008 (first half) – 170 RNDs***; (all year) 405 RNDs****

*Cumulative total of reported HIV cases to end 2007 was 4,781

**Health Protection Surveillance Centre got no reports from 30% of clinicians dealing with newly diagnosed cases! 146, 75 and 54 of 362 cases were heterosexual contacts, homosexual contacts and drug-related respectively.

***Total number of HIV infected cases to 30.6.08 = 4,951. Probable route of transmission known for 127/170: 65% heterosexual (up from 53% for same period in 2007), 20% MSM, and 12% injected drug users.

****Cumulative total of reported HIV cases = 5,243; migrants figured prominently among heterosexual cases; there was an increase among MSM and among heterosexuals but a decline in HIV related to IV drug use (of 36 cases 25 were Irish); and 28 new AIDS cases and 3 deaths.

AIDS, due to HIV (human immuno-deficiency virus²⁹⁴²) infection and its complications, causes many psycho-neurological syndromes: delirium, dementia²⁹⁴³, depression²⁹⁴⁴, mania²⁹⁴⁵, paranoid psychoses,

²⁹⁴¹ 146 were acquired heterosexually, of which 87 were born in sub-Saharan Africa.

²⁹⁴² Mostly HIV-1, discovered in 1986. HIV-1 is related to the harmless simian immunodeficiency virus. HIV-2, related to the sooty mangabey monkey virus, causes some cases in West Africa. The human disease may have come from western equatorial Africa during the 1930s. It may have crossed the species barrier because of eating monkeys or being injured by them.

²⁹⁴³ A subcortical dementia; the term AIDS-dementia complex (a ‘complex’ of dementia, motor, and behavioural aspects) has been replaced by AIDS- or HIV-1 associated dementia complex, and ‘AIDS-related complex’ or ARC is now called ‘symptomatic HIV infection’. A milder form of this disorder is called mild cognitive/motor disorder (MCMD) and is characterised by easy forgetting, problems with word-finding and general intellectual slowness. Not all cases of MCMD develop HIV-1 associated dementia complex.

²⁹⁴⁴ ECT has been used in AIDS patients for major depression and for the uncommon HIV-associated stupor.(Foster & Everall, 2007, p. 487) Depression has been blamed on abacavir, nevirapine (also causes vivid dreams), efavirenz (also associated with PTSD), and aciclovir. Lamivudine and indinavir can also disturb mood.(Foster & Everall, 2007, p. 489)

²⁹⁴⁵ Mania may be due to pre-existing bipolar disorder, organic disorders, or treatment (zidovudine, didanosine, and efavirenz). The term ‘AIDS mania’ refers to mania in late-stage HIV infection which is not thought to be related to bipolar disorder: patients are

schizophrenia-like psychosis, and (on hearing that one has AIDS or is seropositive) bereavement/adjustment reactions – in fact, adjustment disorder occurs in perhaps 90% of cases. Psychosis has occurred with abacavir, efavirenz and nevirapine. High suicide rates have been reported in HIV-infected patients, although rates may have fallen since the introduction of HAART (highly active antiretroviral therapy).²⁹⁴⁶ If HAART is commenced before onset of significant immunosuppression then the likelihood of progression to AIDS is much diminished. Past history of drug abuse may be associated with increased likelihood of psychosis in HIV infected patients despite no current substance use. (Sewell et al, 1994) Neuropsychiatric symptoms in patients with AIDS may be due to direct HIV effects on the brain²⁹⁴⁷ or the effects on the brain due to immunodeficiency²⁹⁴⁸.

AIDS: brain microscopy

Pallor of myelin in white matter

Cytomegalic-like lesions in grey matter²⁹⁴⁹

Multinucleate giant cells containing the great majority of detectable HIV RNA

Certain amount of macrophage infiltration, particularly of the leptomeninges and perivascular spaces

Mild inflammation (reactive astrocytosis and focal necrosis)

Mild to moderate cortical atrophy²⁹⁵⁰

Excess involvement of the basal ganglia, hypothalamus, thalamus and brainstem

AIDS: clinical categories²⁹⁵¹

		Clinical categories		
CD4 cell count per Micro L	A	B	C	
500 +	A1	B1	C1	
200-499	A2	B2	C2	
-200	A3	B3	C3	

Tuberculosis has developed in AIDS cases and may present in unusual forms, e.g. skin nodules, acute pericarditis with cardiac tamponade, cold abscess of the chest wall, and cerebral abscess.

The minority of paediatric cases are infected postnatally, e.g. via a blood transfusion.²⁹⁵² Most cases acquire HIV in utero or perinatally (e.g. via breast milk²⁹⁵³). About three out of four cases develop a

irritable and suspicious rather than 'high'; they are severely insomniac and therefore seem confused; HAART may need to be modified and the usual treatments for bipolar disorder (except valproate because it increases the risk of marrow damage in combination with zidovudine) may be required.

²⁹⁴⁶ A Swiss study (Keiser et al, 2010) found increased suicide risk to be associated with older age, male sex, injection drug use, and advanced illness whereas higher CD4 cell counts were associated with lower suicide rates.

²⁹⁴⁷ E.g. acute meningoencephalitis in the earliest stage and subacute encephalopathy later.

²⁹⁴⁸ Malignant lymphomas (non-Hodgkin's lymphoma large B cell type [strongly associated with Epstein-Barr virus] has become more common than Kaposi's sarcoma; also squamous carcinoma of cervix and anus [associated with human papillomavirus]), cerebral Kaposi's sarcoma (first described 1872 – proliferating vascular endothelial cells; caused by herpes virus 8), toxoplasmosis, cryptococcal meningitis, herpes simplex or cytomegalovirus encephalitis, hypoxia, treatment-related metabolic problems, idiopathic thrombocytopenic purpura, nonbacterial thrombotic endocarditis, and the Ramsay Hunt syndrome with facial palsy and clonic facial spasms. With improved survival rates, **distal sensory neuropathy**, due to HIV or antiretroviral agents, has become a major problem since 1 in 3 cases suffer from it. There are pain, tingling, and burning of the soles of the feet. Patients may become demoralised.

Treatment involves stopping causative drugs, cessation of alcohol intake, management of any other disorder (e.g. diabetes or depression), and reducing pain levels (e.g. analgesics, TCAs, anticonvulsants such as lamotrigine).

²⁹⁴⁹ **Cytomegalovirus (CMV)** may cause subacute encephalitis characterised by headache, pyrexia, apathy, impaired attention, memory dysfunction, and ataxia. Inclusions may be seen in microglia and macrophages. Retinitis may impair vision. Ganciclovir and foscarnet are used in treatment.

²⁹⁵⁰ There is significant loss of neurones in the cerebral cortex, especially in frontal areas. Neurones are also lost in putamen, substantia nigra, and nuclei of cerebellum.

²⁹⁵¹ **Clinical categories:** A = no symptoms, acute HIV reaction, or persistent generalised lymphadenopathy – there may be transient peri-seroconversion symptoms; B = various symptomatic disorders, e.g. thrush, prolonged diarrhoea or pyrexia, or buccal hairy leucoplakia (caused by EBV), etc; C = AIDS (neurological involvement, progressive multifocal leucoencephalopathy, and cerebral *Toxoplasma gondii* infection). These are based on the Centers for Disease Control and Prevention 1993 classification.

²⁹⁵² Donated blood in the USA has been screened for HIV-1 since 1985 and for antibodies to HIV-2 since 1992, leading to a very diminished risk [< 0.001%] risk of transmission of HIV. Paying blood donors in Peru led to an outbreak of HIV in infants – paid donors may not admit to risky behaviour.

progressive encephalopathy and/or microcephaly. Rarely this is caused by cytomegalovirus or primary brain cell lymphoma. Direct HIV damage is the usual mechanism. The classical picture is one of psychomotor retardation sometimes with behaviour problems. According to Cutting, (1992) HIV is transmitted in breast milk but the risk of neonatal death from not being breast fed (diarrhoea, respiratory infection) in developing countries may be greater than from HIV. Others recommend that mothers bottle-feed their infants. (APA, 2002, p. 150) Lymphocyte culture may be used to isolate HIV because antibody tests may remain positive (passive transfer from mother) for up to a year and a half after birth. Injection of cocaine and the exchange of sex for 'crack' was associated with a great increase in HIV and AIDS in the Americas a decade ago. (Farrell, 1991) Prostitutes are at very high risk for contracting HIV and are less likely to use condoms for non-paying clients; also, the partners of prostitutes may have had unprotected sex with other people, including homosexual encounters. In fact, only a minority of people who engage in high risk sexual activity use condoms consistently. (Steiner et al, 2008) Older people may be relatively unaware of STDs and be more likely to practice unprotected sex. (Bouman 2008, p. 690)

Comparison of first time treatment-seeking heroin users in Dublin (Long et al, 2006)

Inner city v suburban

Inner city – older, more HIV and hepatitis C, use of cocaine and regular heroin use

Authors' hypothesis: HIV therefore associated with area of residence and cocaine use?²⁹⁵⁴

Early, unrepresentative studies were considered to have overstated the risk of dementia and less than 5% of cases becoming demented are considered realistic, most cases developing it late in the course of the disorder. Problems with planning, problem solving, sequencing and concept formation were, however, noted to be common in advanced cases of AIDS.

Psychotic patients may be deluded nowadays that they have been given AIDS deliberately. People with depressive or obsessional personalities may worry excessively about AIDS²⁹⁵⁵. Such people may present with chronic anxiety, depression, or even conversion symptoms. Many of these symptoms may mimic the prodromal states of AIDS. Psychopaths with AIDS may present special management problems.

All cases have positive serology by 6 months, most being positive by 12 weeks, some as early as a fortnight. Patients with AIDS dementia have a positive ELISA²⁹⁵⁶ test. Confirmation is by way of Western blot.

HIV needs three enzymes to reproduce within the host: reverse transcriptase, protease, and integrase.

Antiretroviral drugs²⁹⁵⁷

<i>Group</i>	<i>Examples</i>	<i>Some adverse effects</i>
Nucleoside reverse transcriptase inhibitors (NRTIs) ²⁹⁵⁸	Abacavir, Didanosine, Emtricitabine, Lamivudine, Zidovudine, Zalcitabine	Anaemia, cardiomyopathy, fat loss (extremities), hepatic steatosis-lactic acidosis, myopathy, neutropenia, pancreatitis, peripheral neuropathy
Non- nucleoside reverse	Delavirdine, Efavirenz,	Bleeding (in haemophiliacs),

²⁹⁵³ Being breastfed only during the first 6 months of life may carry less risk of acquiring HIV than being breastfed and given other food/liquid. (Holmes & Savage, 2007)

²⁹⁵⁴ Other possible explanations include IV habit and needle-sharing!

²⁹⁵⁵ So-called AIDS-phobia, AIDS panic or pseudo-AIDS syndrome: some of these patients have problems accepting sexual orientation or with sexuality in general, or they may have negative religious or cultural sexual beliefs, and they may be guilty about past sexual 'rule-breaking'.

²⁹⁵⁶ Enzyme-linked immunosorbent assay.

²⁹⁵⁷ Up to date treatment guidelines are available at www.BHIVA.org.uk (UK) and <http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf> (USA). Potential drug interactions are found at www.hivdruginteractions.org (Liverpool, UK).

²⁹⁵⁸ Abacavir and didanosine may increase risk for myocardial infarction. (D:A:D Study Group, 2008)

transcriptase inhibitors (NNRTIs)	Nevirapine	deranged hepatic enzymes, fat redistribution, GIT intolerance, hyperlipidaemia, insulin resistance-hyperglycaemia Efavirenz can cause delirium depression, insomnia, vivid dreaming, dizziness, and poor concentration Efavirenz and Nevirapine decrease methadone ²⁹⁵⁹ levels by half (can precipitate abstinence)
Protease inhibitors (PIs)	Amprenavir ²⁹⁶⁰ , Atazanavir, Fosamprenavir, Indinavir, Lopinavir, Nelfinavir, Ritonavir, Saquinavir, Tipranavir	Hepatitis, rash (Stevens-Johnson)
Others	Raltegravir, Enfuvirtide, Tenofovir	

AZT (zidovudine²⁹⁶¹), which inhibits viral reverse transcriptase²⁹⁶², prevents AIDS dementia in many cases. AZT can suppress bone marrow. It can also cause headache, insomnia, and restlessness. Modern anti-HIV therapy involves reverse transcriptase inhibitors like AZT and lamivudine protease inhibitors such as indinavir. The non-nucleoside reverse transcriptase inhibitors nevirapine and efavirenz have been reported to cause psychosis.(Wise, 2002) There is increased sensitivity in patients infected with HIV to the EPS and anticholinergic side effects of high-potency and low-potency antipsychotic drugs respectively.(APA, 2002, p. 210)

Raltegravir (Isentress), an HIV-1 integrase inhibitor, prevents the virus integrating its genetic material into additional healthy cells during the early phase of cell infection.

The combination of darunavir and ritonavir is promising.

Histone deacetylation is important for quiescence of HIV gene expression in infected resting CD4+ T lymphocytes. Blockade of histone deacetylase 1 leads to increase in HIV. Valproic acid inhibits histone deacetylase and seems to accelerate clearance of HIV from resting CD4+ T lymphocytes.(Lehrman ea, 2005)

A stable partnership may delay progression to AIDS or death in HIV infected patients receiving highly active antiretroviral therapy (HAART²⁹⁶³). (Young ea, 2004) How it does so is not answered by this research (adherence, less depression?). Quiescent CD4 cell provirus reservoirs in HAART-treated cases may potentially prevent total viral eradication. Resistance to anti-HIV drugs is a worry (UK Group on Transmitted HIV Drug Resistance, 2005) as are reports of HIV patients developing florid leprosy lesions during the initial months of antiretroviral therapy.(Lawn & Lockwood, 2007)

Exclusive sexual abstinence only programmes do not appear to affect HIV risk in wealthy countries (Underhill ea, 2007) although methodological problems are common in such research.

Work on the development of a vaccine for HIV-1 remains disappointing.(Buchbinder ea, 2008; Rerks-Ngarm ea, 2009)

Multiple sclerosis (MS)²⁹⁶⁴

²⁹⁵⁹ **Methadone** levels are reduced by ritonavir (including in combination with lopinavir), nevirapine, fosamprenavir, amprenavir, efavirenz, and nelfinavir. Methadone increases concentration of zidovudine and reduces levels of stavudine and didanosine.

²⁹⁶⁰ Do not give amprenavir with disulfiram or metronidazole.

²⁹⁶¹ Or azido-deoxythymidine.

²⁹⁶² Preventing transcription of RNA to DNA and its subsequent insertion into the host genome.

²⁹⁶³ A mixture of inhibitors used to counter emergence of resistance.

²⁹⁶⁴ **MS** is a chronic demyelinating disease of complex aetiology described by Charcot that occurs mainly in temperate climates. It is rare within 23° north and 23° south. Insufficient exposure to ultraviolet radiation in childhood may have an aetiological role.(van der Mei ea, 2003) MS seems to be more common in people born in May and to be less common in those born in November.(Willer ea, 2005) The offspring of low-risk immigrants may develop a similar prevalence of MS to that of their adoptive country, but migrants to South Africa who were older than 15 years retained the high incidence of their birthplace (i.e. the environmental risk may operate in

MS is probably independent of trauma or other illness, although an increase in life events or marked chronic difficulties compared to controls in the 6 months prior to clinical onset has been reported. Premorbid personality is probably normal in most cases. Hysteria is the classical misdiagnosis, and hysterical reactions may complicate MS. Some authors have stressed a tendency to bottle up feelings and others report an unhappy childhood, while still others state that MS patients were always tense and anxious and had immature personalities. Some relapses may coincide with emotional trauma and others do not.

MS

Only 18% have an affected first degree relative

Concordance for MS is higher in MZ than DZ twins: 25-50% v 2-17% in different reports

Susceptibility locus on chromosome 6 has been suggested

Increased frequency of HLA-B7, HLA-A3, HLA-Dw2 and especially HLAD2

Comparison of full-sib and half-sib (one biological parent in common) shows that halving the number of potentially contributing genes lowers the risk of MS by a factor of 2.62 (may favour polygenic hypothesis) MS has been linked to many chromosomes with little replication

Gene variants IL7R-alpha (IL-7 gene) and IL2R-alpha (IL-2 receptor) increase risk of developing MS by 20-30% (see International Multiple Sclerosis Genetics Consortium, 2007)

Link consistently shown with MS with extended haplotype of the MHC²⁹⁶⁵, especially those containing HLA-DRB1*1501 (Dyment *et al.*, 2004)

Depression²⁹⁶⁶ is commoner early on, euphoria appearing later

No real proof that depression is reactive and euphoria is biological – complex in reality

Mood symptoms do not correlate well with disability

Depression is more common with cerebral than with spinal lesions

Temporal lobe involvement may be a risk factor for depression (Schwid *et al.*, 2000)

Fatigue (mechanism obscure) and pain (often widespread and chronic²⁹⁶⁷) are very common in MS

A few cases present with cognitive impairment, which may be the only manifestation of MS

Organic personality change may lead to emotional shallowness or apathy

Overall psychometric performance correlates with measures of severity on MRI

Widespread cognitive deficits with sparing of naming ability and relative preservation of verbal memory

adolescence). MS usually begins between 20-40 years and is very rare before adolescence or after 50 years. It may be slightly more common in women. The prevalence in Northern Ireland in 1987 was 104 definite cases/100,000 of the population. A slow virus (or the measles virus) affecting children has been suggested.

Common early manifestations of MS are ataxia, diplopia, vertigo, other brainstem problems, optic neuropathy consisting of optic neuritis (nerve head – swollen disc) or retrobulbar neuritis (further back – ‘patient cannot see and examiner cannot see’, i.e. fundus appears to be normal), and impaired sensation in lower limbs, and paresis of the limbs. Other problems include intention tremor, nystagmus, impaired colour vision, slurred or scanning speech, urinary incontinence, impotence, seizures, impaired vibration and position sense, hyperreflexia, paraplegia, and extensor plantar responses. Uhthoff’s phenomenon consists of a temporary return of symptoms of acute optic neuritis another illness, temperature change, physical exertion, or other stress; it does not suggest relapse. Lhermitte’s sign is a tingling sensation in the back or limbs on neck flexion. Apart from Lhermitte’s sign, other suggestive findings include worsening of symptoms with exercise or fever, onset before age 50 of trigeminal neuralgia, and recurrent VII nerve paralysis. Treatment of exacerbations is with ACTH and steroids (e.g. IV methylprednisolone followed by prednisone). Longterm steroid treatment carries no clear benefit and has considerable side effects. Prophylaxis for steroid induced mania has taken the form of lithium or low dose neuroleptics. Carbamazepine, although often used for manic attacks, can potentially exacerbate the symptoms of MS, possibly by blocking sodium ion channels. A modest reduction in frequency of episodes has been reported with the various interferons, interferon-beta-1b (but probably not interferon-beta-1a) being capable of causing severe depression and suicide (it is sometimes given with prophylactic SSRI – the literature on the association between depression and beta-interferon is mixed: no increase, increase, and decrease: Carson *et al.*, 2007, p. 345). Glatiramer acetate is another disease-modifying drug with modest effects, with a substantial minority of cases showing a less than optimal response. Immunosuppression with drugs such as azathioprine and methotrexate may be needed for the most progressive cases. Mitoxantrone is a chemotherapeutic drug for non-responsive cases which may cause cardiomyopathy or acute leukaemia. Natalizumab stops T lymphocytes crossing the blood-brain barrier; it can induce progressive multifocal leucoencephalopathy (PML). Rituximab and alemtuzumab can cause PML and thrombocytopenia respectively. (Hutchinson, 2008)

²⁹⁶⁵ Major histocompatibility complex (HLA, human leucocyte antigen) of 140 genes on chromosome 6.

²⁹⁶⁶ ECT is usually safe in MS cases except perhaps if there are gadolinium-enhancing plaques seen on MRI, the latter indicating disease activity.

²⁹⁶⁷ There are many possible mechanisms, e.g. spasticity or dysesthesia, the latter being helped by amitriptyline or gabapentin. Trigeminal neuralgia is an acute manifestation of MS.

Psychoses may be secondary or incidental

Sometimes misdiagnosed as hysteria and the vulnerable may develop an hysterical response

One theory of causation states that anxiety excites a vascular response. Most such theories are highly suspect. Smoking is associated with increased risk for MS and may also accelerate conversion from a relapsing-remitting to a progressive course.(Healy ea, 2009) All degrees of dementia have been reported, especially with defects of memory and speech. Air encephalography revealed enlarged ventricles and increased air collection over the hemispheres. CT scans may show plaques as areas of low density. Alternatively there are high-density areas enhancing with contrast during an acute relapse. MRI is superior to CT.²⁹⁶⁸ Plaques are most common near the ventricles. Rate of progression of dementia is very variable, being fulminant in some cases. When testing visual evoked responses it is normal to get a major downward (positive) wave at about 100-msec (P100). Demyelination of the optic nerve delays this wave with relative preservation of its form. CSF may contain myelin basic protein, oligoclonal bands, and an increase in the percentage of gamma globulin. Depression appears to be predicted by multiple interacting variables, especially trait anxiety and functional status but also alexithymia and level of satisfaction with social support system.(Gay ea, 2010) Depression may respond to SSRIs and supportive or problem-solving psychotherapies. Abnormal laughing or crying may respond to amitriptyline. Amantadine or modafinil may improve fatigue; other approaches include aerobics, rest periods, and heat avoidance. Baclofen²⁹⁶⁹ reduces spasticity. There is some evidence that oral cannabinoids may also be useful for spasticity (Zajicek ea) but they should only be employed if legal, available, if other treatments do not work, and if the patients desists from driving.(Metz & Page, 2003) Donepezil (Greene ea, 2000) and training in compensatory strategies may be helpful for cognitive problems. Thalidomide (Thalidomide Pharmion) because available in 2008 for MS with strict precautions against use in pregnancy. Vitamin D may reduce the risk of relapse.

Progeria²⁹⁷⁰

This is a rare, sporadic, autosomal dominant syndrome.(Korf, 2008; Merideth ea, 2008) A child is born apparently in normal health but stops growing before the third birthday. Many of the changes of senility develop and the end state is eventually reached. All cases end up looking like one another²⁹⁷¹. Lamin A (progerin) truncation²⁹⁷² has been reported (De Sandre-Giovannoli ea, 2003) causing nuclear membrane disruption and altered transcription.

Adult progeria²⁹⁷³

This is excessively rare and may possibly be inherited as an autosomal recessive trait. The gene responsible encodes a helicase enzyme that unpairs DNA strands.(Yu ea, 1996) It can affect the siblings of both sexes. It is possibly a caricature of normal ageing. There is shortness of stature. The average life span is 47 years. Up to 10% of cases develop mesenchymal neoplasia. There are various associated physical defects. Many of the cases have been reported in Japan, but it can occur elsewhere. Some cases have been mentally retarded or had cerebral cortical atrophy.

Cysts of the third ventricle

Colloid cysts are usually silent until the third to fifth decades of life. They may cause delusional depression, delirium, dementia, neurotic syndromes, and schizophrenia-like psychosis. Neurological findings include cranialgia²⁹⁷⁴, papilloedema, false localising signs, increased intracranial pressure, gastrointestinal upset, fainting, diminished level of consciousness, and sudden death due to acute obstruction of CSF.

²⁹⁶⁸ However, use of MRI to confirm MS on the basis of one neurological episode may lead to over-diagnosis and over-treatment.(Whiting ea, 2006) Most lesions are bright on T2-weighted MRI and are best seen with fluid-attenuated inversion-recovery (FLAIR) MRI.

²⁹⁶⁹ Baclofen can cause GIT upset, drowsiness, delirium, and seizures.

²⁹⁷⁰ Hutchinson-Gilford syndrome, Hutchinson being best remembered for the abnormal incisors in syphilis.

²⁹⁷¹ The child does not thrive in the early months of life, remaining small with very little body fat; as the child ages the skin becomes thin and sclerotic, the hair is lost, and osteoporosis and deteriorating cardiac function develop; death usually occurs in the early teens from myocardial infarction.

²⁹⁷² Change from glycine GGC to glycine GGT in codon 608 of the lamin A (LMNA) gene. Lamin A is part of the protein network forming the nuclear lamina inside the nuclear membrane.

²⁹⁷³ Werner's syndrome or segmental progeroid was described by Otto Werner in 1904.

²⁹⁷⁴ Headache may be episodic positional due to cyst on a stalk moving in and out of foramen of Monro.

Akinetic mutism was described by Cairns *et al.* (1941) in a patient with an epidermoid cyst of the third ventricle. This syndrome may occur with midbrain or posterior diencephalic lesions.²⁹⁷⁵ Cystic tumours can be aspirated, which may reverse mutism, although the patient will be unable to remember anything for the time when mute.

Other causes of dementia

These are numerous and include:

Limbic encephalitis - paraneoplastic or primary autoimmune phenomenon²⁹⁷⁶

Boxing injuries to the head

Behcet's syndrome²⁹⁷⁷

Buerger's syndrome²⁹⁷⁸

Polycythaemia rubra vera²⁹⁷⁹

Sarcoidosis

Thalamic degeneration – rare

Subacute sclerosing panencephalitis

Myotonic dystrophy²⁹⁸⁰ - a minority of cases become demented

Polyarteritis nodosa²⁹⁸¹

Cranial arteritis

MELAS syndrome²⁹⁸²

Myoclonic epilepsy with ragged red fibres²⁹⁸³

Sneddon's syndrome²⁹⁸⁴

Cerebrotendinous xanthomatosis²⁹⁸⁵

Granulomatous angiitis²⁹⁸⁶

Cerebral amyloid angiopathy²⁹⁸⁷

²⁹⁷⁵ Late stage normal hydrocephalus may be complicated by akinetic mutism.

²⁹⁷⁶ Paraneoplastic cases are associated with such conditions as small cell lung cancer or seminoma of testis. In such instances it is thought that antibodies against cancer cells (e.g. antiHu) cross-react with normal nerve cells. Primary cases have antibodies to voltage-gated potassium channels; most have no cancer but a few have thymoma; treatment-resistant seizures and hyponatraemia are common; episodic memory is dysfunctional; MRI shows abnormal high temporal lobe signal; EEG often has focal temporal lobe abnormalities; and management includes high dose steroids, plasma exchange, or IV immunoglobulin.

²⁹⁷⁷ **Behcet's syndrome** is found most often in young males. There is often a family history of the disorder, with autosomal recessive transmission in childhood-onset cases. The HLA-B region is associated with the syndrome. Ulcers of the mouth and genitalia and eye problems (e.g. uveitis and retinal vasculitis – sometimes with permanent blindness) occur in episodes over a number of years. Arthritis, erythema nodosum, and thrombophlebitis may be present. CNS involvement may cause fever, stiff neck, headache, and various neurological signs, including brainstem signs such as cranial nerve palsies and diplopia. Other reported neurological effects were dysexecutive syndrome, memory problems, periods of confusion, dementia, psychosis (bipolar or schizoaffective), and dural sinus thrombosis. Pathological findings in cases with CNS involvement include relatively mild perivascular inflammation and areas of infarction, demyelination, and necrosis.

²⁹⁷⁸ **Thromboangiitis obliterans** – described in Leo Buerger (1879-1943, born Austria) in 1908 - found in male smokers (usually in 20s-40s) – rarely affects brain: headache (migraine-like), seizures, and dementia.

²⁹⁷⁹ **Polycythaemia rubra vera**: myeloproliferative disorder with excess red (and usually white and platelet) cells; plethoric facies; increased viscosity of blood; headache, blurred vision, vertigo, delirium, cerebral TIAs, infarction, dementia.

²⁹⁸⁰ Chromosome 19q13 (gene is called DMPK-3'UTR, dominant inheritance, triplet repeat, myotonin kinase produced) usually presents in adults: myotonia (despite weakness, the muscles are difficult to relax, e.g. the patient grasps your hand but cannot let go of it), facial myopathy (lower lip droops, ptosis), distal muscle atrophy, cataracts, and frontal baldness. Hypersomnia is common and patients may sleep for very long periods.

²⁹⁸¹ This rare condition affects small and medium sized arteries (including nutrient arteries). It usually starts in mid-life. Many organs may be affected. Neurological effects include peripheral neuropathy, encephalopathy, cerebral/subarachnoid haemorrhage, damage to cranial nerves, a mass effect from necrotic brain tissue, and delirium. Subcutaneous nodules may be found. Diagnosis, such as skin, kidney or nerve, is confirmed by biopsy.

²⁹⁸² Mitochondrial encephalopathy with lactic acidosis and stroke-like episodes: inherited from mother – usually presents in childhood.

²⁹⁸³ **Myoclonic epilepsy with ragged red fibres** is a mitochondrial myopathy with myoclonic epilepsy, dementia, cerebellar ataxia, nerve deafness, and (not all cases) optic atrophy and peripheral neuropathy. Muscle biopsy shows ragged-red fibres and abnormal mitochondria. Age of onset and clinical severity varies because of heteroplasmy. Many abnormal mutations of mitochondrial tRNA genes have been discovered.

²⁹⁸⁴ Livedo reticularis, strokes, and, in some, dementia.

²⁹⁸⁵ Dementia, tendon enlargement, cataracts, and ataxia.

²⁹⁸⁶ Idiopathic, possibly autoimmune reaction to a virus.

²⁹⁸⁷ Congophilic amyloid angiopathy: mostly sporadic; autosomal dominant forms include the Dutch (APP gene mutation) and Icelandic (latter due to mutation in CST3 gene encoding for the enzyme-inhibiting Cystatin C protein) types. It is more common in

Pure hippocampal sclerosis²⁹⁸⁸
 Neurocysticercosis²⁹⁸⁹
 Cerebral toxocariasis²⁹⁹⁰
 Dialysis
 Malabsorption
 Alcoholism

APP is cleaved to produce the A β peptide, the chief component of AD plaques. A mutation in APP (Glu693Gln) was reported in those few families in the Netherlands with hereditary cerebral haemorrhage of the Dutch type (recurrent cerebral bleeding due to excess A β deposition in brain blood vessel walls – this research showed that APP mutation could cause A β deposition and encouraged research into APP mutation in families with early-onset AD).

Worster-Drought syndrome

Familial British dementia; autosomal dominant; described in 1930s; presenile dementia, spastic paraparesis, and cerebellar ataxia; MRI shows deep white matter lesions and lacunar infarcts; prominent cerebral amyloid angiopathy and AD-like plaques and tangles; however, deposited amyloid is negative for antibodies against the β -amyloid found in AD (Dermaut & Van Broeckhoven, 2002)

Familial Danish dementia

Heredopathia ophthalmoto-encephalica; abnormally long APP; cataracts, deafness, progressive ataxia, and dementia with AD-like neuropathology (Vidal ea, 2000)

Nasu-Hakola disease

Presenile dementia with bone cysts of ankles and wrists; 19q13; rare recessive disorder found mainly in Finland and Japan (Dermaut & Van Broeckhoven, 2002)

The **Mini-Mental State Examination** (MMSE, Folstein ea, 1975) is the commonest bedside cognitive test used by clinicians.(see box) Education can influence scores, necessitating lower cut-off scores.(Nixon & Albert, 1999) The cut-off point is less than 24/30. The MMSE does not reliably discriminate mild dementia (ceiling effect) or severe dementia (floor effect). Early cognitive decline may be missed in people with a high IQ. The MMSE is more useful for tracking cortical than subcortical (including HIV-associated²⁹⁹¹) dementias.(Rao ea, 1991) Neither does it distinguish dementia from delirium and some delirious patients score in the normal range. It is not sensitive to executive dysfunction or every cognitive problem (e.g. dyspraxia). As with other screening tests of cognitive disorder, the predictive value of the MMSE when one moves out of the clinic and into the community²⁹⁹².(Brayne & Calloway, 1991)

Some tests for cognitive impairment

(a) The Mini-Mental State Examination (MMSE)

Patient..... Age years

Examiner..... Time am-pm

What is the year/season/date/day/

females and with increasing longevity. Finnish type familial amyloidosis results from GSN gene mutation that codes for the actin-binding protein gelsolin.

²⁹⁸⁸ This consists of severe cell loss and gliosis in the hippocampus, unknown aetiology, usually in advanced age, and prominent short-term memory loss.

²⁹⁸⁹ *Taenia solium* (in infected meat), especially in poor countries, rarely affects CNS (neurocysticercosis), focal neurological signs, hydrocephalus, personality change, seizures, anaemia, worms in stool, space-occupying lesions on CT or MRI, serological tests, treat with antihelminthics such as albendazole and treat complications (e.g. steroids for increased intracranial pressure or anticonvulsants for seizures).

²⁹⁹⁰ *Toxocara canis* (do roundworm), eosinophils in blood and CSF, positive antibody titre, and treat with drugs such as albendazole.

²⁹⁹¹ The *HIV Dementia Scale* (Power ea, 1995) may be used for this disorder.

²⁹⁹² The case:non-case ratio falls as one moves away from the clinic.

month?	5	()
Where are we? (country/county/town/ e.g. hospital/floor)	5	()
(2) Registration		
Name any three items (1 sec. each). Repeat all three. Give 1 point for each correct answer. Now repeat them until learned. Count all trials and record.	3	()
Trials		
(3) Attention and calculation: Serial 7s (i.e. 100, 93, 86 etc). 1 point for each correct. Stop after 5 answers. * Alternatively, spell 'would' (or 'world') backwards. **	5	()
(4) Recall: Ask for the 3 objects as in (2). Give 1 point for each correct answer.	3	()
(5) Language		
Show a pencil and watch (name them). (2 points).		
Repeat the following: 'No ifs, and or buts'. (1 point).***		
Follow a 3-stage command: 'Take a piece of paper in your right hand, fold it in half, and put it on the desk'. (3 points).		
Write: 'Close your eyes', and ask him to read and obey. (1 point).		
Write a sentence (noun and verb). (1 point).		
Copy design – 2 partly overlapping 5-sided figures. (1 point).		
(Look for where sides cross and correct number of angles).	9	()
RECORD TOTAL SCORE OUT OF 30		
What is his level of consciousness along this continuum (Alert, drowsy, stupor, or coma)?		
The total can be brought up to 40 points by adding tests that mainly test right hemisphere function:		
(1) Draw a triangle, square and circle, or construct three shapes with matches (3 points).		
(2) Draw a clock face, filling in numbers (take off one point for each error) (2 points).****		
(3) Cross each of random lines shown in a square (subtract one point for each omission) (5 points).		
*93, 86, 79, 72, and 65: score total number of correct answers. **Score number of letters in correct order, e.g. 'dlorw' = 3. ²⁹⁹³		
Another test of repetition would be the Babcock sentence: 'One thing a nation needs to be rich and great is a large, secure supply of wood'. *See Manos, 1999. The <i>Clock Drawing Test</i> is a good screen of executive function (e.g. a patient with a frontal lobe lesion might join the hands in the wrong place because he/she is 'stimulus bound' ²⁹⁹⁴ to the time he/she has been asked to indicate, or put numbers outside the clock face); it can also detect neglect syndromes ²⁹⁹⁵ (numbers may appear clustered on one side of the clock face).		
(b) Test for Severe Impairment (scores in brackets for correct response)		
Patient.....	Age	years
Examiner.....	Time	am-pm
Date.....		
Clinical problem.....		
Motor performance – ask person to demonstrate use of comb (1), to put top on pen (1), write name (legibly – 1): total = 3		
Language comprehension - ask person to point to his ear and to close his eyes (1 each), and to indicate red pen from red, blue and green pens (1), and repeat for green pen (1): total = 4		
Language production – pointing at your nose ask patient what it is (1), the colour of two different pens held up consecutively (1 each), pointing at a key ask patient what it is (1): total = 4		
Immediate memory – your open hand contains a clip and patient must say which hand it is in (by pointing - 1), with closed hand repeat question (1), with your hands moved behind your back (1): total = 3		
General knowledge – ask how many ears you possess (1), ask patient to count your fingers (1), how many weeks in a year (1), ability to sing most of words of 'Happy Birthday' along with you (1): total = 4		
Conceptualisation – which is odd one out (show 2 clips and a pen – 1), give a red pen and ask him to place it next to same-coloured pen (red and green pens on desk – 1), move clip from one of your hand to another several times and ask him which hand you will put it in next and after he responds put the clip in the correct hand [and if he is wrong tell him what hand you would put it in and ask him again which hand you would put it in next - 1]: total = 3		
Delayed memory – show thread, clip and key and ask which one was not used already in the testing (correct if points to thread – 1): total = 1		
Motor performance – thank patient for being with you and offer him your hand (if he shakes your hand – 1): total = 1		
Grand total = 24		

Test for Severe Impairment (TSI) (Albert & Cohen, 1992) is used for severely cognitively impaired patients. It minimises reliance on verbal skills.

²⁹⁹³ It is important to realise that some languages do not include or concept of spelling, e.g. Mandarin.

²⁹⁹⁴ **Stimulus bound:** Dementing patients have problems shifting frames of reference. They become distracted by accidental impressions/events and cannot shift attention away from them.

²⁹⁹⁵ A patient with a right-sided stroke might, when drawing an object such as a horse, leave out the left side of the picture or, when asked to perform the *Trail Making Test* (join dots in sequence) neglect the left side of the exercise (not use dots on that side of the diagram).

Functional Assessment Staging (FAST) (Reisberg, 1986) consists of a 7-point scale with subdivisions, e.g. 1 = no subjective or objective difficulty and 7(f) = loss of ability to hold up head independently or the neck is contracted and immobile. FAST stage 7, which has 6 substages, represents over half of the potential duration of AD. FAST can track the progress of AD much further than the MMSE which suffers from a 'floor effect' (stage beyond which there is no further drop in the scores). FAST depends on carer testimony. Wise and Strub (1999) point out that the examiner should not only ask patients to remember 3 objects (verbal/dominant) but they should also ask them to recall 3 shapes (non-dominant hemisphere).

The **Dementia Rating Scale-2 (DRS-2)** (Jurica et al, 2001) tests attention, memory, reasoning, and construction. This brief test with a deep floor (tests low levels of function) employs a screening approach: moderately difficult items are presented first, allowing other items in that domain to be skipped if the patient passes. The DRS-2 can be used to track progress of AD.

The **Addenbrooke's Cognitive Examination**²⁹⁹⁶ (ACE) (Mathuranath et al, 2000) includes the MMSE as well as asking the subject to remember a name and address (a more difficult test of anterograde memory), questions about current events, verbal fluency tests, and more probing evaluation of language and perception.

Tests for causes of dementia

FBC, ESR, Hgb, TPHA, FTA, T4, Free T3, TSH, urea and electrolytes, calcium, B12, folate, CT and MRI scans, EEG, echoencephalography, arteriography, lumbar puncture (LP), etc - all tests need some degree of clinical justification on the grounds of cost-effectiveness, availability, likely results, and invasiveness.

Thyroid screening may be misleading in people on phenothiazines, antiparkinsonian drugs, or lithium.

CT gives poor delineation of the posterior fossa. Polycythaemia occurs in multi-infarct dementia and haemangioblastoma of the cerebellum. Macrocytosis (with raised MCV) is often seen in alcoholism.

Presenile dementia slows down most of the components of the visual evoked response. The responses of the visual system to appropriate repetitive stimuli are isolated from the background EEG using a computer technique known as averaging. This may prove to be of diagnostic value in psychiatry in the future. It has already found clinical use in the investigation of multiple sclerosis.

Epilepsy

Epilepsy²⁹⁹⁷, a seizure tendency symptomatic of a brain affection, follows a chronic course with repeated, unprovoked seizures. It is the commonest chronic neurological disorder.

International League Against Epilepsy definitions

Epileptic seizure = clinical manifestation thought to be due to an abnormal and excessive discharge of a set of brain neurones

Epilepsy = disorder with at least 2 epileptic seizures that are unprovoked by an immediate identifiable cause

Rarely if ever is the cause of epilepsy centrencephalic²⁹⁹⁸. The seizure threshold is 50-100% higher in males than in females. Pseudoseizures (non-epileptic attack disorder or non-organic/non-epileptic seizures²⁹⁹⁹) are not discussed here except to state that the ultimate diagnostic procedure is videotelemetry.

5% of people have a seizure³⁰⁰⁰ at some point in their lives and 0.5% has epilepsy

²⁹⁹⁶ Cut-off of 83/100 = dementia.

²⁹⁹⁷ Gk, *epilambanein*, to lay hold of/to seize.

²⁹⁹⁸ An outdated term since spike and wave activity may have a cortical origin rather than arise from a subcortical pacemaker.

²⁹⁹⁹ There is no satisfactory term. Pseudoseizures must be distinguished from *self-induced seizures*, usually associated with childhood, wherein a person with epilepsy deliberately sets about inducing a seizure, e.g. by jumping up in down in front of the slats of a venetian blind; motivation varies from pleasure to coping with stress.

³⁰⁰⁰ A seizure is an abnormal cerebral neuronal paroxysmal discharge that produces events detectable by the patient and/or an observer.

Prevalence of active epilepsy in adults is 4-6/1,000³⁰⁰¹

80-90% of second seizures will follow within 1-2 years

Majority of those who develop epilepsy do so before their twentieth birthday, rendering them educationally vulnerable

70% cases of epilepsy are idiopathic/primary (theories include imbalance between GABA and glutamate or a kindling phenomenon where repeated subconvulsive stimuli eventually cause seizures)

70% cases of epilepsy are partial (focal), the remainder being generalised (*vide infra*)

70% of cases of partial epilepsy are complex partial (formerly 'psychomotor'), i.e. half of all cases of epilepsy; most such cases arise from temporal lobe foci, although any lobe may be involved in practice: the aura may indicate the lobe of origin; the electrical disturbance produces the characteristic symptoms by spreading to the temporal lobe

A significant number of epileptics drive without informing licensing authorities and against medical advice, often for financial reasons and to avoid social stigma. Polytherapy may promote accidents by impairing performance. A wide range of figures for relapse rates are to be found in different studies of people who have had a single seizure.³⁰⁰²

A normal interictal EEG does not disprove a diagnosis of epilepsy, many epileptics have a normal interictal EEG, and an abnormal EEG is not proof that an 'attack' was epileptic. The scalp EEG is usually normal during a simple partial seizure. The EEG during a complex partial seizure will show unilateral or bilateral epileptiform activity, especially in temporal or frontotemporal areas. Spike and wave formations are found in 2% of people who do not have epilepsy. An EEG may or may not be helpful after a first seizure in adults. CT should be ordered if there has been a clear partial seizure or if there are focal neurological signs. Functional imaging (PET/SPECT) can be used during an ictus and postictally to show hypermetabolism and hypometabolism respectively in the epileptic focus. Methohexitone can assist, especially when used with sphenoidal electrodes, to localise interictal spikes.

Anticonvulsants appear to be safe when co-administered with ECT. (Sienaert & Peuskens, 2007) Grand mal (tonic-clonic) epilepsy can be associated with depression³⁰⁰³ that responds to ECT³⁰⁰⁴ or to drug treatment.

A single fit of exogenous or endogenous origin does not produce the progressive and sustained relief of depression that is produced by a course of ECT. Precipitants of epilepsy include laughing (gelastic³⁰⁰⁵ - Gk, *gelastikos*, to laugh), startle, flickering light (photic), reading, fatigue, hunger, eating (Abenson, 1969), dehydration (including a hot bath), fever, and rare individual precipitants such as remembering a specific event or a particular body movement. These reflex epilepsies affect 1-6% of epileptics. Any modality can be affected but the visual system is most commonly implicated. Other precipitants of epilepsy include lack of sleep, emotional stress, infection, and alcohol or drug ingestion or withdrawal. Catamenial epilepsy³⁰⁰⁶ is epilepsy manifesting just before or during menstruation. (Herzog, 2000) Kindling is discussed elsewhere.

Epileptic psychoses

(a) with *disturbed consciousness*³⁰⁰⁷

³⁰⁰¹ It was suggested by Brainwave Ireland (founded 1967; 353+(0)1+4557500; 249 Crumlin Road, Dublin 12; info@epilepsy.ie; www.epilepsy.ie/index.cfm/spKey/about.html) and UCD Centre for Disability Studies in 2009 that 9/1,000 people aged over the age of 5 years in Ireland have treated epilepsy.

³⁰⁰² The risk of subsequent seizures after a first seizure in adulthood is highest for patients whose initial seizure occurs between midnight and 9 a.m. Risk of recurrence is three times higher for someone who is less age 50 years, who has a family history of febrile fits or seizures of any kind, and whose first fit occurs between midnight and 8 a.m. (i.e. usually during sleep). The rate of recurrence was significantly higher for patients with EEGs showing generalised or localised epileptiform activity. 20-30% of newly diagnosed epileptics will develop chronic epilepsy.

³⁰⁰³ Depression associated with an actual complex partial seizure comes and goes suddenly. Much rarer are pleasant ictal feelings.

³⁰⁰⁴ As may some epileptic 'cloudy states' or rages.

³⁰⁰⁵ This may also be a manifestation of seizure activity (complex partial). Such laughter is unlike normal laughter and is not usually viewed as being funny by an observer. *Hamartoma of the hypothalamus* may cause **gelastic seizures** as well as precocious puberty and aggressiveness; most cases are cognitively impaired, although at least some of this may be due to the seizures or their treatment. If the patient cries during laughter the term *dyscrastic seizure* (Gk, *dyskrasia*, bad mixture) may be employed.

³⁰⁰⁶ Catamenial (Gk. *katamēnia*, menstrual period) pneumothorax is another rare association with onset of a menstrual period.

³⁰⁰⁷ States following paroxysms, petit mal status, psychomotor or complex partial status, those not chronically related to seizures, delirious states.

(b) with *normal consciousness*³⁰⁰⁸

Traditional classification of mental problems of epilepsy

- (i) Postictal (following a fit)
- (ii) Interictal (between fits)
- (iii) Preictal (before a fit)
- (iv) Ictal (during a fit)
- (v) Peri-ictal (preictal + ictal + postictal)

Preictal problems represent prodromata that come on gradually and last from hours to days, e.g. irritability, tension, malaise, fatigue, low mood, and headache. A prodrome is more frequently encountered with localisation-related epilepsy but it may be seen with generalised epilepsy.

Ictal disorders of psychiatric importance include aura, automatism, and non-convulsive status epilepticus. The *aura* (a simple partial seizure) consists of premonitory symptoms of focal origin and lasts a matter of seconds. It results directly from abnormal electrical discharge, e.g. in complex partial seizures a strange sensation may arise in the epigastrium that ascends to the throat. Other symptoms include vertigo, tinnitus, odd or indescribable feelings in various body parts such as head (*cephalic aura*), genitals, special sense changes, intense emotion, micropsia/macropsia, déjà vu, jamais vu, depersonalisation, and a variety of complex hallucinations. There may be more than one symptom as part of an aura. A primary motor cortex focus may cause clonic jerking of muscles. Dystonic posturing may occur in some cases. Most *automatisms* occur during a seizure or during post-ictal delirium but some patients with simple partial seizures have such phenomena (e.g. deglutition or lip-smacking) when in apparently clear consciousness.

Postictal states may last 1-2 minutes and may consist, for example, of confusion (delirium), fugue, twilight state, or aggressiveness. Status epilepticus may be associated with more prolonged confusion and may be confirmed by EEG. Post-ictal psychoses commence after a short post-ictal lucid interval and resolve within a few days; they are the commonest of the epilepsy-associated psychoses; they are abrupt in onset; affective symptoms (especially agitation) accompany the psychosis; and a minority (15% after 15 years) go on to develop chronic interictal psychosis, especially those with severe seizures and structural change.

Factors that may feed into postictal states

Psychosocial (stigma)
 Early onset epilepsy (failure of fits to remit, frequent seizures, male sex, or left-sided lesions)
 Temporal lobe (especially bilateral) and other focal lesions
 Poor seizure control
 Genetic predisposition to epilepsy or psychiatric disorder or both
 Intellectual disability
 Acquired brain conditions like trauma
 Drugs (anticonvulsants, other drugs, and alcohol)
 Polypharmacy³⁰⁰⁹

According to Lambert et al., (2003, p. 1109) moderate alcohol intake by epileptic patients is acceptable.

Inter-ictal symptoms/disorders have been classified into mood (anxiety and/or depression – the commonest epilepsy-associated psychiatric problems), schizophrenia-like, behavioural/personality-related³⁰¹⁰, and dementia. Dissociative seizures are also included here. Earlier onset of interictal psychosis may be associated with generalised epilepsy, normal intellectual functioning and a family history of psychosis. (Adachi et al., 2010) ‘Seizure phobia’ refers to excessive fear of having further seizures. It may respond to CBT.

³⁰⁰⁸ The latter can be subdivided into those of (a) duration of less than three weeks, often periodic, e.g. dysphoric, manic, depressive, alternating psychoses with productive symptom, and (b) long duration (more than three weeks, paranoid, schizophreniform, manic-depressive, and dementia).

³⁰⁰⁹ The clinician should consider stopping an ineffective first anticonvulsant when the addition of a second drug controls seizures. (Mellers, 2009, p. 371)

³⁰¹⁰ This idea is less reputable than it was in the past.

Classifying epileptic seizures

Generalised (often no warning or the warning may be non-specific)

Focal/partial/local (often has a specific aura)

Unclassified

Focal (partial) epilepsy may become secondarily generalised.

Generalised epilepsy (convulsive or non-convulsive) includes idiopathic epilepsy (grand and petit mal epilepsy), congenital or perinatal epilepsy, metabolic or hypoxic epilepsy, traumatic cases, toxic cases, febrile³⁰¹¹, infection, and any cause of focal epilepsy.

Focal epilepsy is divided into temporal lobe³⁰¹² and focal motor (including Jacksonian³⁰¹³) epilepsy. The aetiology of focal epilepsy includes unknown (sometimes familial), and congenital or perinatal, tumour, haemorrhage, abscess, trauma, infection³⁰¹⁴, and hypoxic/ischaemic.

Benign childhood epilepsy affects children aged 3-16 years. It has a favourable prognosis. Presenting with simple partial seizures it may or may not progress to secondary generalised attacks. The EEG shows centrottemporal spikes.

The patient runs or walks in circles during a 'cursive' (complex partial) seizure. An 'ambulatory automatism' (semi-purposeful wandering/searching/'escaping') may occur as part of a complex partial seizure. Deviation of the head and eyes occur in '(ad-) versive' seizures (frontal lobe epilepsy³⁰¹⁵), and its lateralising significance is disputed³⁰¹⁶. (Moore, 2001, p. 331) *Epilepsia partialis continua* refers to persistent focal seizures (partial status). Complex partial seizure status refers to continuous complex partial seizures.

Epilepsy

Differential diagnosis

Organic - syncope, hypoglycaemia, transient ischaemic attacks, migraine, sleep disorders

Non-organic - temper tantrums, breath holding, hyperventilation, hysteria, panic attacks, schizophrenia, aggressive outbursts in an unstable personality, night terrors, malingering, and factitious disorder

Aetiology

Idiopathic/constitutional – the biggest group

Hereditary³⁰¹⁷/familial – petit mal, some cases of temporal lobe epilepsy (TLE)³⁰¹⁸, aminoacidurias, trisomy 21, lipidoses, mutations of voltage-gated channels/ligand-gated ion channels/neurotransmitter receptors

³⁰¹¹ Simple benign cases must be distinguished from fever-activated epilepsy.

³⁰¹² Partial *complex* cases involve spread and *loss of/disturbed consciousness*, the commonest type to see a psychiatrist; the other type is partial *simple* seizures – with *no impairment of consciousness*.

³⁰¹³ **John Hughlings Jackson** (1835-1911) who described this epileptic 'march' married his cousin Elizabeth Dade Jackson in 1865. She developed Jacksonian seizures! (Draaisma, 2009, p. 130) In fact, Louis-François Bravais of France had described the same manifestation of epilepsy before Jackson in 1827. Bravais lost out when Charcot named the phenomenon for Jackson! Jackson is best remembered for his idea of hierarchical arrangement of the nervous system: the last parts to develop (e.g. neocortex) inhibit older/lower parts and damage to newer areas lead to positive/release phenomena/gain of function (e.g. brisk jaw jerk) and/or negative/loss of function phenomena (e.g. paresis).

³⁰¹⁴ Especially herpetic.

³⁰¹⁵ Involvement of supplementary motor cortex leads to head turning and ipsilateral arm extension (*fencer's posture*).

Familial nocturnal frontal lobe epilepsy usually starts in adolescents or young adults with clusters of brief motor seizures (grunts/gasps/vocalising at first then thrashing movements or stiffness, with clonic jerks; 2-20 seconds in duration but sometimes longer;) during n-REM sleep. The patient awakens recurrently and shows stereotyped movements. Sleepwalking may occur and may be accompanied by unintelligible speaking or screaming. Patients may or not be aware that seizures have occurred and typically feel tired by day. The aura includes epigastric, sensory or psychological phenomena. Medication, such as carbamazepine, helps. It is inherited as an autosomal dominant trait. Different mutations are associated with *schizophrenia* (or just its negative symptoms), apathy, or intellectual retardation and/or behavioural problems. The affected genes are CHRNA4 (20q13.3) and CHRNA2 (1q21).

³⁰¹⁶ However, others hold that upward eye deviation is found in generalised epilepsy and deviation away from the lesion/focus is found in focal epilepsy, especially if the frontal eye fields are involved. Eye movement direction is unreliable as a lateralising guide when the seizure emanates from a temporal lobe.

³⁰¹⁷ In many cases there appears to be many genes involved.

Developmental defects – phakomatoses, intrauterine (rubella, CMV, toxoplasmosis), irradiation

Birth trauma – perinatal anoxia, cerebral contusion, cerebral haemorrhage/thrombosis

Anoxia in infancy/childhood

Tumours – primary/secondary

Vascular – mature infarcts, A-V malformation

Infection – febrile convulsion (cf. text), viral encephalitis³⁰¹⁹, bacterial or TB meningitis, cerebral abscess, cysticercosis³⁰²⁰, neurosyphilis, echinococcus³⁰²¹, toxocariasis, toxoplasmosis

Inflammatory – SLE/PAN/MS

Metabolic – uraemia, water intoxication, low Na/Ca/Mg, hypoglycaemia

Toxic – alcohol, barbiturates, amphetamines, lignocaine, TCAs, phenothiazines, lead, etc (Kainic acid³⁰²² the related toxin in seafood, demoic acid, probably cause convulsions by inhibiting GABA neurotransmission.)

Degenerative – AD, CJD, Huntington's disease; *Rasmussen syndrome* consists of unilateral brain atrophy, continuous seizures, and cognitive decline arrested by removal of atrophic brain tissue.

Rare forms of epilepsy

Atypical absence – slower EEG, clinically like petit mal, of mentally retarded (Lennox-Gastaut syndrome, which sometimes follows on from West's syndrome), seizures often refractory

Tonic seizures – tonic posturing of limbs or trunk

Infantile spasms (West's syndrome) – brief and sudden head flexion – salaam attacks – often failure to develop – regression – onset 3-9 months – may be refractory, or may respond to vigabatrin, steroids and, if the latter do not work, a ketogenic diet (Hong ea, 2010)

Gangliosidosis³⁰²³

Myoclonic epilepsy³⁰²⁴ – (a) single or repetitive sudden convulsive movements of limbs/trunk; (b) mostly children with idiopathic epilepsy – early morning attacks; (c) photosensitivity myoclonus and epilepsy; and (d) hereditary myoclonic epilepsies – generalised seizures and myoclonus with degenerative disease, e.g. Lafora body disease (autosomal recessive familial disorder; children/adolescents with myoclonus, major seizures and dementia – death within a few years – polyglucosan-Schiff-positive intracellular inclusion bodies in brain, muscle, liver or skin eccrine sweat glands) – a (recessive) gene (Cystatin B-5' UTR) for progressive myoclonic epilepsy³⁰²⁵ has been mapped to 21q. Dravet's syndrome (severe myoclonic epilepsy of infancy, a progressive encephalopathic state) starts (often as febrile seizures initially) in infants and seems to be related to mutations in the sodium channel gene SCN1A

Juvenile myoclonic epilepsy (Janz syndrome) is linked to chromosome 6p (unlike benign familial neonatal convulsions³⁰²⁶ with genes mapped to 8q24 and 20q13.3) and presents in late childhood/early adolescence – myoclonic jerks (mainly early morning) +/- progression to generalised tonic-clonic attacks

Note: Myoclonic and atonic³⁰²⁷ (astatic seizure/drop attack) forms of epilepsy are difficult to control, but may respond to sodium valproate or clonazepam.

Acquired aphasia with epilepsy (Landau-Kleffner syndrome)

The cause is unknown, but encephalitis has been suggested. The child's language develops normally but later, usually at 3-9 years of age, it loses both receptive and expressive language, despite retention of general intelligence. The EEG is abnormal, usually with

³⁰¹⁸ **Autosomal dominant partial epilepsy with auditory features (autosomal dominant lateral TLE)** is due to mutations at 10q24. It is rare. There are simple partial seizures accompanied by auditory +/- visual hallucinations.

³⁰¹⁹ Encephalitis is more likely to be complicated by epilepsy than is meningitis and aseptic meningitis does not appear to be epileptogenic. Also, cerebral abscess leads to epilepsy in about a third of cases.

³⁰²⁰ Secondary to swallowing cestodes (tapeworms): Encephalitis may accompany heavy infestation. Most often cerebral problems are delayed by years when larvae die: epilepsy, ataxia, internal hydrocephalus, and change in personality: calcification of cysts in brain is not as marked as in muscle; x-ray of striated muscle/CT/MRI/biopsy of subcutaneous nodules/serology; treat with praziquantel and steroids; surgery for hydrocephalus.

³⁰²¹ Hydatid disease: brain cysts can cause focal seizures.

³⁰²² Systemic or intra-cerebral kainate injection causes long-lasting limbic seizures. This is followed by hippocampal and other limbic lesions. The electrographic and lesioning are not unlike those in TLE. There is a preference for CA1 and CA3 regions, GABAergic interneurons, pyriform cortex, and other limbic regions. (Ben-Ari, 2008)

³⁰²³ A group of lipid storage disorders, e.g. Gaucher's disease.

³⁰²⁴ An example of a myoclonic disorder that is not associated with seizures is *paramyoclonus multiplex*. The patient is usually an adolescent with widespread muscle jerks.

³⁰²⁵ **Unverricht-Lundborg disease (Baltic or Mediterranean myoclonic epilepsy)**, an autosomal recessive disorder commencing between 6 and 18 years of age, involves stimulus sensitive myoclonus, generalised seizures, ataxia, dysarthria, intention tremor, and dementia. Most cases are due to an unstable expansion of a dodecamer repeat in the 5' region of the cystatin B gene on 21q22.3. A few cases are due to point mutations at the same site. Cystatin B is important in maintaining the structure of nerve cells.

³⁰²⁶ **Benign familial neonatal convulsions (BFNC)** is an autosomal dominant disorder starting anywhere in the first 4 months after birth. Unprovoked generalised or multi-focal seizures of tonic and/or clonic type are seen. There may be breathlessness, eye symptoms, or other indicators of autonomic involvement. Most patients remit by 6 months of age. A minority re-occur during the school years or in young adulthood when seizures may be proved (e.g. by lack of sleep).

BFNC must be distinguished from **benign familial infantile convulsions** (autosomal dominant early childhood partial epilepsy, onset 4-6 months with remission before 3 years; mutations on different chromosomes in different families) and **benign familial neonatal/infantile convulsions** (same family may have onset in neonatal period or early infancy; mutations in voltage-gated sodium channel subunit SCN2A).

³⁰²⁷ Brief loss of muscle tone with falls +/- loss of consciousness.

bilateral temporal but often widespread abnormalities. There are almost continuous spike and wave discharges during slow wave sleep. Most develop seizures around the time that the language changes occur. Onset may be acute or subacute. Two-thirds are left with a receptive language deficit, but the remainder recover completely. Early diagnosis and speech training are important. Remedial or special schooling may be required. Multiple subpial resections may be employed in treatment.

Acquired epileptic opercular syndrome

This is a variant of Landau-Kleffner syndrome. There is progressive loss of voluntary movement of the mouth. The patient has problems with oral expressive movements such as kissing. Feeding difficulties and drooling may also be present. The EEG shows almost continuous spike and wave discharges bilaterally in the rolandic areas during slow wave sleep.

EEG in epilepsy

<i>Appropriate history</i>	<i>Abnormal EEG</i>	<i>Is there epilepsy?</i>
Present*	absent	probably
Absent	present	no
Absent	absent	no
Present	present	yes

*Epilepsy is most likely present if there is a collateral history, if you can see the event, if there is a suggestive cause like tumour or epiloia, if there are signs like scars/bitten tongue/incontinence, if there is a family history (40% of idiopathic generalised cases), etc. You must rule out pseudoseizures, syncope, etc.

10% of normals have epileptiform EEG activity but no history of seizures. Half of epileptic patients have normal routine EEG. After 4 spaced routine EEGs there is a 92% chance of detecting an abnormality. Nasopharyngeal leads carry placement problems, discomfort and frequent artefact. Sphenoidal EEG (via cheeks into sphenopalatine fossae) is used preoperatively.

Syncope (fainting) follows a temporary reduction in cerebral blood supply. Aura (epigastric sensation, vertigo, visual and somatosensory phenomena) is common. There may be myoclonic jerks³⁰²⁸, deviation of the eyes, flickering of eyelids³⁰²⁹, and vocalisation that may confound the unwary diagnostician. Prolactin levels may be raised with syncope.

Stages of tonic-clonic seizures³⁰³⁰

Prodrome – hours/days – uneasiness/irritability/headaches/appetite change

Aura – seconds/minutes – e.g. epigastric sensation (*Déjà vu* may indicate right temporal focus – Plamini & Gloor, 1992)

Tonic – 10-30 seconds – arms flexed and adducted, legs extended, air expelled as a cry, cyanosis, & unconscious

Clonic – 1-5 minutes – violent muscular jerking, bitten tongue, incontinent

Postictal – minutes/hours – unconscious, flaccid, extensor plantar responses, no corneal reflex, headache, confused, muscle aches, +/- automatic or violent behaviour

International Classification of epileptic seizures (simplified)

FOCAL/PARTIAL/LOCAL

With motor symptoms (with [Jacksonian] or without *march* [spread], versive, postural, phonatory [with sounds or arrest of speech]), with somatosensory or special sensory symptoms (somatosensory³⁰³¹, visual³⁰³², auditory³⁰³³, olfactory, gustatory, vertiginous), with autonomic symptoms/signs, with psychic symptoms (e.g. dysphasia, fear, macropsia, musical hallucinations, thought crowding³⁰³⁴, forced thinking³⁰³⁵).

COMPLEX FOCAL

Depending on whether impaired consciousness is present at the start or develops later in the course of the seizure, and whether there is secondary generalisation.

GENERALISED

Absence, atypical absence, myoclonic, clonic, tonic, tonic-clonic, atonic.

International classification of epilepsies and epileptic syndromes

³⁰²⁸ Usually these consist of minor twitches and must be distinguished from tonic-clonic seizures.

³⁰²⁹ *Eyelid myoclonia* with absences (jerking eyelids, eyes may jerk upwards, and the head may be pushed backwards) is a manifestation of an idiopathic generalised epileptic syndrome as is *perioral myoclonia* (absences with jerking of perioral and masticatory muscles).

³⁰³⁰ Generalised tonic-clonic seizures may have autonomic manifestations, e.g. pupillary athetosis (**hippus**), i.e. rhythmic contraction and dilation of the pupils. Less commonly there may be mydriasis or miosis.

³⁰³¹ Partial sensory seizures arise in sensory cortex. Unpleasant contralateral face/limb sensations (tingling/electric) experienced - can spread in Jacksonian-like manner in a seconds (much faster than focal sensory episodes in migraine).

³⁰³² Discharges from the occipital area cause flickering lights and flashes of red or white that must be differentiated from the zig-zag of migraine.

³⁰³³ Auditory seizure phenomena (hissing, roaring, buzzing) are due to discharge from Heschl's convolution (anterior transverse temporal gyrus) and superior temporal convolution.

³⁰³⁴ A feeling of disorganised thoughts being hurried along.

³⁰³⁵ A subjective compulsion to dwell on a certain word or topic.

LOCALISATION-RELATED (FOCAL, LOCAL, PARTIAL), e.g. primary reading epilepsy.

SYMPTOMATIC, e.g. temporal lobe epilepsy

GENERALISED EPILEPSIES & SYNDROMES – idiopathic (age-related such as benign neonatal convulsions, childhood absence epilepsy [pyknolepsy], etc), cryptogenic (= cause suspected) or symptomatic (e.g. Lennox-Gastaut syndrome), symptomatic (of a known disorder).

UNDETERMINED AS TO BEING FOCAL OR GENERALISED, e.g. Landau-Kleffner syndrome.

Causes of death in epilepsy

Unrelated

Seizures

Unexplained sudden death

Drowning³⁰³⁶

Other accidents

Suicide (c. 9%)³⁰³⁷

Underlying cause of epilepsy (e.g. tumour, CVA, degenerative illness)

Status epilepticus (7-39% short-term)

Unknown

The epilepsy population has a standardised mortality ratio (SMR) of 2-3, the idiopathic group having only a slightly increased rate whereas cases arising from known causes account for most of the increased mortality. Population-based studies suggest that mortality is related more often to underlying aetiology rather than the seizures.(Tomson & Forsgren, 2005)

Prolactin: The serum prolactin rises to 1,000 munits/L 20 minutes after most, but not all, generalised seizures³⁰³⁸ (returning to baseline after 6 hours) and is unchanged or moderately raised following pseudoseizures and complex partial seizures. There may be no rise after serial seizures or following status epilepticus. Syncope may raise prolactin levels. Pseudoseizures may be associated with modest elevations of prolactin.

White cell count (WCC): The WCC may increase transiently after a seizure (noradrenaline release and demargination of white cells), but there is no associated 'left shift' as might occur with infection.

Cardiac investigations: Ambulatory ECG for dysrhythmias, echocardiography (structural problems) and tests for changes in blood pressure on standing.

Prognosis: Factors associated with a poor prognosis are a high frequency of tonic-clonic seizures before treatment, partial seizures, neurological deficit, psychiatric and social problems (stress, low socioeconomic status and poor educational attainment), a family history of epilepsy, and a poor response to treatment.(Shorvon, 1991; Betts, 1992; Callaghan ea, 1992) Good outcome is associated with benign epilepsies³⁰³⁹, generalised absence seizures, provoked seizures, long remissions, and recent onset. Onset of idiopathic seizures before age 15 years have shown a cumulative risk of recurrence of 40% at 2 years, and EEG abnormalities increase the seizure recurrence risk. Drug-resistant epilepsy may be more common when seizures are not arrested early on by treatment.(Reynolds, 1990) Data from life insurance statistics suggest a standardised mortality ratio about 2.5 times that of a non-epileptic population.

Febrile seizures: One definition of a febrile convulsion is a seizure associated with fever in infancy or childhood without evidence of intracranial infection or a defined cause other than infection outside the CNS. It is the most common type of seizure. About one child in 30 has at least one febrile convulsion between the ages of 6 months and 6 years, especially between 2 and 4 years. Death is rare.(Vestergaard ea, 2008)

Recurrences of febrile seizures

³⁰³⁶ E.g. during unsupervised bathing.

³⁰³⁷ Risk factors include past psychiatric history, past suicide attempts, and early onset of epilepsy (especially in adolescence). The FDA issued warnings in 2008 that antiepileptic drugs may increase suicidal thinking and behaviour but Gibbons ea (2009) found the opposite in bipolar patients taking this class of medicines!

³⁰³⁸ The prolactin level should be measured 20 minutes after a seizure (post-ictal level) and then compared with the level found in blood at least 6 hours following a seizure or taken at the same time of day when there is no seizure (baseline level).

³⁰³⁹ E.g. benign Rolandic epilepsy.

Occur in one-third of cases

Associated with low risk for epilepsy: 2-4%

Associated with recurrence - fever lasts only a brief time before the fit; temperature not too high before the seizure; complex features of first attack; neurodevelopmental disorders; child < 18 months old; a family history of febrile convulsions; family history of epilepsy; complex febrile seizures (different sources disagree on some of these risk factors, due in part to differences in definition)

About 2.4% of those children who were previously normal will go on to develop at least two non-febrile seizures, i.e. epilepsy. Individual fits respond to rectal diazepam administered by parents. Sadleir and Scheffer (2007) suggest buccal or intranasal midazolam for the 9% of cases with prolonged febrile seizures. Longterm prophylaxis was probably overused in the past. In fact, in the small number of cases who do develop epilepsy the causative role of febrile seizures is tenuous. Phenobarbitone (phenobarbital) treatment is associated with lower IQ scores that persist for many months after the drug is stopped. (Farwell et al, 1990) Carers and/or family require education and reassurance.

Rarely one sees families who seem to have an autosomal dominant inheritance. In some cases febrile seizures persist after age 6 years, plus or minus afebrile seizures (*generalised epilepsy with febrile seizures plus*).

Absence (petit mal) seizures (3 Hz spike-and-wave EEG activity) are seen especially in children and have a tendency to remit over time. By adult life up to 4 out of 5 cases will have remitted. Also, as time passes, the attacks become shorter and more infrequent. Absence attacks very often convert to generalised tonic-clonic attacks: 40% after 5-10 years convert. Absence seizures are thought to be due to abnormal thalamocortical circuitry. There is a strong genetic predisposition. Hyperventilation precipitates attacks.

Autoscopy: Denning and Berrios (1994) described 38 males and 18 women with autoscopy from the literature. 59% had a neurological disorder, most frequently epilepsy. Right- and left-sided lesions were equally represented. Psychotic disorder was also present in 59%, e.g. delirium or depressive.

Temporal lobe epilepsy (TLE) is common³⁰⁴⁰. All limbic structures have a low seizure threshold. The pathology varies from study to study but ischaemia at birth seems important³⁰⁴¹. The anterior temporal and the frontal lobes are highly susceptible to damage from head injury³⁰⁴², and contracoup lesions are commonest at these sites. MRI may reveal loss of hippocampal volume or symmetry. Functions attributed to the limbic structures are many. It therefore is no surprise that the aura may take many forms, such as smells (usually noxious), sorrow, apprehensiveness, elation, visceral sensations, vertigo, tunnel vision (concentric constriction of visual field), or there may be no aura. Déjà vu, jamais vu, grimacing, smacking of lips, depersonalisation, derealisation and aggressiveness may all characterise a seizure. The patient may experience suspiciousness, extreme fear or rage as part of the ictus. Aggressive outbursts may also occur between attacks. Alternatively the patient may become confused and, for a brief while, carry out some semi-purposive action. Disturbed behaviour may occur in a state of clouded consciousness (psychomotor or complex partial status/fugue/twilight state/furor) and this may persist for hours, days, or even weeks. Neuroleptics may be required. The attack may stop of its own accord, or it may be terminated by a grand mal seizure or by a single electroshock (ECT). The author has seen a couple of patients with TLE who believed that one of their eyes contained an evil spirit and who made repeated attempts to pluck the eye out.

Features of complex partial seizures:

Autonomic and visceral ('epigastric aura', dizziness, flushing, tachycardia, other bodily sensations)

Perceptual (distorted perceptions, déjà vu, and olfactory, somatic, visual, auditory hallucinations)

Cognitive (disturbed speech, thought and memory)

Affective (fear and anxiety)

Psychomotor (automatisms, grimacing and other bodily movements, repetitive or more complex stereotyped behavior, changes in breathing, autonomic symptoms)

³⁰⁴⁰ Fyodor Dostoyevsky (1821-1881), Russian writer (*The Brothers Karamazov* and *Crime and Punishment*) and philosopher, had epilepsy (first seizure at age 9 years), perhaps TLE. This may have inspired him to create characters with epilepsy, e.g. Prince Myshkin in *The Idiot*.

³⁰⁴¹ Chromosomal abnormalities (4q) occur in some families with mesial TLE. (Hedera et al, 2007)

³⁰⁴² As illustrated by the research on monkeys conducted by R H Pudenz and C H Sheldon during the 1940s.

The focus in the cases of psychomotor seizures is usually in the temporal lobe and sometimes in the inferior frontal lobe³⁰⁴³.

Complex partial status is associated with confusion, psychosis, fluctuating consciousness, automatisms, episodic hallucinations, marked mood changes, and a diagnostic EEG. IV diazepam is given early because prolonged status may cause persistent intellectual deficits.

Amnesic seizures are characterised by amnesia³⁰⁴⁴ with no other features. The patient is able to carry on normally during the ictus but cannot remember what they did during this time.(Palmini ea, 1992) Onset is in early adulthood. Other seizure types, such as complex partial seizures, can be recognised from the history.

Epilepsy and schizophrenia-like psychosis (ESLP): The connection between ‘schizophrenia’ and epilepsy are possibly more tenuous than when Slater studied this phenomenon.(Slater ea, 1963) Negative studies suggest that sampling bias (e.g. using clinic cases) may have led to a spurious connection. Methodological issues, such as use of discharge diagnosis rather than research diagnosis, hinder interpretation of positive studies. Nevertheless, depth recording of patients awaiting temporal lobectomy has supported the notion that left (see box) temporal foci might carry a special risk for schizophrenia. In a study involving MRI and MRS (Maier ea, 2000) spectroscopic abnormalities were more pronounced in the epilepsy groups (TLE only and TLE + psychosis) and were bilateral, and abnormalities in a group with a diagnosis of schizophrenia only were left-sided. Specific regional hippocampal/amygdala volume reductions were most marked in the group with TLE + psychosis and were bilateral. Left-sided regional volume reductions identified in the dominant hemisphere of schizophrenic patients were also present in the TLE + psychosis group, but not in TLE-only patients. Perhaps this region in the left temporal lobe plays a major part in the genesis of psychosis.

Problems with conclusions about left-sided foci (Sachdev, 2007, p. 275)

Some negative laterality studies

Varied rigour when establishing laterality (e.g. are surface electrodes adequate?)

A one-sided focus does not prove that the other side is normal

Left-sided foci may just be more common for temporal lobe epilepsy

ESLP may have generalised seizures plus a temporal focus

Diagnosis of psychosis is very language dependent, biasing left-sided lesions

Lack of neuropathological support for predominance of left-sided lesions

*Forced normalisation*³⁰⁴⁵ is the situation where the EEG becomes more normal in an epileptic who then develops a paranoid, manic or schizophrenia-like psychosis (*alternative psychoses*), depressed, anxious, dissociated, or simply becomes behaviourally disturbed. The author has had good results with a single application of ECT in such cases. One theory is that chronic temporal ictal lesions cause kindling of activity in other brain areas, especially forebrain limbic areas, with the gradual development of psychosis. Over-controlled epilepsy (by drugs or vagus nerve stimulation: Gatzonis ea, 2000) should lead to a reduction of anticonvulsant doses. Dolmatil has been suggested for epileptic psychosis. A regime that allows the odd seizure and a clear sensorium is superior to complete control at the expense of cognitive impairment.

Temporal lobectomy may be a risk factor for schizophrenia-like psychosis.(Sachdev, 1998)

³⁰⁴³ If the focus is the frontal lobe, seizures often occur in clusters, the start and end of the seizure are often sudden, there is little in the way of confusion later, and content is often bizarre: subject might act as if riding a bicycle or having sexual intercourse, or may emit sounds.

³⁰⁴⁴ Mostly anterograde, sometimes combined anterograde-retrograde, and rarely retrograde. Kapur (1990, pp. 140-151) described *transient epileptic amnesia*: episodes of amnesia, usually occurring in an older person whilst waking, lasting up to an hour and sleep EEG may be necessary to reveal epileptic origin; whilst amnesia may be the only ictal manifestations other TLE phenomena may occur.

³⁰⁴⁵ Described by Heinrich Landolt (1917-1971) of Switzerland in 1953, *forcierte Normalisierung*, paradoxical or spurious normalisation, this phenomenon was inspired by seeing patients who's EEGs improved as their behaviour worsened. Not all short-lived inter ictal psychoses show forced normalisation and some cases of post-ictal psychosis show forced normalisation.(Sachdev, 2007, p. 270)

In general, schizophrenia-like psychosis associated with cerebral trauma is more likely if there is a genetic predisposition to schizophrenia or if there is severe injury with significant brain damage and cognitive impairment.

Findings of Qin et al (2005)

- Increased incidence of schizophrenia and schizophrenia-like psychosis in people with history of epilepsy
- Family history of psychosis or epilepsy is a risk factor for schizophrenia and schizophrenia-like psychosis
- Effect of epilepsy greatest if there is no family history of psychosis
- The increased risk for schizophrenia and schizophrenia-like psychosis does not differ by type of epilepsy but is increased with a greater number of hospital admissions and is greater for those who are first admitted for epilepsy at later ages

Findings of Adams et al (2008):

- 319 cases of focal epilepsy admitted for video EEG monitoring
- Significant association found between prevalence of depressive symptoms and non-lesional focal epilepsy
- No significant differences in prevalence of neuropsychiatric disorders between epilepsy arising in temporal lobe or outside it

Geschwind syndrome (Benson, 1991) is a somewhat controversial interictal syndrome said to be found in some longstanding cases of TLE. The patient experiences certainty, the 'truth' ('eureka' feeling), clairvoyance, mystical or cosmic consciousness, all of which may seem to 'float', i.e. the patient is unable to link the experience to a specific content.

Epileptic automatism may be defined as a state of clouding of consciousness which occurs during or immediately after a seizure and during which the individual retains control of posture and muscle tone and performs simple or complex movements and actions (e.g. undressing) without being aware of what is happening. It is rarely a justifiable defence for crime. Automatism is legally defined as an unconscious involuntary action and two types are recognised: 'insane' (absent *mens rea* - caused by disease of the mind - insanity verdict with compulsory detention in hospital) and 'non-insane' (mind affected by some external factor - complete acquittal). From the medical standpoint this approach is naïve and the court should have discretionary powers of disposal in individual cases.

Most cases of violence in association with epilepsy occur when attempts are made to restrain a patient who is experiencing a seizure.³⁰⁴⁶

Interictal depression is common. Rates of depression, often atypical and dysthymic with brief intervals of euthymia, and suicide are about 4 to 5 times those found in the population at large, and suicide may be 25 times the general population rate in people with TLE. (Harris & Barraclough, 1997) Some depressive feeling are found in the majority of epileptics. The combination of interictal dysthymia and intermittent irritability, impulsiveness, anxiety and somatic symptoms has been called interictal dysphoric disorder by Blumer et al. (1995) Brain and brainstem changes in 5-HT_{1A} receptor density have been reported in major depressive disorder and in TLE using PET and Lothe et al (2008) used PET to confirm changes in central serotonergic pathways³⁰⁴⁷ (probably decreased extracellular serotonin concentration but possibly receptor upregulation) in depressed TLE patients.

Interictal panic disorder affects about one-fifth of epileptics. (Pariente et al, 1991)

Anticonvulsants (AEDs)

A small number of patients treated with AEDs may experience thoughts of self harm or suicide and patients should be monitored for these and for depression. (Irish Medicines Board, 2009)

³⁰⁴⁶ An association between **violence and epilepsy** is more likely under the following circumstances: the person has proven epilepsy, there is no obvious external gain/motive, he was obviously having a seizure when he was violent and the stereotyped seizure pattern for that individual is consistent with the reported behaviour, and the behaviour/thinking is not structured/deliberate/conscious as when the patient goes to another part of the house to collect a dangerous weapon where he knows it to be stored.

³⁰⁴⁷ Especially found in raphe nuclei, insula, cingulate gyrus, and epileptic hippocampus.

General rules include avoiding high levels and polypharmacy, monitoring behaviour and school performance, and avoiding barbiturates in children where possible. When changing from one drug to another: add second drug slowly to full dosage and only then withdraw first drug slowly. Monotherapy should be tried for six months for epilepsy, before any changes in medication are made. Carbamazepine is a commonly used drug, phenytoin being less often employed than heretofore. Sodium valproate has teratogenic effects in women during their childbearing years. Any young woman free from fits for 2 years should be offered the choice of withdrawing from anticonvulsant treatment. Proposed mechanisms for mental effects of anticonvulsants include neuropathological damage, folate deficiency, effects on monoamine metabolism, and effects on hormone metabolism. Anticonvulsant-induced encephalopathy (e.g. phenytoin or valproate) may produce a (reversible) dementia-like picture, +/- focal signs and dyskinesias, in association with increased CSF protein levels. Consider this diagnosis in an epileptic who develops cognitive impairment³⁰⁴⁸.

Most AEDs work by enhancing GABA neurotransmission. Antiepileptic drugs (AEDs) promote metabolism of the contraceptive pill. Therefore a different form of contraception may be required. ECT is rendered less effective if the seizure duration is shortened with Lidocaine. Certain anticonvulsants, such as phenobarbitone (phenobarbital), may cause depression. Toxic levels may cause 'sticky' (slow) cerebration and movement. Ataxia is then likely. However, phenobarbital³⁰⁴⁹ is cheap and may be affordable in non-affluent societies. (Kale & Perucca, 2004) Frequent fitting and recurrent head trauma may lead to coarsening of the personality. Drugs may be stopped as a form of protest against having the condition. Folate deficiency may be due especially to phenytoin (Epanutin) but over-treatment with folic acid may cause dyscontrol because of its own effects on plasma anticonvulsant levels. Reduced sex drive in treated epileptics may in part be due to increased destruction of sex hormones by induced liver enzymes.

Anticonvulsant and other drugs

Carbamazepine (Tegretol; O'Shea, 2002b) is an iminodibenzyl related to imipramine. It can also be classified as a carboxamide. Carbamazepine suppresses repetitive neuronal firing by stabilising voltage-gated sodium channels. It is indicated for generalised tonic-clonic seizures, partial seizures, paroxysmal pain (e.g. trigeminal neuralgia), alcohol withdrawal, BZD withdrawal, mania, and prophylaxis of bipolar affective disorder and perhaps unipolar melancholic depression. It may exacerbate petit mal (absence) seizures. Carbamazepine should be avoided in those patients who have AV conduction defects³⁰⁵⁰ or porphyria. It should be stopped if there is an allergic skin reaction or deterioration in liver function. Routine liver function tests may be performed more often for legal reasons rather than for cost-effectiveness and some experts suggest that hepatotoxicity, a rare phenomenon with anticonvulsants, may be picked up more readily by clinical examination than by laboratory examination. White cell counts and LFTs should be performed at baseline and, perhaps, at intervals thereafter. However, has been argued that routine WCC counts will miss agranulocytosis because of its rarity and sudden onset. It may be safer to ask patients to report pyrexia, pharyngitis, other infection, petechiae, or weakness and pallor. Non-progressive or fluctuating leucopaenia (and anaemia), often early in treatment, is common and usually harmless. Should the leucopaenia be severe or accompanied by clinical signs (e.g. pyrexia or sore throat) the drug should be stopped and the WCC checked. Serious side effects, such as agranulocytosis and aplastic anaemia, occur in only 1 in 10,000 to 120,000 treated patients³⁰⁵¹. It may be necessary to cover sudden withdrawal with a BZD. Carbamazepine may interfere with driving and it can cause folate deficiency. The half-life of

³⁰⁴⁸ There are many causes of **cognitive dysfunction** in association with epilepsy: primary brain dysfunction, brain damage caused by seizures including status, head injury, medication, other drugs including alcohol, and the psychosocial difficulties that may accompany the disorder. Between 10-20% of epileptic children have persistent or progressive intellectual impairment, especially when seizures are poorly controlled and when there are adverse psychosocial circumstances. Perhaps as a result of atrophy of the hippocampus as a result of seizure activity, deterioration of memory function is common in adults whose TLE is poorly treated.

³⁰⁴⁹ Drug-induced falls in **testosterone levels** may cause sexual problems in either sex. Anticonvulsant drugs, by inducing liver enzymes, may increase circulating levels of sex hormone-binding globulin with consequent reduction in levels of unbound testosterone. Phenobarbital, phenytoin and carbamazepine are particularly likely to do this, but lamotrigine is unlikely to do so.

³⁰⁵⁰ Anything greater than first degree heart block.

³⁰⁵¹ Some authors put it at 1 in >575,000 treated patients/year.

carbamazepine is 13-17 hours and there is 70-80% protein binding. Drugs such as cimetidine, dextropropoxyphene, diltiazem, erythromycin, INAH, viloxazine³⁰⁵², and verapamil inhibit the metabolism of carbamazepine. Nifedipine does not have this effect. Fluoxetine may increase carbamazepine levels. Valproate raises the concentration of the toxic 10,11-epoxide metabolite of carbamazepine so that while carbamazepine levels may be normal the patient may be toxic since the metabolite is not being measured. Carbamazepine induces liver enzymes and can reduce the effectiveness of some drugs, e.g. antipsychotics, steroids (including oestrogen), theophylline, warfarin, and other antiepileptic drugs. TCA plasma levels may be reduced by 40-45% for the same reason. The dosage of anticoagulant drugs may require modification. Contraceptive drugs may show reduced efficacy and there may be breakthrough bleeding or spotting; it is recommended that a pill containing at least 50 mcg of oestrogen is used or that another method of contraception is employed. Strictly, carbamazepine should be avoided within two weeks of MAOI therapy to avoid hypertensive crisis, but the combination has been safely employed. Side effects of carbamazepine are usually most marked early in treatment.

Carbamazepine: side effects

CNS – dizziness, diplopia, blurred vision, headache, somnolence, ataxia, confusion (with agitation in elderly), dystonia, worsening of multiple sclerosis symptoms
 GIT – dry mouth, nausea, diarrhoea, constipation, anorexia
 Metabolic – water intoxication, hyponatraemia
 Endocrine – low T4 level with normal TSH level³⁰⁵³
 Skin – reversible generalised erythema in c 3%, and (rarely) severe reactions like exfoliative dermatitis, Stevens-Johnson syndrome (rash with symptoms equivalent to a severe burn – may kill from superimposed bacterial infection or lead to disfigurement), toxic epidermal necrolysis, hair loss
 Haematology – leucopaenia (may be reversed by lithium), thrombocytopaenia, agranulocytosis, aplastic anaemia, thromboembolism
 Others – oedema (dose-dependent), fever, proteinuria, lymphadenopathy, acute renal failure, cardiac conduction disorders³⁰⁵⁴, hepatitis³⁰⁵⁵, immunoglobulin deficiency
 Overdose³⁰⁵⁶ – tremor, excitement, seizures, hypo- or hypertension, diminished consciousness, EEG and ECG (including arrhythmias) changes

*Oxcarbazepine*³⁰⁵⁷ (Trileptal – 150 mg, 300 mg, and 600 mg tablets and 60 mg/ml oral suspension): This 10-keto analogue of carbamazepine is used for partial seizures with/without generalised tonic-clonic seizures, as mono- or adjunctive therapy. (Anonymous, 2002c) It may offer improved tolerability over carbamazepine and there is disputed evidence that it might be efficacious in bipolar disorder (Hirschfeld & Kasper, 2004; Grunze, 2008) Dose is adjusted in elderly or with poor renal function or risk of *hyponatraemia*. Dosage adjustment not needed for mild/moderate hepatic impairment. Monitor serum sodium for hyponatraemia (2.5% incidence – severe cases can lead to seizures). Weigh regularly (to detect fluid retention) if there is cardiac insufficiency/failure. Very rarely causes hepatitis, usually with good outcome. May render anovulants ineffective (may need higher potency contraceptive or supplementation with barrier method). Inhibits CYP2C19 and therefore can affect phenobarbitone (phenobarbital), phenytoin, etc. Can induce CYP3A4 and 3A5 so increasing metabolism of dihydropyridine calcium antagonists, anovulant pills, and anticonvulsants such as carbamazepine. It does not reduce the anticoagulant effect of warfarin. No autoinduction has been noted. Avoid with MAOIs on theoretical

³⁰⁵² Withdrawn from market.

³⁰⁵³ Clinical hypothyroidism is unusual and may be due to reduced TSH response to TRH. Whilst lithium causes a decreased thyroxine with increased TSH, carbamazepine causes a decrease in thyroxine with normal TSH.

³⁰⁵⁴ Quinidine-like action of this tricyclic drug: consider valproate for patients with heart disease who have bipolar affective disorder.

³⁰⁵⁵ Less than 5% of patients experience a benign rise in liver enzyme levels and perhaps less than 1 in 10,000 patients experience a serious acute hepatic necrosis and then usually during the first weeks of therapy.

³⁰⁵⁶ Following massive overdose, peak plasma concentrations may be reached on second or third day after ingestion.

³⁰⁵⁷ This is the 10-keto analogue of carbamazepine. Liscarbazepine is an active metabolite of oxcarbazepine which has been tried for mania with little success. Eslicarbazepine, an isomer of liscarbazepine, is being studied as a possible mood stabiliser.

grounds because it is a TCA relative. There is a possibility of neurotoxicity if it is combined with lithium. Avoid breastfeeding (milk-plasma ratio = 0.5) and possible teratogenicity (cleft palate?). Common problems: fatigue, asthenia, dizziness, headache, somnolence, agitation, apathy, amnesia, ataxia, impaired concentration, confusion, depression, nervousness, nystagmus, tremor, nausea, vomiting, constipation, diarrhoea, abdominal pain, hyponatraemia (esp. in elderly), acne, alopecia, diplopia, vertigo. Uncommon: leucopaenia, increased transaminases +/- alkaline phosphatase, urticaria. Rare: angioedema, rash (Stevens Johnson, SLE), fever, lymphadenopathy, abnormal LFTs, eosinophilia, thrombocytopaenia, arthralgia, cardiac arrhythmia (A-V bloc, etc), hepatitis, hyponatraemic seizures, confusion, encephalopathy. Between 25-31% of patients with allergy to either oxcarbazepine or carbamazepine are allergic to both drugs. Oxcarbazepine's metabolite MHD³⁰⁵⁸ blocks voltage-sensitive sodium channels. Elimination of metabolites is mainly renal.

Sulthiame (Ospolot): Sulthiame, an anti-epileptic sulphonamide like acetazolamide, may increase phenytoin levels into the toxic range.

Barbiturates: These can cause hyperactivity, attention deficit disorders, behavior disorder, and cognitive deficits. Phenobarbital raises the seizure threshold probably by membrane stabilisation.

Primidone (Mysoline): Converted to phenobarbitone by liver. It has been associated with psychosis and depression.

Phenytoin (Epanutin): May act by limiting the spread of discharge, probably by membrane stabilisation. Can be given once daily because plasma half-life = 24-36 hrs. There may be facial coarsening, gingival hyperplasia, acne and hirsutism. Osteomalacia may occur due to reduced calcium absorption. Chronic encephalopathy can occur with high therapeutic levels, and acute delirium (especially in the elderly) is also described. Abnormal cognition can occur with low folate levels. There have been some cases of fatal acute liver disease, usually when given with other anticonvulsants. It is best avoided in presence of active liver disease. Sulphonamides decrease phenytoin metabolism and may precipitate phenytoin toxicity.

Valproate: A short chain fatty acid³⁰⁵⁹ that is useful for generalised epilepsy. (Marson ea, 2007a) Chronic encephalopathy can occur with high levels. Weight gain can occur. Thrombocytopaenia is a relatively frequent side effect of valproate in the elderly. (Trannel ea, 2001) Beta-blockers reduce tremor caused by either lithium or valproate. Aspirin increases valproic acid levels.

Ethosuximide: This succinimide may be associated with psychosis, especially in young adolescents.

Benzodiazepines: BZDs, valproate, barbiturates and vigabatrin may work by enhancing the effects of GABA. Diazepam can be given by rectal infusion for status epilepticus. Intravenous lorazepam may provide a more prolonged anticonvulsant effect than is achieved with intravenous diazepam. (Leppik ea, 1983) (ECT may also be used to treat status: Petrides ea, 2004) Clonazepam's effects are reduced after a few weeks. There may be increased aggressiveness or children may become irritable and hyperactive. Clobazam (Frisium) is often better tolerated than clonazepam but it has the same problem of tolerance, but it may be of use for special occasions, catamenial seizures, or for seizures occurring in clusters.

Drug treatment protocol for convulsive status epilepticus³⁰⁶⁰ (abbreviated from Renganathan ea, 2007; Mellers, 2009, p. 375)

Lorazepam 4 mg IV bolus repeated if needed after 10 minutes

OR

Diazepam 5-10 mg over 1-2 minutes repeated at 15 minute intervals if needed (max: 20 mg)

OR

Midazolam 10 mg by buccal route given by carer or ambulance personnel, repeatable 15 minutes later

IF SEIZURES CONTINUE:

Inform anaesthetist

Phenytoin 15-18 mg/kg IV not faster than 50 mg/minute (half this for elderly) – then 5-6 mg/kg bolus every 6 hours

OR

Phenobarbitone 10 mg/kg (not faster than 100 mg/minute) – then 1-4 mg/kg/day PO, IV or IM

IF SEIZURES CONTINUE:

³⁰⁵⁸ Formed by hepatic cytosolic enzymes.

³⁰⁵⁹ Valproate, tiagabine and vigabatrin are fatty acids.

³⁰⁶⁰ **Status epilepticus** = epileptic activity persisting for at least half an hour. If the seizure is tonic-clonic it is called convulsive status. Status affects 1 in 20 adults during life, but the figure for children is one-quarter. Treatment is needed when at least 5 minutes elapses. Absence status, although benign, may be stopped with benzodiazepines. The same applies to complex partial status. (Mellers, 2009, p. 375)

Involve anaesthetist
 ICU, intubation, cardiorespiratory support
Thiopentone 100-250 mg bolus over 20 seconds – then 50 mg bolus every 2-3 minutes until seizures stop – may require follow-on infusion

Lamotrigine (Lamictal, Lamotrigine Ranbaxy): Useful for partial (Marson *et al*, 2007b) and generalised tonic-clonic seizures that are not satisfactorily controlled by other AEDs. Lamotrigine inhibits excitatory presynaptic neurotransmitter release, especially glutamate. It also blocks sodium channels and 5-HT₃ receptors. Does not induce or inhibit hepatic drug-metabolising enzymes. A limited number of reports of breakthrough seizures, unexpected pregnancies and of menstrual bleeding disorders (such as breakthrough bleeding) have been reported to GlaxoSmithKline in women on a combination of lamotrigine and the contraceptive pill. Anovulants decrease serum levels of lamotrigine and such levels may then rise on stopping the contraceptive pill. Lamotrigine increases sense of well-being. Some patients report an improvement in sexual interest (unlike other AEDs). Rare associated problems are severe allergic skin rash (Stevens Johnson or toxic epidermal necrolysis/Lyell syndrome) and psychiatric (sometimes aggressive) reactions. Drugs that induce liver enzymes like carbamazepine or phenytoin can halve the half-life of lamotrigine, while sodium valproate, which inhibits its metabolism, can double the half-life of lamotrigine. Lamotrigine may precipitate carbamazepine toxicity. Side effects include rashes, headache, nausea and vomiting, dizziness, diplopia, ataxia, and, in high doses, tremor. Leucopaenia and thrombocytopenia can occur. Hypothroidism is a rare complication. Lamotrigine has been reported to cause a condition resembling Tourette's syndrome in children that is reversible on stopping the drug. (Kellett & Chadwick, 2004, p. 331) Avoid lamotrigine during pregnancy or lactation.

Vigabatrin (Sabril): A GABA analogue (one of the gamma-amino acids) that irreversibly inhibits the enzyme responsible for GABA catabolism (GABA transaminase) thereby increasing GABA availability in the synaptic space. Vigabatrin has been suggested as an add-on treatment for partial seizures, with/without secondary generalisation, uncontrolled by other drugs or monotherapy for infantile spasms. In practice, its use is restricted because of ophthalmic problems to very severe epilepsy (e.g. West syndrome). Finnish research originally raised concerns about risk of inducing dystonia, dyskinesia, and hypertonicity as well as 'cytotoxic oedema' on MRI. The latter appear to be more likely in babies receiving doses of at least 125 mg/kg/day. However, these MRI changes were asymptomatic and transient and usually resolved whether vigabatrin was continued or not. (Wheless *et al*, 2009) Vigabatrin therapy should only be initiated by epileptologists, neurologists or paediatric neurologists. It can cause drowsiness, fatigue, nervous irritability, aggression and psychosis (especially if there is a history), depression, disturbed vision (*irreversible visual field defects in one-third of cases – may take months or years to develop*) and memory, excitement and agitation in children, and increased frequency of (especially myoclonic) seizures. All patients should be screened at the start of treatment and regularly thereafter for visual field defects. Dose reduction is indicated for significant renal impairment. Dose may need adjustment because of combination with other agents. Avoid during pregnancy or lactation. Interestingly, vigabatrin may have utility in treating cocaine dependence. (Brodie *et al*, 2009) A risk-benefit analysis should be conducted before prescribing vigabatrin. According to Clarke (2009, p. 1142) vigabatrin 'is no longer advocated' because of the effects on vision. *Lacosamide* (Vimpat) is an adjunctive treatment for partial-onset seizures with/without secondary generalisation in epileptic patients aged at least 16 years. It modulates sodium channel activity in a novel way. It binds to collapsin response mediator protein-2 (CRMP-2³⁰⁶¹). It may be associated with depression, headache, somnolence, asthenia/fatigue, dizziness/vertigo, problems with balance/gait (may fall), pruritus, nausea/vomiting/constipation/flatulence, tremor, nystagmus, double and blurred vision, memory/cognitive impairment, and skin laceration.

*Gabapentin*³⁰⁶² (Neurontin, Rangsabax): Although structurally resembling GABA it has no direct effect on GABA. Has its own CNS binding site ($\alpha 2$ - δ subunit of calcium channels) and does not interact with the GABA receptor. It is used as an add-on drug for partial seizures, with/without secondary generalisation. Mood stabilising properties are poor, although a role as an anxiolytic (e.g. in social anxiety disorder) has been suggested. It may relieve some cases of tardive dyskinesia. (Hardoy *et al*, 1999) It was said to have

³⁰⁶¹ CRMP-2 is a phosphoprotein mainly found in neural tissue and has a role in neuronal differentiation and the control of axonal outgrowth.

³⁰⁶² Short half-life of 6 hours.

analgesic effects in people with neuropathic pain, possibly by an action on N-type calcium channels, but marketing forces may have been at play here (see Landefeld & Steinman, 2009). It can cause sedation, fatigue, ataxia, dizziness, nystagmus, headache, tremor, nausea and vomiting, diplopia, amblyopia, rhinitis, pharyngitis, dysarthria, nervousness, dyspepsia, amnesia and myalgia. Rare associations include pancreatitis, increased liver enzymes, erythema multiforme, Stevens Johnson syndrome, and (of unproven association) unexplained death. There are no major interactions. Avoid during pregnancy or lactation. Avoid antacids because they reduce gabapentin absorption.

Tiagibine (Gabitril): A nipecotic acid derivative that specifically inhibits GABA uptake (at GAT1 GABA transporter) into neurones and glia. An add-on therapy for partial seizures, with/without secondary generalisation, it does not interact with oral contraceptive drugs, and predictable effects are due to linear pharmacokinetics. Plasma level monitoring is not required.

*Topiramate*³⁰⁶³ (Topamax): This drug selectively blocks glutamate receptors, is a calcium antagonist, it potentiates GABA, and it inhibits carbonic anhydrase. Topiramate, an add-on therapy for epilepsy, has a spectrum similar to phenytoin or carbamazepine. There is an associated risk of renal calculus³⁰⁶⁴ (espc. if combined with other carbonic anhydrase inhibitors such as acetazolamide³⁰⁶⁵). Dose-related cognitive impairment may occur. *Acute myopia and secondary angle-closure glaucoma* have been reported, typically within first month of therapy (acute onset of decreased visual acuity and/or ocular pain with myopia, redness, shallow anterior chamber, raised intraocular pressure with or without mydriasis: stop the drug quickly and treat any raised intraocular pressure). Weight loss may occur as may metabolic acidosis. It has been used as adjunctive therapy in bipolar disorder, e.g. it may reduce weight gain when combined with olanzapine (Vieta et al, 2004); however, evidence for efficacy of topiramate in mania is lacking. (Grunze, 2009)

Levetiracetam (Keppra): This S-enantiomer pyrrolidine derivative is available for persons over 16. It is employed as adjunctive treatment for partial seizures with or without generalisation. Unknown mode of action, but GABA is involved. Side effects include somnolence, asthenia, dizziness, agitation, hostility³⁰⁶⁶, emotional lability, depression, ataxia, and (rare) psychosis. No drug interactions to date. (Anonymous, 2002b)

Zonisamide (Zonegran): A sulfa drug that blocks sodium channels and T-type calcium channels. Weight loss may occur (due to carbonic anhydrase inhibition). It is used for difficult-to-treat partial epilepsy. Zonisamide causes renal stones in 2-4% and it carries a small risk of Stevens Johnson syndrome.

Pregabalin (Lyrica): Used as adjunctive therapy for partial seizures and for anxiety disorders, fibromyalgia, and neuropathic pain of diverse aetiologies. Pregabalin is related to gabapentin. It is more selective on $\alpha 2\text{-}\delta$ subunit of calcium channels than gabapentin.

Felbamate (Felbatol): This appears to work on NMDA and GABA receptors. It is used in USA and one specialist Irish centre for refractory epilepsy. (Kearney & Delanty, 2009) It can cause stimulation. Aplastic anaemia and severe liver damage have been reported.

Treatment with drugs (see preceding notes)

- (a) Generalised – tonic +/- clonic – carbamazepine, sodium valproate, phenytoin
 - simple absence – sodium valproate, ethosuximide
 - complex absence or atonic – sodium valproate, clonazepam, clobazam (Frisium)
 - infantile spasms – ACTH/steroids, clonazepam
- (b) Partial – simple, complex and secondarily generalised – carbamazepine, sodium valproate, phenytoin
- (c) Second line drugs include phenobarbitone, primidone, clonazepam, clobazam, vigabatrin, and lamotrigine.
- (d) Depression in epilepsy – SSRIs are the drugs of first choice but they may interfere with anticonvulsant levels (sertraline and trazodone may be safer in this regard); start low and go slow; and consider need to increase anticonvulsant drug dosage when adding an antidepressant. Maprotiline and bupropion (especially if dose > 450 mgs/day and in eating disorders) can be particularly epileptogenic.

³⁰⁶³ A carbohydrate derivative of fructose, it was proved to be of limited value in treating diabetes.

³⁰⁶⁴ The risk is about 1.5%. Keep the patient adequately hydrated. The cause is carbonic anhydrase inhibition.

³⁰⁶⁵ Acetazolamide is a sulphonamide.

³⁰⁶⁶ Potentially this may lead to assault.

(e) Neuroleptics in epilepsy³⁰⁶⁷:

- Avoid clozapine³⁰⁶⁸, chlorpromazine and loxapine (highly epileptogenic)
 - Haloperidol is drug of choice
 - Risperidone or sulpiride suitable for longterm use
 - Trifluoperazine, fluphenazine, zuclopenthixol, molindone, and thioridazine are second choice agents
 - Combinations of neuroleptics increase risk of seizures
 - Start low and titrate slowly
 - Monitoring blood levels of combined neuroleptic-anticonvulsant therapy may help
 - If psychosis is attributable to an anticonvulsant, change the anticonvulsant
- Anti-epileptic drugs during pregnancy* (Tomson & Hiilesmaa, 2007)
- Cause slight increase in malformation rate
 - Avoid valproate unless it is the only drug that controls the seizures
 - Use monotherapy and lowest effective dose
 - Compliance is paramount
 - Measure serum level at least during each trimester
 - Use folate prophylaxis (up to 5 mg/day)

Surgery is used for patients not responding to optimal drug therapy and for whom the epilepsy is intolerable. The patient/guardian must understand the issues involved, seizures should be disabling despite appropriate medication trials (at least 2 different drugs) and not be due to idiopathic generalised epilepsy, and tests results must suggest that surgery will be helpful (an epileptogenic zone should be identified so that just the right amount of tissue is resected). Comprehensive presurgical evaluation³⁰⁶⁹ is not always readily available and patients often come to surgery after many years of epilepsy. This delay, added to long waiting lists, does not help to improve seizure and functional outcomes. Procedures include focal resection of epileptic tissue, modified hemispherectomy, corpus callosotomy, stereotactic procedures, and multiple subpial resections. (see Shorvon, 1991) The latter procedure, used when onset of seizure activity arises in areas of exquisite cortex, involves multiple cuts that preserves vertical but reduces lateral neural transmission, i.e. it preserves columnar pathways. Multiple subpial resections are effective for Landau-Kleffner syndrome. The lower the IQ the more likely is pathology to be diffuse and the less likely is there going to be a good outcome from surgery. About 60% of patients are seizure free at 10 years post-surgery compared to 5-14% who are not operated on. (Ryvlin & Rheims, 2008) Experienced centres experience a 1% rate of neurological impairment from infectious or vascular causes.

Complications of temporal lobectomy

Death (< 0.5%)

Visual field defect (usually asymptomatic; symptomatic in 15%)

Transient diplopia (common with en block resection)

Persistent hemiplegia (2%)

Psychiatric disorder (2%)

Persistent dysphasia (1%)

Memory impairment (rarely severe; lesser degrees are common)

Chronic and excessive protectiveness over many years by carers may jeopardise post-operative function despite lack of seizures.

³⁰⁶⁷ Benzodiazepines may suffice for post-ictal psychosis. If antipsychotics are used they should be stopped when symptoms abate.

³⁰⁶⁸ This is not an absolute injunction. (Langosch & Trimble, 2002) If clozapine is used it should be commenced in hospital. Combined with carbamazepine it may cause agranulocytosis, or sedation and weight gain if used with valproate. Lamotrigine and clozapine may be preferable.

³⁰⁶⁹ Detailed personal and collateral history and physical examination, interictal EEG (including videotelemetry), MRI, PET, ictal SPECT, and magnetoencephalography are useful. The intracarotid amytal (Wada) test can be used to determine language dominance, although fMRI may eventually displace the Wada. Intracranial EEG recordings (subdural grid to locate superficial epileptogenic zone [EZ]; depth electrodes [including stereo EEG] to detect deep EZ) are often necessary. Electrical stimulation of a suspected EZ may reproduce the ictus.

Vagal nerve stimulation, used for intractable epilepsy, involves placing a small computer in the chest wall with electrodes sitting on the vagus nerve. A hand-held magnet can trigger intermittent pulses if an aura is experienced. Efficacy may depend on impulses travelling back to the brain³⁰⁷⁰. It is suggested that it may reduce seizure frequency by about 30%.

Transplantation surgery: Phenytoin and phenobarbital may reduce immunosuppressant drug levels with the risk of precipitation of graft rejection. Carbamazepine and gabapentin are the preferred drugs for seizures in such cases. (Surman & Prager, 2004, p. 666)

Interventions during a seizure: Ensure a patent airway. Only move the person if there is danger (e.g. fire) and *do not insert anything in the mouth*³⁰⁷¹ (tongue biting occurs immediately a seizure starts and tongue-swallowing is a myth except with partial seizures arising in the Sylvian region³⁰⁷²). When the fitting stops put the person in the semi-prone position and stay with him/her until all drowsiness and confusion clears. Recurrent or prolonged seizures require medical intervention: airway, O₂, and IV anticonvulsant such as 10 mg diazepam if necessary. Aetiology (including anticonvulsant levels) may need investigation.

Dangerous activities: Anything that poses a danger should be discouraged until over 6 months seizure-free, e.g. cycling.

Notes on driving

*Republic of Ireland*³⁰⁷³

- Pattern of nocturnal seizures only must be established for 12 months before being allowed to drive a car

*UK*³⁰⁷⁴

- Do not drive until no seizure for 12 months after a single seizure
- Epileptics must have no seizure for 12 months or, in the case of exclusive nocturnal attacks, none for 3 years; no driving during withdrawal of anticonvulsants and for 6 months after withdrawal
- Heavy goods/public vehicle drivers not allowed a licence if any seizure after 5 years of age unless off medication for over 10 years with recurrence and must have no epileptogenic cerebral lesion
- It is recommended that one should not drive during withdrawal of medication after seizure remission or for 6 months thereafter
- Any seizure means one can never be an airline pilot

EU

- Permission to drive in one state may not apply in another state

USA

- No consensus on when a patient with *dementia* should stop driving, some experts saying immediately, and others suggesting that the mildly demented are safe driving slowly in familiar, well-lit environments (APA, 2002)

Tumours affecting the CNS

The commonest cerebral tumours in adults are metastatic and are often multiple and widespread. Since the annual incidence of primary tumours of the CNS in the UK is 6.6/100,000 of the population, they are bound to overlap with psychiatric disorders. One French study in the 1960s found that 1/200 admissions to a psychiatric unit had a brain tumour. In childhood primary CNS tumours are the second commonest malignancy after the leukaemias. Interestingly, a low grade tumour is more likely to present with a seizure than is a rapidly infiltrating neoplasm. Ross *et al* (2003) found that of survivors of cancer in childhood and

³⁰⁷⁰ Nucleus solitarius in the brainstem, hippocampus and cortex.

³⁰⁷¹ A tooth may be broken by people putting a spoon or depressor into the mouth with the danger of aspiration.

³⁰⁷² Here, tongue involvement carries a risk of aspiration. The usual victim is a sleeping adolescent.

³⁰⁷³ Psychiatrists are poor at documenting advice given to patients re the effects of treatment and symptoms on driving. (Langan, 2009)

³⁰⁷⁴ See Shorvon (1995) and Beghi and Sander (2005) for Britain and Europe.

adolescence only survivors of brain tumour had an increased risk of hospitalisation for a psychiatric disorder.

Brain tumours can lead to compression symptoms, meningitis, dementia, cerebellar degeneration, degeneration of posterior root ganglia, peripheral neuropathy, and myopathy. The tumour may be wholly outside the CNS in many instances. Depression³⁰⁷⁵, delirium and dysmnnesia are also found in association with malignant disease. Tumours causing abulia are most often found to affect the frontal lobes. Abulia may respond to methylphenidate or dexamphetamine.

Panic attacks are not uncommon presenting features of brain tumours, including tumours of the pituitary gland. Limbic system involvement may be associated with a clinical diagnosis of 'schizophrenia'. A detailed clinical history and a careful physical examination are still the best predictors of brain pathology. CT is the usual first neuroimaging technique employed, although MRI allows better visualisation of the posterior fossa, i.e. use CT if tumour resides above the tentorium and MRI if the tumour lies below the tentorium. In practice, the yield of abnormal results is small. Patients who need a thorough investigation include those who have intellectual deterioration, impaired consciousness, unexplained personality changes of 'frontal lobe' type, and suspected increase in intracranial pressure.

Steroid therapy may cause irritability, insomnia, lability of affect, and psychosis. Whilst dexamethasone-induced mania often abates quickly, prolonged attacks may occur and necessitate lithium or anticonvulsant drug therapy. Dexamethasone may cause insomnia, delirium, psychosis, peptic ulceration, myopathy, osteopenia, or increase the risk for *Pneumocystis carinii* pneumonia. Radiotherapy may cause acute cognitive dysfunction or a sub-cortical dementia that may not present for months or even decades.(Armstrong ea, 2002) Radiation is most likely to cause memory dysfunction in the elderly and in those receiving high doses. Chemotherapy rarely causes cognitive dysfunction when employed to treat primary brain neoplasia. Debulking³⁰⁷⁶ can improve psychological function, although oedema may need to resolve before this becomes obvious. However, frontal lobe lesions are a risk attached to such interventions.

Prolactinoma: These are benign neoplasms, accounting for 40% of pituitary tumours. Over 90% are small and intrasellar. Prolactinomas are divided into microadenomas (<10 mm in diameter) and macroadenomas (>10 mm in diameter). Prolactin levels are highest with the larger tumours. Hyperprolactinaemia can cause infertility and gonadal dysfunction.

Normal prolactin levels³⁰⁷⁷ in females and males are <25 and <20 µg/L respectively. Levels rise 10 times in pregnancy. Drugs rarely raise prolactin levels above 100 µg/L.

Idiopathic hyperprolactinaemia should be followed up in case small tumours are missed.(Schlechte, 2003) Premenopausal females may develop amenorrhoea³⁰⁷⁸ and infertility, and 80% have galactorrhoea.

Hyperprolactinaemia may be detected after stopping the anovulant pill, but there is no evidence incriminating the anovulant pill to prolactinoma formation. Headache and neurological signs are rare. Tumours tend to be larger at time of diagnosis in males. There may be cranial nerve signs, loss of vision and hypopituitarism. Although rarely present at the start, impotence, infertility, and decreased libido can occur, and galactorrhoea and gynaecomastia are uncommon.

Reduced spinal bone density occurs with prolonged hyperprolactinaemia in both sexes, and a return of prolactin levels to normal leads to increased but still reduced bone density.

A single prolactin level documents hyperprolactinaemia but, because of the pulsatility of prolactin production, the test should be repeated if prolactin levels are 25-40 µg/L. Most causes of increased

³⁰⁷⁵ Depression was the most important determinant of quality of life in a group of patients with cerebral tumours.(Pelletier ea, 2002)

³⁰⁷⁶ Surgical removal.

³⁰⁷⁷ **Prolactin levels are raised by** craniopharyngioma, acromegaly, granulomatous infiltration of the hypothalamus, large non-functioning pituitary tumours, primary hypothyroidism (some cases), hepatic cirrhosis, chronic renal failure (reduced clearance), exercise, meals, stimulation of the chest wall or breast examination, chest wall neoplasia, herpes zoster, polycystic ovarian syndrome, physical or psychological stress, amoxapine, metoclopramide, phenothiazines, butyrophenones, risperidone, olanzapine (transiently), SSRIs, verapamil, reserpine, methyl dopa, oestrogen (as in the oral contraceptive pill), cannabis, and cocaine. Aripiprazole may normalise haloperidol-induced hyperprolactinaemia whilst the patient remains on haloperidol.(Shim ea, 2007)

Macroprolactinaemia: prolactin attached to IgA antibody (needs to be distinguished from raised total prolactin by special tests, e.g. gel filtration chromatography) – macroprolactin cannot cross the walls of blood vessels in order to reach tissue receptors – look for this in all cases of hyperprolactinaemia – if not causing a problem (and if monomeric prolactin level is normal) do not investigate.

Disconnection hyperprolactinaemia: pituitary tumour presses on pituitary stalk blocking tonic inhibition of dopamine from hypothalamus on secretion of prolactin.

³⁰⁷⁸ One can have oligomenorrhoea or regular menses in some cases.

prolactin are ruled out with history taking and physical examination, a pregnancy test, and assessment of thyroid and renal function. The ultimate test is MRI.

Microadenomas may not require treatment if menses are regular. Bromocriptine can be used for infertility and a DA agonist or an oestrogen-progesterone combination may be prescribed for amenorrhoea. For intrasellar macroadenomas one can use bromocriptine for infertility and a DA agonist for amenorrhoea. For extrasellar macroadenomas bromocriptine and/or surgery is the treatment for infertility, whilst a DA agonist (bromocriptine, cabergolide, quinagolide) and/or surgery can be used for amenorrhoea.

Incidentaloma: This is a non-functioning tumour of an endocrine gland, e.g. pituitary or adrenal.

Pseudotumour cerebri: This condition includes raised intracranial pressure, classically in a young obese woman. Papilloedema, loss of vision, and sixth cranial nerve palsy may be present. Cases are divided into primary (idiopathic intracranial hypertension) and secondary³⁰⁷⁹. Headache, when present, is usually pulsatile. Management of primary cases includes weight loss, repeated lumbar puncture, diuretics, topiramate, emergency steroids to save sight, and surgery³⁰⁸⁰.

Craniopharyngioma: These tumours may affect sight (optic chiasma) and cognition, memory problems not being entirely explicable by raised intracranial pressure. Other reported findings (by some but not all studies) are excessive sleepiness and eating, bouts of aggression, and (often medication-resistant) depression.

Hyperostosis frontalis interna: There are frontal skull hyperostosis³⁰⁸¹, headache, menstrual problems, obesity, and excess body hair (hypertrichosis). Females outnumber males and the disorder may present from adolescence onwards. Some cases have no neuropsychiatric manifestations whereas others may have neurotic or personality problems, or psychosis. Memory problems and dementia have been reported.

Personality change due to a medical disorder

A persistent change in personality may indicate serious pathology. DSM-IV-TR recognises labile, disinhibited, aggressive, apathetic, paranoid, other, combined, and unspecified types. Causes include head trauma, subdural haematoma, tumours or infarction of the brain, disease of the frontal or temporal lobes or the corpus callosum, various dementing disorders, normal pressure hydrocephalus, AIDS, neurosyphilis, CJD, B12 deficiency, manganese or mercury poisoning, limbic encephalitis, metachromatic leucodystrophy, adrenoleucodystrophy³⁰⁸², and granulomatous angiitis. Abulia (mute, lacks motivation and feeling) must be distinguished from depression.

Focal lesions of the hemispheres

Frontal and temporal lesions are more often associated with personality change and psychosis respectively.

Frontal: There may be a grasp reflex (see table), spastic paralysis and ataxia of the contralateral upper limb, anosmia, incontinence and personality change. Damage to the prefrontal area mainly causes mental disturbances ('frontal lobe syndrome'). Damage to the motor/pre-motor area causes limb weakness, incontinence, akinesia, mutism, apraxia, and Broca's aphasia. A variety of factors influence the type of symptoms to be found with frontal lobe lesions, such as localisation, size, type, and course of lesion, as well as premorbid personality and age.

Frontal lobe

³⁰⁷⁹ There are numerous causes, e.g. neoplasm, obstructed ventricles, cerebral vein thrombosis, cardiac failure, COPD, eclampsia (magnesium sulphate reduces fit frequency in eclampsia), sleep apnoea, vitamin A and derivatives, tetracyclines, lithium, withdrawal of corticosteroids, renal disease, hypoparathyroidism, lead toxicity, Lyme disease, SLE, hypertensive encephalopathy, etc.

³⁰⁸⁰ E.g. fenestration of the optic nerve sheath.

³⁰⁸¹ X-rays show thickened inner frontal skull bone table plus exostoses pushing into the cranial cavity.

³⁰⁸² **Adrenoleucodystrophy:** Rare, X-linked recessive (numerous mutations at Xq28 which codes for ALD protein, a peroxisomal membrane component) inherited disorder with adrenal insufficiency and leucoencephalic myeloneuropathy. Defective oxidation of saturated very long chain fatty acids leads to their accumulation. (Moser, 1997) Rarely starts in adults but may present with psychosis, mania, and cognitive dysfunction. Environment (e.g. head trauma) plays a role as identical twins may differ. Controversial proposed treatments include Lorenzo's oil (mixture of glyceryl trioleate and glyceryl trierucate) and dietary fat restriction.

Dorsolateral damage - apathy (right fronto-subcortical in one study of stroke: Brodaty et al, 2005), psychomotor slowing, diminished fluency of speech, perseveration, reduced executive function (organising, sequencing, planning), utilisation behaviour (patients pick up an object and use it continuously until it is removed by another person), and poor abstracting ability

Orbitofrontal damage - labile affect, disinhibition, impulsiveness³⁰⁸³, poor judgement, lack of insight, and poor abstracting ability

Medial lesions - greatly reduced speech output, akinesia, and, sometimes, apathy (Lauterbach, 2000)

Inferior lesions – tumours and other lesions may cause anosmia

With frontal lobe tumours, psychiatric symptoms occur especially with anteriorly placed tumours. Common symptoms are headache, epilepsy, disturbed micturition³⁰⁸⁴ and neurological abnormalities. The symptoms may be paroxysmal. These symptoms are usually present at the time of diagnosis, even in those with early psychiatric problems, and should be looked for. The commonest psychiatric symptoms associated with frontal lobe tumours are impaired consciousness and progressive intellectual deterioration, followed by mood and behavioural disturbances. In some cases, especially with meningiomas³⁰⁸⁵, there may be no neurological symptoms until the tumours are large and causing displacement. These cases may be referred to a psychiatrist because of progressive personality change and intellectual decline. Frontal lobe release reflexes³⁰⁸⁶ are commoner in demented than in non-demented elderly people.

Localised lesions of the hemispheres

Non-dominant

Occipital³⁰⁸⁷ – homonymous hemianopia, hemianopic scotomata, visual agnosia, prosopagnosia³⁰⁸⁸ (poor face recognition), crude visual hallucinations

Frontal – disinhibition, lack of initiative,³⁰⁸⁹ dyssociality, poor memory, incontinence,³⁰⁸⁹ grasp reflex, anosmia

Parietal - neglect of non-dominant side³⁰⁹⁰, agnosia, homonymous constructional apraxia, spatial disorientation, dressing apraxia, homonymous hemianopia, contralateral tactile/kinaesthetic hallucinations, tactile perseveration³⁰⁹¹

Temporal – poor non-verbal memory, loss of complex hallucinations, musical skills, complex hallucinations,

Dominant

Do.

Do.

Dyscalculia, dysphasia, dyslexia, apraxia,

hemianopia

Dysphasia, dyslexia, poor memory,

homonymous hemianopia³⁰⁹²

³⁰⁸³ This is sometimes demonstrable with a Go-No-Go task, e.g. 'Tap once when I tap once but don't tap when I tap twice'.

³⁰⁸⁴ This, contrary to popular belief, does distress the patient.

³⁰⁸⁵ There does not appear to be a specific personality change associated with **tumours of the temporal lobe**. Instead such change may resemble that found with frontal lobe tumours. About one half of patients with tumours of the temporal lobe develop epilepsy. Sudden onset of symptoms such as forced thoughts, dreamy states, terrible fear, depersonalisation, and déjà vu should bring one to consider temporal lobe epileptic aura.

³⁰⁸⁶ Examples are the snout reflex (tap patient's upper lip with a finger so that his lips purse and the mouth pouts forwards), and the grasp reflex (using your own index and middle finger, stroke the patient's palm crosswise or his fingers lengthways: the patient grasps your fingers and cannot let go despite your request that he does so).

³⁰⁸⁷ Other phenomena associated with occipital lesions include palinopsia (images leave persistent after-traces), metamorphopsia (distorted scenes), and polyopia (more than one visual image). If infarction occurs in one occipital lobe (posterior cerebral artery) there will be a homonymous hemianopia with sparing of the macular area (supplied by middle cerebral artery). If the pole of one occipital lobe undergoes infarction there will be a small scotomatous homonymous hemianopia. If both occipital lobes are severely damaged from any cause there will be Anton's syndrome (QV).

³⁰⁸⁸ This and asimultagnosia (unable to perceive unity of visual scene) tend to occur when there is co-involvement of parietal/temporal lobes.

³⁰⁸⁹ Incontinence is classically associated with bilateral frontal lobe damage.

³⁰⁹⁰ A person with a non-dominant parietal lobe lesion may ignore left turns during a journey.

³⁰⁹¹ The person continues to perceive contact long after contact ceases.

³⁰⁹² Visual hallucinations that occur within a hemianopic field are suggestive of temporal lobe dysfunction.

homonymous hemianopia

Atavistic (primitive) reflexes associated with frontal lobe disease

These are described differently by different authors. They **can** and **often do** occur in normals, but more than one strongly favours abnormality such as AD, multi-infarct dementia, or AIDS involving the CNS.

Glabellar reflex: damage to frontopontine pathways to facial nerve nucleus – Parkinson's disease, Parkinsonism, dementia, cerebral atrophy, frontal lobe tumours – tap glabella from behind head – not common in drug-induced Parkinsonism

Grope reflex: touch hand of patient and latter will reach out for your hand; extreme cases allow the examiner, by successive touching, to guide the patient's hand through space ('magnet reaction') or, indeed, in the absence of touching, there may be automatic groping for objects seen by the patient

Snout reflex: tap nose and look for excess facial grimacing

Sucking reflex: stroke lip and look for pouting/sucking lip movements (normal in babies and gone by 18 months)

Chewing reflex: put tongue depressor in mouth and look for reflex chewing movements

Grasp reflex: stroke palm and patient will grasp your finger (may resist removal of your finger – sometimes, if you stroke the dorsum of his fingers, he will let go)³⁰⁹³

Palmomental (palmar-mental) reflex: scratch palm and watch wrinkling/puckering of chin³⁰⁹⁴ on same side or scratch base of thumb and look for slight downward movement of lower lip and jaw

Common office tests of frontal lobe functioning

- Naming as many animals as possible in 60 seconds (verbal fluency)
- Getting the patient to reproduce various 3 hand positions or sequentially tap with both hands (motor sequencing³⁰⁹⁵)
- Go/no-go tasks ('tap the table once if I tap it once, but do not tap if I tap twice')
- Abstraction (e.g. 'what do a motorcar and a bicycle have in common?')
- Problem solving (e.g. 'there are 12 books on 2 shelves, the top shelf having twice as many books as the bottom shelf. How many books on each shelf?')³⁰⁹⁶

Parietal: spatial disorientation (tendency to get lost), apraxia, aphasia, agnosia, alexia, perceptual rivalry, and contralateral homonymous hemianopia. Non-dominant lesions are likely if there is agnosia or perceptual rivalry. The others are associated with dominant lesions. *Gerstmann's syndrome*³⁰⁹⁷ occurs with dominant lesions: right-left disorientation³⁰⁹⁸, dyscalculia, and finger agnosia with dysgraphia. Gerstmann described a single case in 1924. It has been suggested that all of its components came together by chance. In reality, any combination of the symptoms can be found. The rare post-traumatic (esp. occlusion of posterior cerebral artery³⁰⁹⁹ supply to the dominant hemisphere) *Charcot-Wilbrand syndrome* is sometimes associated with Gerstmann's syndrome: visual agnosia, inability to revisualise images, and partial or complete loss of dreaming.

Astereognosia or tactile agnosia is the inability to identify simple objects placed in the hand with the eyes closed. It usually indicates a contralateral parietal lobe lesion. Autopagnosia, where the patient totally

³⁰⁹³ This must be distinguished from the *magnet reaction* found in catatonic and organic brain disorders: examiner touches patient's palm – as examiner withdraws his fingers the patient's hand follows them.

³⁰⁹⁴ *Mentum* = protruding part of chin.

³⁰⁹⁵ Also called reciprocal co-ordination. Such motor sequencing can be tested by, e.g. the *fist-ring test*: alternatively make a fist and a ring with one hand and then with the other hand.

³⁰⁹⁶ The answer, of course, is 8 and 4.

³⁰⁹⁷ Josef Gerstmann (1887-1969), psychiatrist in Vienna who left for England in 1938 and then USA. Gerstmann described his syndrome in 1924.

³⁰⁹⁸ Test by asking patient to obey commands, e.g. 'touch your right ear with your left forefinger'.

³⁰⁹⁹ The chief manifestations of infarction in the territory of the posterior cerebral artery are contralateral hemianopia +/- visual agnosia, spatial disorientation or visual hallucinations. Depending on the site of damage there may be an amnesic disorder, Anton's syndrome (QV) or alexia without agraphia. The same object may be seen repetitively or a central object may be seen even after it has been removed from view (*visual perseveration*).

ignores or fails to identify a limb or the whole contralateral side of the body, is due to a more extensive lesion.

Temporal: elaborate visual sensations, epilepsy, hallucinations (auditory, gustatory, and olfactory), illusions, receptive aphasia (with dominant lesions), transient amnesias, homonymous upper quadrantanopia, and *déjà vu*.

Occipital: crude visual hallucinations with irritative lesions, contralateral homonymous hemianopia with destructive lesions.

Corpus callosum: apraxia of left hand, anomia for objects held in left hand, and alien hand syndrome. Paranoid thinking and koro have also been reported (Durst & Rosca-Rebaudengo, 1988).

Agenesis of the corpus callosum³¹⁰⁰: This may be complete or partial. There is a genetic cause in a minority of cases and an association with trisomy disorders³¹⁰¹ is well known. Some cases are attributable to intrauterine toxin exposure or infection to metabolic disorders such as excess glycine. Whilst the condition is usually reported in childhood it may be discovered at any stage of life, even at autopsy. Complete absence may be associated with hydrocephalus and a variety of CNS abnormalities³¹⁰². Seizures, spasticity, intellectual disability (only when there are other malformations), and hydrocephalus are reported associations. It seems that the brain is able to compensate for the absence of this structure in many cases, e.g. by increased use of commissures. *Andermann syndrome*, described in 1972, may run in families and consists of intellectual disability, callosal agenesis, facial dysmorphism, peripheral neuropathy, and psychosis; psychosis may relate to cerebellar atrophy. (Hemmings & Bouras, 2007, p. 207) According to Paul et al (2007) developmental defects of the corpus callosum may be associated with a variety of psychiatric disorders, including depression, schizophrenia, and behavioural problems in childhood, including autistic traits.

Tumours of the corpus callosum: In most cases there is a quick development of intellectual decline, with memory affected first. Personality changes reminiscent of frontal lobe damage may be an early feature. Sleepiness, stupor and diminished activity may indicate diencephalic involvement. Florid psychosis is not unknown and a catatonic picture may be observed.

Head injury

Head injuries³¹⁰³ are one of the commonest reasons for attendance at Irish hospitals. Gloag (1991) reckoned that 70,000 people in Britain suffered from the effects of serious head injury, with an additional 2,000 receiving such injuries each year. 2-5 males are affected for each female. The young male is the classic victim, this group being subject to an excess of road accidents and assaults. Neuropsychiatric manifestations are a more important cause of disability following traumatic brain injury than are neurophysical consequences (Fleminger & Ponsford, 2005) and carer stress may be greater in cases of head injured than with paraplegic partners. (Rosenbaum & Najenson, 1976) Emotional and behavioural sequelae of head injury (e.g. low mood, selfish, irritable, angry, and aggressive) and cognitive difficulties (e.g. difficulty remembering and slowed thinking) in the patient, and poor coping powers, lack of a feeling of being cared for, and radical changes in social circumstances in the carer, as well as lack of money or information feed carer distress. Mixed anxiety-depression (cothymia) is the commonest psychiatric consequence of cranial trauma. The patient with traumatic brain injury (TBI) may grieve for lost functional abilities and may suffer from exacerbations of pre-trauma traits and/or personality change.

Pathophysiology of head injury

³¹⁰⁰ 1:4,000 births.

³¹⁰¹ Trisomy of chromosomes 8, 13, and 18.

³¹⁰² Heterotopia, microgyria, arachnoid cysts, spina bifida, and meningomyelocele.

³¹⁰³ Physical examination details are beyond the scope of this text, e.g. Battle's sign (retro-tympanic blood) infraorbital ecchymosis, and abnormal pupils.

(a) Primary - diffuse axonal damage³¹⁰⁴ - shearing and torsion forces tear axons and support fibres, especially in the brainstem but also caudally; and contusion - especially the frontal and temporal lobes because of bony protuberance and the hard dura

(b) Secondary

Intracerebral (haemorrhage, oedema, subarachnoid haemorrhage, hydrocephalus)

Extracerebral (autonomic changes with failure to compensate for changes in blood pressure and oxygen levels leading to ischaemia and anoxia)

Stretching of nerve fibres may unleash a metabolic cascade that disrupts the blood-brain barrier, interferes with auto-regulation of the brain, causes oedema, impairs metabolism, alters perfusion, disrupts the delicate balance across membranes of ions, activates destructive molecules, leads to free radical generation, and initiates changes in gene expression. Membrane defects near the nodes of Ranvier (*mechanoporation*) and opening of ligand-gated channels by glutamate leads to influx of Na^+ , Ca^{++} , and Cl^- , and efflux of K^+ ions. Very high levels of K^+ ions outside the cell inhibit action potentials. Consciousness is lost. Ca^{++} influx activates proteases (calpains and caspases).

A prolonged period of post-traumatic amnesia (PTA), measured from the time of the injury to the resumption of normal continuous memory, is associated with neurological complications³¹⁰⁵, psychiatric disorders and generalised intellectual impairment, and personality change. Retrograde amnesia (for events before the injury) is not a good predictor of outcome. (O'Shea & Condren, 1996)

Post-traumatic syndrome (post-concussional syndrome/disorder, PCS) is more likely to follow minor injuries to the cranium than it is to follow major traumata. It is important to distinguish between symptoms and the syndrome, although the specific symptoms of the syndrome are not universally agreed. Importantly, lack of appropriate control groups makes it difficult to state for certain which manifestations stem from the original injury to the brain. Also, mild traumatic brain injury does not predict PCS. (Bryant, 2008) The retrospective assessment of mild traumatic brain injury creates interpretation problems of its own. (Fear ea, 2009) PTSD symptoms often overlap with those of PCS (Bryant & Harvey, 1999) and post-concussional symptoms are more likely in the presence of depression or PTSD. Also, the manifestations of PCS overlap significantly with those of somatoform disorders. In practice, symptoms of PCS vary enormously between patients and the same symptoms are common in people without a history of head injury.

ICD-10 PCS

Head injury + at least 3 of 8 symptoms

DSM-IV PCS

Significant cerebral concussion + duration of symptoms > 3 months + symptoms start/get worse post-injury + some cognitive dysfunction

PCS

Headache

Dizziness³¹⁰⁶

Abnormal fatigability

Insomnia

Sensitivity to light and noise

Irritability, anxiety, depression, poor concentration and memory

Some degree of intellectual impairment

Decreased tolerance for alcohol³¹⁰⁷

³¹⁰⁴ It appears that when the injury occurs the axolemma is stretched and compressed. Calcium enters the axon and activates proteases. Proteases damage microtubules and neurofilaments leading to accumulation of products normally transported by these structures. The result is swelling of the axon, lobule formation, and division of the axon with development of a 'retraction ball'. This process takes 24-48 hours to reach completion. Over the ensuing weeks/months there is sprouting from the proximal segment, an attempt at repair.

³¹⁰⁵ E.g. dysphasia, motor disorder and persistent memory and calculation problems.

³¹⁰⁶ Otolological damage predicts later dizziness.

³¹⁰⁷ The person gets drunk easily. Some people will drink more because of disinhibition or stress.

Vasomotor instability
Impaired sexual interest and performance

Risk factors (Fann ea, 2007, pp. 416-8)

Female
Older
Previous traumatic brain injury (TBI)
Psychological stress
Lack of social support
Poverty
Current litigation (but see below)
Severe depressive symptoms

PCS has a complex aetiology. Early symptoms may owe more to physical factors whereas prolonged complaints may have a psycho-social colouring. Fenton ea (1993) found that while young men were most at risk for minor head injury that older women were most at risk of chronic sequelae. They also found that the emergence and persistence of the 'post-concussional syndrome' were associated with pre-injury social problems. Anxiety and 'compensation neurosis' may contribute to Miller's 'accident neurosis'. (Miller, 1961). In one 3-month follow-up of 60 randomly selected cases of closed adult civilian injuries, 80% had a neuropsychiatric problem midway in the study, 43% having PCS. Pre-injury intensity of neurosis predicted the level of post-accident complaints. Tarsh and Royston (1985) traced and followed 35 claimants in a domestic setting with accident neurosis from 1 to 7 years after compensation was received. Few had recovered and any recovery that did occur seemed unrelated to the time of compensation.³¹⁰⁸ Over-protection by relatives appeared to prolong symptoms. The authors noted that the legal process and the delays involved caused great distress. (see also Cassidy ea, 2000) Fleminger (2009a, p. 195) points out that impending litigation may intensify and prolong disability but that the mechanism behind this is rarely fully conscious. Also, conflictual advice, capital outlay, and having to repeat complaints to a number of specialists heighten frustration and anxiety. The nature of the legal process (adversarial tort versus no fault) may complicate matters. Also, there may be less motivation to complain of symptoms in countries where there is little possibility of financial compensation. Fleminger (2009a, p. 198) writes that overestimating premorbid health is common to all injured patients.

The syndrome of 'post-concussional' or 'post-traumatic' dysfunction is not static. It changes over time. Symptom decline is most dramatic during the first week after injury. Anxiety is most likely to be found in cases lasting longer periods. A complex interaction of factors is at work. Organic factors are more obvious in early complainers, psychological ones in later complainers. However, medicine is a clinical, one-to-one, doctor/patient affair, and, whilst generalisations may be true, the individual should be examined for his own sake.

Watson ea (1995) followed up minor head injury cases. Perceived levels of stress at the time of injury, and afterwards, did not relate to symptom formation. Chronic symptoms were associated with continuing brainstem dysfunction.³¹⁰⁹ The degree of transient cortical dysfunction appeared to relate directly to the intensity of early organic symptoms. Fann ea (2004) found the prevalence of any psychiatric disorder in the first year after moderate to severe traumatic brain injury (TBI) to be 49%, 34% after mild TBI, and 18% in unexposed, matched comparison subjects.

In an Australian study of (any) trauma victims (Bryant ea, 2010) at one year 31% reported a psychiatric disorder and 22% developed a psychiatric disorder that was novel for the sufferer, the commonest new disorders being depression, GAD, PTSD, and agoraphobia; PTSD, panic disorder, social phobia and agoraphobia were more likely with a history of mild TBI; but functional impairment, and not mild TBI, was associated with psychiatric disorder. Interestingly, Yaffe ea (2010) found that PTSD among US veterans attending medical centres were at almost double the risk of developing dementia compared with those without PTSD. Is PTSD a cause of dementia, does it damage the hippocampus, is damage caused by

³¹⁰⁸ Similar findings were reported by Deb ea. (1999)

³¹⁰⁹ Pinkston ea (2000) found that many post-concussive symptoms predicted performance on neuropsychological tests better than did mild TBI, a finding against an organic aetiology.

cytokines or cortisol or homocysteine, does PTSD unmask dementia, is the connection explained by cryptic TBI, or is the finding spurious? Were they drinking excessively?(Thomas ea, 2010)

The classical syndrome is seen less frequently in childhood, although head injury is common in childhood and accounts for 25% of all traumatic deaths in children less than 15 years of age. Severed neurones may heal³¹¹⁰ but develop incorrect connections, which may cause persistent sensory abnormalities and major problems in processing multiple stimuli, e.g. concentrating on a lesson when there is much ambient noise. New learning skills are affected more than memory for already learned facts and skills³¹¹¹. The child may be said to be 'lazy' and have social problems³¹¹² and secondary emotional problems. Skilled and repeated assessment should be supplied for such children.

The most troublesome long term morbidity after head injury is caused by behavioural and emotional consequences, including sexual inhibition, aggression, apathy, anxiety, and lability of mood.

Syndromes that may follow local injury (McClelland, 1988)

Frontal - disinhibition, euphoria, reduced vitality

Temporal – aggressiveness

Basal - reduced spontaneity and vitality

Other psychological changes - anxiety, depression, tension, fatigue, irritability, obsessionality, and hypochondriasis

According to Fleminger (2009a, p. 209) aggression after head trauma is associated with being younger when injured, being depressed, frontal injury, and premorbid antisocial behaviour. Lack of confidence, hopelessness, and self-deprecation may be more reliable symptoms than biological complaints (e.g. disturbed sleep) when diagnosing depression in head injured patients.

Post-traumatic seizures can be divided into immediate (seconds/minutes), early (within 7 days), and late seizures. The earlier the seizure onset the more benign is the prognosis for epileptic progression. The vast majority of seizures will occur during the first week. The frequency of *epilepsy* following head injury varies from 0.75 - 2.5% in peacetime to 45% in wartime³¹¹³. Penetrating injuries and injuries affecting multiple cerebral lobes are more likely to lead to epilepsy than are closed injuries or unilobular injury. A history of alcohol abuse increases the risk for post-traumatic epilepsy. The risk of epilepsy following mild or severe brain injury or skull fracture in children and young adults is increased and lasts for years; a family history of epilepsy increases the risk of epilepsy following mild or severe brain injury.(Christensen ea, 2009) Petit mal is rarely, if ever, due to trauma. Antiepileptic drugs are poor at preventing seizures after head injury and phenytoin may even slow recovery.(Hammeke & Gennarelli, 2003, p. 1161)

Evoked potentials measure conduction velocity in the CNS. Central conduction velocity is extremely sensitive to trauma. Information from evoked potentials provide helpful prognostic indicators: the degree of recovery of these central conduction times correlates with clinical improvement.(McClelland, 1988)

SPECT and other functional imaging procedures may show areas of hypoperfusion in cases of mild TBI when structural imaging is negative.(e.g. Korn ea, 2005) However, other causes of hypoperfusion (e.g. schizophrenia or depression) should be borne in mind.

Increased age is associated with a reduced chance of returning to work, increased memory problems, an increased incidence of anxiety and fears, and an increased mortality rate. Chronic high alcohol intake delays reparative processes within the CNS.

Legal liability should be decided early, or a 'no fault' system of compensation should be introduced.

*Reduplicative paramnesia*³¹¹⁴ is a delusion that one is not where one is but is instead in another place. It is often associated with neurological deficit such as that following CVA or head trauma.

Fleminger (2003) reviewed the management of agitation³¹¹⁵ and aggression³¹¹⁶ following head injury.

Fleminger (2003) warns that haloperidol is overused and can cause akathisia and worsening of confusion. Attention to differential diagnosis is important, e.g. alcohol withdrawal. Beta-blockers are best for agitation

³¹¹⁰ More so in the younger child.

³¹¹¹ Therefore, the smaller the store, the harder it is to catch up.

³¹¹² E.g. difficulty getting on with others, and disinhibition.

³¹¹³ Fleminger (2009, p. 198) states that post-injury epilepsy affects 2-5% of those with closed injuries (where temporal lobe epilepsy is the commonest form) and 30% when there is dural penetration.

³¹¹⁴ Described by Pick in 1903.

³¹¹⁵ Found in 10% of severe cases as part of delirium and tends to cease spontaneously.

³¹¹⁶ Often impulsive and due to personality change.

and aggression but have troublesome side effects. Olanzapine and quetiapine have useful sedative effects. Carbamazepine or valproate may help in the presence of epilepsy or mood disorder. Depression or anxiety may respond to trazodone. Minimum effective doses should be used and the need for continued prescribing should be reviewed frequently. *Reactive nursing* (nurse only gives attention if patient disturbed) may reinforce the problem. According to Fleminger (2003) early transfer to a specialised rehabilitation unit³¹¹⁷ leads to better outcome than delayed stays on medical or surgical units. The availability of such units, especially ones with a high tolerance for disturbed behaviour, may be less than the ideal.

Boxing and head injury: 361 boxers died in the ring worldwide from 1945-1993. Repeated minor blows to the head may be associated with dysarthria, bradykinesia, ataxia, intellectual impairment, morbid jealousy, cerebral atrophy on CT scanning, loss of cortical neurones and neurofibrillary degeneration (*vide infra*), and signs of cerebellar, pyramidal and extrapyramidal damage. There may be perforation of the septum pellucidum. The boxer can look forward to a worsening of all these until he finally quits the ring. Indeed, 15-20% of boxers will develop dementia after a professional career. Boxing must be included in the differential diagnosis of dementia. Blows damage the cortical (especially frontal and temporal) surface and cause multiple disruptions of neuronal networks (*Strich lesions*). Bleeding may occur, especially in the substantia nigra and deep periventricular tissues. MRI has shown generalised cerebral atrophy and many tiny clefts in the hemispheres. 'Punch drunk syndrome' or *dementia pugilistica* consists of slurring of speech, ataxia, dementia and early demise. Plaques and tangles of similar distribution to those in AD are found, but they fail to take up standard silver stains that are employed for AD (*no beta-amyloid neuritic plaques*). Gliosis and atrophy are concentrated in the medial temporal lobe, i.e. limbic system (memory/behaviour). A swinging blow to the jaw causes the head to rotate in the vertical plane. Head guards do not protect from rotational injuries, only making the head a bigger target. Eye injuries are common – retinal tears and drainage abnormalities. Boxing has been banned in a number of Scandinavian countries.

Loosemore et al (2007) found no evidence for chronic traumatic brain injury in the literature on amateur boxing although the 'quality of evidence was generally poor'.

McCrory (2003) concluded that head to ball contact in soccer is unlikely to cause brain injury but head to head contact, which is difficult to prevent, might do so.

A direct and active therapist stance is necessary. The environment of head-injured patients may need modifying in order to minimise disturbed behaviour. Troubling stressors and excessive demands should be avoided. Routine, structure, task simplification, modification of environmental stimulation, and removal of annoyances may be needed. Realistic hope should be instilled, mourning should be assisted, strengths should be identified, and self-esteem bolstered. Anosognosia should not be confused with denial. Memory aids, use of concrete communications, and short psychotherapeutic sessions may help. CBT might help in reducing psychological distress (Tiersky et al, 2005) but more research is required to confirm this. The patient should be taught skills that assist coping, relaxation, and stress management. Problem-solving skills and breaking down goals into achievable ones will assist progress. Options should be rehearsed. Mittenberg et al (1996) reported that participating in education programs aimed at normalising reactions can improve post-concussional symptoms. People who look after the head-injured also need education. They will need to learn the middle road between excessive protection and risk-taking if the patient is to achieve optimal independence and competence.

Headache³¹¹⁸

Childhood headache, which is associated with psychosocial adversity, may be a risk factor for adult headache and psychiatric symptoms in adulthood. (Fearon & Hotopf, 2001)

³¹¹⁷ A structured, open environment, with normal sleep/wake schedule and relief of boredom.

³¹¹⁸ Headache is also known as cranialgia or cephalalgia. Whereas all pain is felt in the brain, brain parenchyma is pain insensitive. Structures above the tentorium are innervated by the ophthalmic division of the V cranial nerve, whilst structures below the tentorium are innervated by C2 and C3. Cerebellar lesions usually cause pain posteriorly, and pain from occipital lobe lesions is felt anteriorly. A careful history (e.g. past headaches) and a physical examination (e.g. for focal signs) are important. However, because of a contribution from the caudal nucleus of V nerve, pain from upper cervical spine or posterior fossa can also be referred to the front of the head. (Evans & Mathew, 2005, p. 3)

Causes of headache (partial list: see Headache Classification Subcommittee of the International Headache Society, 2004)

Trauma, post-coital, post-tussive, sneezing, sinusitis, cervical spondylosis, carcinomatosis

*Lumbar puncture*³¹¹⁹

Drugs: alcohol, caffeine, nicotine, nifedipine (calcium antagonist), glyceryl trinitrate (GTN)³¹²⁰, hydralazine (vasodilator), indomethacin, dipyridamole, ergotamine, and antidepressants

Dental: impaction, infection, and malocclusion

Ophthalmic: glaucoma, refractive error, and retrobulbar neuritis

Increased intracranial pressure: tumour, abscess, haematoma, benign intracranial hypertension (idiopathic intracranial hypertension, pseudotumour cerebri), infection (e.g. encephalitis), and cerebrovascular accident (10% of cases of polycystic kidney disease have intracranial saccular aneurysm)

Skull: Paget's disease

Haematological: anaemia, hypoxia, and hypercapnia (pulmonary)

Cardiovascular: migraine, hypertension³¹²¹, influenza and other systemic infections

*'Psychogenic'*³¹²²: tension, depression (Wang et al, 1999)

Endocrine: Hypothyroidism³¹²³, Addison's and Conn's diseases, pheochromocytoma

Inflammation: meningitis³¹²⁴, subarachnoid haemorrhage, systemic infection, and cranial arteritis

Medication-overuse headache

Chronic headache due to frequent intake of analgesics or triptans (5-HT₁ agonists)

May affect 1% of population

Treatment involves withdrawal of offending drugs and clear restrictions on further use of painkillers

Haemodialysis³¹²⁵

Mild/moderate severity, bilateral, tight/pressure, starts during the procedure

Lasts a few hours

Sometimes severe/throbbing with features of migraine or tension headache

ACE inhibitors may help

Posterior reversible encephalopathy syndrome

Rare MRI finding

Bilateral posterior cerebral oedema

Associated with various illnesses (eclampsia, SLE, hypertensive encephalopathy) and immunosuppressant drugs

Cervical spondylosis

Classically affects older people

Usually early morning headache, because neck is stiff from lying in bed

³¹¹⁹ Post-LP headache is exacerbated by the erect posture so the recumbent position is prescribed for some hours after the procedure +/- analgesics. Headache may persist for many days in some cases. It can be treated if necessary by injecting 20 ml of the patient's venous blood into the CSF, a so-called autologous intrathecal blood patch.

³¹²⁰ GTN may cause headache (can be worse than anginal pain), hypotension, or syncope.

³¹²¹ Most cases of hypertension do not suffer from headache. Headache is more likely with cerebral bleed or encephalopathy. Chronic renal failure may be associated with headache, emesis, and left ventricular failure. Mediastinal obstruction is associated with bursting headache on lying/bending. A collapsing pulse may cause throbbing headache and fingertip pulsation.

³¹²² An old name for severe, blinding headache of supposed hysterical origin was *clavus hystericus*.

³¹²³ The mechanism is unknown and treatment involves giving T₄.

³¹²⁴ **Kernig's sign:** flex hip to 90° and then try to straighten knee (positive: pain and hamstring spasm). Brudzinski's sign: flexion of head on chest causes drawing up of lower limbs. Many cases of bacterial meningitis suffer **headache** for months after the initial illness.

³¹²⁵ A few such headaches are due to removal of caffeine by the dialysis, i.e. a withdrawal syndrome.

Tension headache is caused by stress. It is constant and of long duration. It may be absent for long periods. There is usually no response to painkillers. It feels like a tight band around the head or like a weight on the head. It tends to be symmetrical, have a particular distribution (bifrontal, bioccipital, and nuchal), be of mild to moderate intensity, to have a stable intensity, to get worse as the day progresses, to lack features of migraine, and is often of high frequency (sometimes daily). It responds to reduction in stress, psychotherapy, environmental manipulation, alcohol, tranquilisers, etc. NSAIDs, especially aspirin, may be more effective than paracetamol, and amitriptyline and biofeedback-assisted relaxation training may assist in prevention. (Loder & Rizzoli, 2008)

Migraine³¹²⁶ pathophysiology is probably more complicated than simple ischaemia. Evidence implicates oestrogens, 5-HT, neuropeptides (e.g. calcitonin gene-related peptide), brainstem nuclei, periaqueductal grey matter, cortical spreading depression³¹²⁷ of Leao (Leao, 1944), and activation of vasculature supplied by the trigeminal nerve. Nocturnal migraine occurs during REM sleep. Sufferers (migraineurs) have been characterised as 'anxious and neurotic', but, whilst they do suffer an excess of anxiety and depression (probably more than other headache sufferers: Fleminger, 2009b, p. 504), their disorder has profound effects on their lives. Rasmussen (1992) found that people with tension headache rather than migraine had high neuroticism scores on the Eysenck Personality Inventory. Indeed, previous descriptions of migraineurs as being particularly 'neurotic' may have been due to confinement of studies to clinic samples. (Ziegler & Paolo, 1995) The lifetime prevalence is 16% (18% for women, 6% for men). Migraine with aura is more likely to be familial than is migraine without aura, but the likelihood of a latter case having a similarly affected close relative is increased nonetheless. The risk of a child developing migraine is, respectively, 45% and 70% if one or both parents have the disorder. Being pregnant may relieve migraine and two-thirds of cases improve with physiological menopause, the opposite number worsening with surgical menopause. (Evans & Mathew, 2005, p. 231)

Some migraine triggers

High-oestrogen contraceptive pill, menses, ovulation, HRT
Aged cheese, chocolate, monosodium glutamate, aspartame
Reserpine, alcohol, nitrites, nitroglycerin, ranitidine, hydralazine
Stress and removal of stress
Lights, smells, high altitude
Tiredness, sleeping for too long
Hunger
Head injury
Strong physical activity
Changes in weather

60% of cases experience a prodrome lasting hours to days independent of the experience of an aura.

Migraine prodromes

Depression³¹²⁸
Overactivity, irritability, euphoria, restlessness
Photophobia, phonophobia
Hypersomnia
Hyperosmia
Yawning
Food cravings, loss of appetite

³¹²⁶ Migraine affects 15% of UK adults. (Fuller & Kaye, 2007)

³¹²⁷ **Cortical spreading depression** = neuronal and glial depolarisation wave accompanied by decreased nerve cell activity and hypoperfusion spreading across cortex at a rate of a couple of millimetres every second. The same phenomenon can be induced in animal studies by applying a strong solution of potassium. The wave may be preceded by a brief hyperaemic phase, possibly the cause of the lights that occur during an aura. The headache may be caused by meningeal irritation by cytokines and NO released by the wave.

³¹²⁸ According to Samaan et al (2009) found that not only is there a general relationship between headache and depression but also that among patients suffering recurrent headache there is a specific relationship between depression and migraine with aura.

Constipation or loose stools
Neck stiffness

There may be an aura, visual or paraesthetic. Aphasia may occur as part of the aura. Digitolingual paraesthesias (*cheiro-oral syndrome*) are a common part of the aura – numbness and pins and needles start in the fingers of one hand and extend into the arm and face, especially the nose and mouth area ipsilaterally; this usually follows the visual disturbance but uncommonly occurs without it. *Teichopsia* consists of visual hallucinations, especially of battlements, and is characteristic of migraine. (St Hildegard of Bingen, 1098-1179, may have had migraine-induced visions.)

‘*Migrainous syncope*’ (loss of consciousness) may occur early or late in an episode but tends to come on slowly with a gradual recovery thereafter; much more uncommon is coma, incontinence and seizure. *Delirium* may complicate an attack: there may be different combinations of dysphasia, agnosia, apraxia, amnesia, temporal lobe phenomena (e.g. déjà vu), disorientation, reduced arousal, complex visual and auditory hallucinations, paranoid thinking, and various levels of upset. Should no headache follow, diagnostic confusion is likely! *Disturbed body image* may occur at any stage of an attack – bodily components seem bigger (e.g. taller), smaller, twisted, increased in number (including having more than one body), or removed.

Pain is severe and throbbing or non-throbbing, and often arises early in the morning. It can affect one (hemicrania) or both sides of the head. It may be unilateral and then generalise. Headache lasts 4 to 72 hours. Most attacks last less than a day and those lasting more than 72 hours are referred to as *migraine status*. The patient tends to lie down in a dark room (photophobia), may vomit, or faint if standing. The resolution phase is associated with fatigue, irritability, scalp tenderness, depression or euphoria. Pain may be felt in the face and is then often misdiagnosed as being due to sinus problems. In fact most migraineurs may hold this belief. Migraine attacks may be accompanied by psychiatric symptoms and sufferers may have increased rates of affective and anxiety disorders, nicotine dependence, and alcohol or illicit drug abuse or dependence. The lifetime prevalence of anxiety disorder and major depression has been estimated at 54% and 34% respectively in migraine patients (27% and 10% in controls respectively). Having an aura may increase psychiatric comorbidity. Dilsaver ea (2009) found that in patients who were suffering from a major depressive episode, and regardless of patients’ polarity, having a family history of bipolar disorder (BP) increased the risk for having migraine headaches. Ortiz ea (2010) found that migraine occurred in 24.6% of BP patients (34.8% BP II v 19.1% B I) and the combination of migraine and BP was associated with an excess of suicidal behaviour, social phobia, panic disorder, GAD, and OCD.

Migraine with aura is associated with an increased risk of ischaemic stroke, migraine angina, as well as other ischaemic vascular events such as myocardial infarction, the risk varying by vascular risk factors.(Kurth ea, 2008)

The International Headache Society recognises migraine with (classic migraine – up to 30% of cases) and without (common migraine or *hemicrania simplex*, the most frequent type) aura. However, the same individual may experience attacks of either of these types and even an aura without headache (*migraine equivalent* or *acephalgic migraine*). Seventy percent of people with migraine with aura also get attacks without aura. In older cases without headache the term *late-life migraine accompaniment* may be used. If headaches occur less than twice monthly analgesics may be tried. Acute (abortive) treatments include paracetamol (acetaminophen), aspirin (often with metoclopramide), caffeine, NSAIDs, ergotamine (by nasal spray or *per rectum*), triptans (sumatriptan³¹²⁹, zolmitriptan, etc), parenteral metoclopramide,(Colman ea, 2004) and opiates (very severe cases only). Lane and Baldwin (1997) have raised concerns that triptans (5-HT_{1B/1D} agonism) may cause a central serotonergic syndrome if combined with other serotonergic drugs (MAOIs, SSRIs, TCAs, lithium). In 2006 the FDA warned that there is a risk of serotonin syndrome when triptans are combined with SSRIs or SNRIs but the American Headache Society (Evans ea, 2010), although advising vigilance, states that the evidence does not support these concerns.

³¹²⁹ Combined sumatriptan and naproxen for acute treatment of migraine may be more effective than either drug taken alone.(Brandes ea, 2007)

If headaches occur more often, use preventive treatment. Seizure activity may be precipitated by the aura of migraine, in which case valproate may be useful as an anticonvulsant and migraine prophylaxis. There may be an increased risk for suicide attempts in migraine sufferers. 5-HT receptor antagonists relieve migraine, especially sumatriptan (Imigran) that blocks 5-HT_{1D} receptors and frovatriptan (Frovex) that has affinity for 5-HT_{1D} and 5-HT_{1B} receptors. If the migraine sufferer is depressed, amoxapine or trazodone may be useful because of their high affinity for serotonin receptors. MAOIs (espc. phenelzine) were found to be useful in migraine in the past. Beta-blocking drugs, SSRIs, TCAs, divalproex, gabapentin (but see Landefeld & Steinman, 2009), topiramate (may reduce chronic migraine to episodic migraine: Edvinsson & Linde, 2010), flunarizine, and naproxen are used as prophylactic agents. Botulinum toxin has also been used for this purpose (when attacks last for at least 15 days in every month): injections are given in forehead, sides of neck, and back of neck. Telcagepant, a new calcitonin gene-related peptide receptor blocking drug, does not (unlike triptans) cause vasoconstriction, is probably as effective as the triptans for migraine prophylaxis.(Edvinsson & Linde, 2010)

Suggested approaches to managing migraine (after Goadsby, 2006)

- With failure of analgesics/NSAIDs in acute migraine try oral sumatriptan, rizatriptan, almotriptan, eletriptan or zolmitriptan (naratriptan or frovatriptan for slower effect/better tolerability; ergotamine orally or dihydroergotamine nasal spray for infrequent headache)
- For nausea or problems with taking tablets try sumatriptan or rizatriptan nasal sprays or rizatriptan (dissolvable wafer) or zolmitriptan (dispersible)
- For headache recurrence use ergotamine (rectally), naratriptan or eletriptan; when acute treatments are poorly tolerated try naratriptan or frovatriptan
- For early emesis use sumatriptan suppository or s.c. injection
- For headache related to menses use nocturnal ergotamine orally or oestrogen patches for prophylaxis and triptans or dihydroergotamine nasal spray for treatment
- For rapid escalation of symptoms s.c. sumatriptan or I.M. dihydroergotamine

Complicated migraine means that focal signs and symptoms of the aura persist beyond the headache phase. An aura lasting between 1 hour and 1 week is called *migraine with prolonged aura*. Persistence of signs lasting over 1 week or evidence on a scan of cerebrovascular accident is termed *migrainous infarction*: to make the diagnosis, the infarction must occur during a typical attack of migraine with aura; the usual infarct involves a wedge of posterior occipital lobe; and risk factors include young, female, smoking, and anovulant use.

Chronic migraine (transformed migraine) is the term used for attacks that increase quickly in frequency over at least a three-month period. Depression is common and often severe. Some, but not all, may be due to over-treatment (rebound headache) and such cases need to be detoxified very slowly. Stress may be important in other cases.

Familial hemiplegic migraine (rare, heterogeneous, autosomal dominant, chromosomes 19p13, 2q24) is associated with transient hemiparesis (with sensory, visual, or language dysfunction) preceding headache. A minority are confused during attacks. Most cases have symptoms of basilar migraine. A few cases develop permanent cerebellar signs. Affected genes code for various products, e.g. calcium (P/Q-type) and Na⁺/K⁺ pump.(Dichgans et al, 2005)

Basilar migraine (Bickerstaff migraine), which is more common in youth, is associated with double vision, tinnitus, dysarthria, bilateral paraesthesiae/paresis, impaired hearing, vertigo, and diminished consciousness. There is evidence of brainstem and occipital lobe dysfunction.

Childhood periodic syndromes (e.g. episodic midline abdominal pain) may be due to migraine. Other types of 'migraine' are *ophthalmoplegic* (headache plus diplopia) and *retinal* (attacks of monocular scintillations, scotomata, blindness, and headaches) migraine.³¹³⁰

HaNDL (headache, neurological deficits, and CSF lymphocytosis) occurs in people aged 15-40 years. There is often a migraine history and one-quarter experience a virus-like illness in the weeks before onset. There are a variable number of episodes of varying fleeting neurological deficits (incl. sensory, motor,

³¹³⁰ **Retinal migraine** is either extremely rare or of questionable validity and **ophthalmoplegic migraine** is now seen as a form of cranial neuralgia rather than a form of migraine.(Fleminger, 2009b, p. 501)

dysphasic), headache (moderate/severe bilateral throbbing), and occasional pyrexia. A minority experience migraine-like visual symptoms. The patient eventually recovers completely. CT and MRI are normal. CSF shows lymphocytic pleocytosis and increased protein level, but no oligoclonal bands. Viral studies are negative.

Cluster headache (migrainous neuralgia): This may be due to a disorder of the hypothalamus. Most cases are male, often heavy smokers and drinkers³¹³¹. Affected women often have atypical attacks. It is always strictly unilateral. It usually affects above one eye³¹³², though sometimes it may affect a cheek or even occur close to an ear. It often strikes at the same time each day. It may occur 1-3 times a day. It lasts a few hours (20 mins – 3 hrs, average 45 mins.). It usually occurs daily for 1-4 months and then remits for 6 months - 5 years. The eye often waters and becomes bloodshot. The ipsilateral nostril becomes blocked and may run. Sometimes the patient develops ptosis or even transient ipsilateral Horner's syndrome. A partial Horner's syndrome (minor degree of ptosis and meiosis), transient or permanent, may persist between attacks. Alcohol or aromatics often precipitate cluster headache. Cluster headache, like nightmares, may rouse the patient from REM sleep.

Analgesics have no useful effect. Cluster headache can be relieved by ergotamine given before an attack. If the condition is expected to last for a few weeks, corticosteroids can be used. If it lasts for much longer, use lithium. Treatment of an attack may involve oxygen (100%, 7-12 litres/minute: vasoconstrictive effect and reduces release of calcitonin gene-related peptide), sumatriptan (subcutaneous [6 mg] or nasal), zolmitriptan (nasal or oral), dihydroergotamine, nasal lidocaine, corticosteroids, and various other procedures, e.g. steroid occipital nerve injection. Various compounds have been advocated as prophylactics, e.g. steroids (prednisolone 60 mgs for 5 days; then reduce by 10 mgs every 2 days), lithium (Bussone ea, 1990), pizotifen, methysergide, topiramate, and verapamil (240-960 mg). Percutaneous radiofrequency trigeminal rhizotomy may be useful for chronic intractable cluster headache. Also, stimulation of the occipital nerves with electrodes implanted in the suboccipital region may be useful for chronic intractable cases. (Burns ea, 2007) The latter procedure may be slightly less effective but safer than hypothalamic deep-brain stimulation. (Leone ea, 2006)

The *differential diagnosis of tension, migraine and cluster headaches* is helped by the following facts.

Males constitute 9 out of 10 cases of cluster headache (CH – sharp, boring) and 4 out of 10 cases of tension headache (TH - dull), whereas 3 times as many women as men suffer from migraine (MH – throbs, pulsates). CH is felt around the eye, TH is diffuse, and MH can occur on one side of the head, in the temple, the front of the head, or around an eye. The greatest periodicity is shown by CH. CH occurs at least daily for months, MH happens a number of times per month, and TH varies from one attack to a few dozen attacks over a month. CH, the most severe type of the three, is relatively brief. The CH patient moves about whilst MH sufferers lie still, often in a darkened room. A family history, aura, photophobia or phonophobia, nausea or vomiting will favour migraine. Of course there is nothing to stop someone with one of these headache types having, say, a tumour. Also, MH sufferers are more prone to TH.

Secondary (symptomatic) cluster headache can be due to many intracranial disorders, e.g. parasellar meningioma. The diagnosis should be considered if there is no periodicity to the attacks, if there is some headache between attacks, if response to treatment is unsatisfactory, and if there are neurological signs (apart from miosis and ptosis).

Giant cell arteritis

Disorder of aorta plus its main tributaries

Largest arteries may dilate, dissect, or rupture

Late middle age onwards (most commonly 75-85 years of age)

Skin may be tender over inflamed superficial artery (pain when combing hair)

Thick, non-pulsatile **temporal** (and/or occipital) **artery** may be seen and felt

May be loss of weight, general lassitude, and depression

Delirium, coma, memory problems

ESR is usually raised (raised ESR and C-reactive protein has a 97% specificity)

Biopsy of the temporal artery is indicated in individual cases

³¹³¹ Both alcohol and glyceryl trinitrate can precipitate attacks.

³¹³² The Tolosa-Hunt syndrome, which responds to steroids, consists of pain in the eye area with oculomotor paresis on the same side.

Monocular or binocular visual loss due to ciliary artery involvement
 Patients whose vision is being destroyed often experience visual hallucinations (Nesher et al, 2001)
 Sometimes have ophthalmoplegia, peripheral neuropathy, myalgia and muscle wasting
 May have facial or oral pain with jaw claudication³¹³³ and difficulty opening mouth/protruding tongue
 Arteries elsewhere, e.g. heart and vertebral, may be occluded – infarction (carotid/vertebral)
 Advanced cases may develop scalp necrosis
 Manage with steroids, e.g. prednisolone +/- anticoagulants
 If treated properly, disease tends to remit in months/years

Susac's syndrome (retinocochleocerebral vasculopathy)

Possible autoimmune infarcting disorder described by John Susac during the 1970s
 Classical case is a young woman
 Deafness plus cerebral and retinal microangiopathy, mainly in young women
 Headache, encephalopathy, personality change, dementia
 After a few years there is variable remission +/- recurrences

Sinusitis

Knowledge of anatomy and a search for local signs (e.g. tenderness or non-illumination) should help in diagnosis
 X-rays may be required
 Visualisation of ethmoid and sphenoid sinuses may require CT or MRI

Trigeminal neuralgia

Diagnosed by UK GPs in 27/100,000 people/year (Bennetto et al, 2007)
 Usually occurs in middle to late age
 Considered in most cases to arise from an ectatic blood vessel (usually a branch of superior cerebellar artery) pressing on trigeminal ganglion
 Can herald multiple sclerosis in younger patients
 Occasionally due to tumour of cerebellopontine angle
 Repeated stabs of lancinating pain in one or more branches of trigeminal nerve
Tic douloureux refers to grimacing or facial spasm during attack
 Attacks may be precipitated by stimulation of specific spots (*trigger zones of Patrick*)
 Precipitants include opening the mouth, eating, swallowing, and hot or cold drinks
 Treatment often involves using carbamazepine (give to level of tolerance)
 Ablation has been used employing radiofrequency lesion or cryoprobe
 Rarely, surgery performed in posterior fossa
 If ganglion is destroyed on one side the pain may recur contralaterally
 Can place piece of material between ectatic blood vessel and ganglion
Anaesthesia dolorosa: severe neurogenic pain due to excess damage to facial sensation when treating trigeminal neuralgia

Glossopharyngeal neuralgia

Triggers include swallowing, chewing, coughing, yawning, or talking

Greater occipital neuralgia

Common
 Presents as pain (ache, pressure, throb, or even shooting) lasting minutes to days in various parts of the head, including retro-orbital
 May (or may not) follow trauma to head or neck
 Aetiology varies - nerve entrapment, myofascial, upper cervical facet joints, or posterior fossa lesion

³¹³³ Jaw claudication characteristically occurs whilst eating.

Raised intracranial pressure

Often presents in the early morning

Fades as the day goes on

Meningitis

Onset usually more gradual than for subarachnoid haemorrhage

Fever is common

Subarachnoid haemorrhage (SH)

Risk factors: tobacco, excess alcohol, hypertension, exertion, large/multiple aneurysms, autosomal dominant polycystic kidney disease

10% are familial

May have been a history of 'warning leaks' (headaches)

May be initial transient unconsciousness

Usually conscious when seen

Severe headache of sudden onset (*thunderclap headache*³¹³⁴), as if struck from behind

Meningism may take some hours to develop

May be mistaken for intoxication or 'psychogenic'

CT positive in 86% of cases (free blood in the subarachnoid space shows as hyperdense area)

MRI using fluid-attenuated inversion recovery (FLAIR) pulse sequences gives better pictures than CT (Noguchi et al, 1995)

CT angiography almost as good as conventional angiography

Clear CSF taken < 3 hours post onset of headache does not rule out SH (takes a long time for blood to diffuse throughout CSF) – only do lumbar puncture where CT scan is negative and if the clinical picture is highly suggestive and there are no focal signs, the patient is alert, and platelet count is adequate

High morbidity and mortality – today, 2/3 survive bleed and 1/3 have significant neurological dysfunction

Further bleeding – 2-3% over 10 years following clipping/coiling

There may be evidence of hypopituitarism

Common: anxiety (incl. worrying about recurrences), organic brain syndromes³¹³⁵, major affective disorder

Early complications – delirium, akinetic mutism

Longer term – chronic headache, various degrees of organic impairment (may or may not improve; may be subjective and/or objective – dementia can be severe), dysphasia

Suicide - 10% in one series

Epilepsy – 5% in first year

Coma > 24 hours or heavy alcohol intake are associated with poor outcome

Cerebral ischaemia (due to vasospasm, hypotension, etc) is a common sequel – nimodipine (calcium antagonist) is given for 3 weeks to reduce risk of ischaemia

Hydrocephalus can cause mental deterioration any time after subarachnoid bleed – short-term shunting may be required

Refer to neurosurgeon for angiography and surgery – coiling³¹³⁶ of aneurysms via intra-arterial catheter has largely taken over from clipping

Benign sex headache (BSH) can occur during sexual intercourse or masturbation (or unaccustomed vigorous exercise in unfit persons). Kritz first described *post-coital headache* in a formal way in 1970. There may be a dull, tight or cramping sensation in the occiput or generally, building in severity until orgasm or abruptly starting with orgasm. Headache may occur at other times. BSH is more likely if

³¹³⁴ Also caused by migraine [*crash migraine*], dissection of the carotid artery, and a number of other disorders.

³¹³⁵ Change in personality often includes irritability or emotionality. Cognitive dysfunction and poor psychosocial functioning are common. (van Gijn et al, 2007) Sometimes there is an improvement in personality – one antisocial patient of this author became a warm, affectionate citizen!

³¹³⁶ A coil of platinum is placed within the aneurysm that then evokes reactive thrombosis. Platinum coils are non-magnetic, thus allowing MRI.

attempting intercourse on a number of occasions in close succession, if fatigued, or if stressed. Uncommonly, vascular complications may result from hypertension during intercourse (such as subarachnoid bleeding). However, some post-coital headaches may be due to hypotension. BSH may even affect the passive partner. Frequent headache can often be prevented with propranolol or indomethacin.

Medications and illicit substances associated with sex-related headaches (examples)

Amyl nitrate
Phosphodiesterase-5 inhibitors
Contraceptive pill
Amiodarone
Cannabis
Amphetamines
Cocaine

The *pregnant* headache sufferer with acute migraine may initially try paracetamol followed by ibuprofen if inadequate relief ensues.(Duncan ea, 2008) Combined oral contraceptives should be avoided in women with migraine with aura because of increased risk of ischaemic stroke³¹³⁷. Peri-menstrual exacerbation of migraine may respond to simple painkillers but may require triptans such as sumatriptan. Hormone replacement therapy can potentially exacerbate migraine.

Attention-deficit hyperactivity disorder (ADHD)

ADHD, a heterogeneous disorder, has often excited controversy.(Timimi & Taylor, 2004; Zwi & York, 2004; Anonymous, 2008b) Terminology has changed significantly over time³¹³⁸.(Polanczyk ea, 2007b) ADHD is a DSM-III (and thereafter DSM-IV-TR³¹³⁹) concept whereas hyperkinetic disorder is a (narrower) DSM-II (hyperkinetic reaction of childhood) and ICD concept.(Santosh ea, 2008, p. 782) Many American children who receive this diagnosis might have been designated as conduct disorder in Europe, (Zwi ea, 2000) although Faraone ea, (2003) whilst admitting that DSM-IV produces higher prevalence rates³¹⁴⁰, discovered no significant difference between American and non-American children in terms of prevalence rates for ADHD. Nevertheless, treatment rates for ADHD differ markedly between countries.(Anonymous, 2007a) Goodyer (2008, p. 107) points out that the traits contained in the ADHD concept (inattention, hyperactivity, and impulsivity) could be measured quantitatively (rather than forming a category) since they are not discontinuous with more 'normal' values; however he also admits that the higher values show more heritability and poorer prognosis.

Global use of all medicines for ADHD in children aged 5-19 years rose threefold between 1993 and 2003.(Anonymous, 2007) American outpatient treatment rates for ADHD increased from 0.9 to 3.4 per 100 children from 1987 to 1997.(Olson ea, 2003) Kessler,(2004) stated that 4.4% of the US population met criteria for ADHD and that patients tended to be in treatment for co-morbid disorders (e.g. depression or alcohol abuse) rather than for the ADHD. According to Popper ea (2003, p. 838) 2-4% of the school population in the US receive psychostimulant medications. The American expansion of treatment was paralleled by an increase in the number of stimulant prescriptions, leading to organised protest meetings³¹⁴¹. A small study from Kentucky found that 5.5% of medical students had received a diagnosis of ADHD, 72% of these receiving the diagnosis while in college.(Tuttle, 2007) Telephone calls to American poison centres concerning misuse of drugs for ADHD increased during the period 1998-2005. This increase paralleled prescription rates for these medications.(Setlik ea, 2009)

³¹³⁷ Relative risk = 8.72.(Duncan ea, 2008)

³¹³⁸ 'Minimal brain dysfunction' was a forerunner of ADHD.(Wender, 1971) ADD refers to 'attention deficit disorder' (i.e. inattention without the overactivity) and may account for a third of ADHD cases.

³¹³⁹ **DSM-IV-TR** states that symptoms must be inconsistent for developmental age and intellectual ability and those symptoms must have lasted for at least 6 months and that some of the impairing symptoms must have been present before age 7 years. Symptoms must impair in at least 2 settings, e.g. school/work and home. Impairment has to be 'clinically significant'. **DSM-IV-TR subtypes of ADHD:** predominantly inattentive (20-30%), predominantly hyperactive-impulsive (<15%), and combined (50-75% of cases).

³¹⁴⁰ However, Simon ea (2009) who found in their meta-analysis that the prevalence of ADHD in adults declined with age suggested that DSM-IV underestimated the prevalence of the condition. They reported a pooled prevalence of adult ADHD of 2.5%.

³¹⁴¹ See <http://www.fightforkids.com>

Polanczyk *et al.* (2007b) found a worldwide pooled prevalence of 5.29% but Europe and North America differed significantly from Africa and the Middle East in prevalence estimates. However, geography played a limited role in explaining variability, the main contribution coming from methodological factors: diagnostic criteria, information source, and requirement of impairment.

Head injury in early childhood does not appear to cause ADHD. (Keenan *et al.*, 2008) Philipsen *et al.* (2008) found that ADHD was associated with emotional abuse in childhood and greater severity of adult borderline symptoms. Mcardle *et al.*, (2002) in their study of children in Newcastle upon Tyne, concluded that while conduct disorder occurs against a background of family conflict and poor child-care, hyperactivity, by contributing to a pattern of confrontation-punishment, is sometimes complicated by disturbed social conduct. Early onset of antisocial behaviour may be linked to a variant of the COMT gene, although the effect is interactive with lower birth weight and environment. (Thapar *et al.*, 2005) Low birth weight (LBW) itself may interact with the environment, *e.g.* Bohnert and Breslau (2008) found attention problems were associated with LBW in urban areas but not in suburban areas. Intrauterine growth retardation (small for gestational age) in very low birth weight subjects confers a risk for behavioural and emotional problems related to ADHD in young adulthood. (Strang-Karlsson *et al.*, 2008) Linnet *et al.* (2003), in their review of the literature, looked at maternal lifestyle practices during pregnancy and the risk for ADHD in offspring and found a suspicion that maternal smoking may be associated with ADHD and similar symptoms, a conclusion supported by others (Thapar *et al.*, 2003; Fowler *et al.*, 2009; Pringsheim *et al.*, 2009). Researchers (Mick *et al.*, 2002; Burt and Hendrick, 2003, p. 1519) have raised similar concerns about alcohol use by the pregnant mother. Button *et al.* (2005) suggest that maternal smoking during pregnancy may contribute in independent ways to both to ADHD and antisocial behaviour in offspring. Not all studies agree with the role of maternal smoking or alcohol use in the pathogenesis of ADHD, (Knopik *et al.*, 2005) and gene-environment interaction is known to be complex. (Knopik *et al.*, 2006; Thapar & Rutter, 2009)

Candidate genes that may be associated with ADHD include DRD-4 and -5, DAT-1, DBH, 5-HTT, HTR-1B, and SNAP-25. It is suggested that ADHD may be associated with DNA variation at the dopamine (DA) transporter gene (DAT-1) (Brookes *et al.*, 2006) and DA DRD-4 or -5 gene and this may explain a small part of the known tendency to run in families. (DAT-1 knockout mice show increases in activity levels.) Transmission of different alleles may be stronger in familial v non-familial cases. DAT1 genotype may interact adversely with maternal alcohol use during pregnancy. (Brookes *et al.*, 2006) It may also explain heterogeneity in selective attention in ADHD. (Bellgrove *et al.*, 2009) Drugs like methylphenidate may work by inhibiting the DA transporter (the noradrenergic system may be involved modulating methylphenidate action: Polanczyk *et al.*, 2007a). The DRD-4-7 variant mediates a blunted response to DA and the number of 7-repeat alleles may predict ADHD. This area requires further research and there are some conflicting reports. Van Dyck *et al.* (2002) found no evidence for altered DA transporter levels in adult ADHD. Thapar *et al.* (2007) looked at meta-analyses of molecular genetic studies and concluded that the 48-base pair variable number tandem repeat variant in the D4 gene and the CA(n) microsatellite marker in the D5 receptor gene are associated with ADHD whilst results for the 480-bp variable number tandem repeat in the dopamine transporter gene are mixed.

Haberstick *et al.* (2008) made heritability estimates of 0.3-0.38 for DSM-IV ADHD subtypes in young adults with retrospectively reported childhood ADHD. Knopik *et al.* (2005), in a study of female twins, found that 86% of residual variance in ADHD risk (after allowing for prenatal and childhood predictors) was due to genetic effects and 14% to non-shared environmental influences. Hudziak *et al.* (2005) reported that genetic analysis yielded a model that included genetic dominance (48%), additive genetic factors (30%), and unique environmental factors (22%). According to Biederman (2004), who estimates heritability of ADHD at a high 75% (Biederman & Faraone, 2005), the most important risk factor for ADHD is parental ADHD. He lists other factors as cigarette or alcohol exposure, low birth weight, and psychosocial adversity.

Children with ADHD have been shown to have higher mean blood lead levels than do their siblings. (Popper *et al.*, 2003, p. 840)³¹⁴²

Goos *et al.* (2009) found an inhibitory control deficit in children with ADHD and in their parents and suggested that this may represent an endophenotype of the disorder.

³¹⁴² Bouchard *et al.* (2009) reported that young adults with low lead exposure who had relatively high lead levels were at greater risk for major depression and panic disorder, suggesting that even traditionally 'safe' levels may do damage. One wonders what would be found if other substances were measured, *i.e.* do you find what you seek with statistics.

Although still subject to debate, there is some evidence that artificial additives, including colourings³¹⁴³ and the preservative sodium benzoate may contribute to hyperactivity in young children. (Bateman *et al.*, 2004; Kemp, 2008) Kemp (2008) suggests that an 'appropriately supervised and evaluated trial of eliminating colourings and preservatives' should be part of standard treatment.

Psychostimulants do not appear to slow cortical development. (Shaw *et al.*, 2009a) According to Flory *et al.*, (2007) lower serotonergic responsivity in childhood ADHD predicts later antisocial personality disorder. PET scanning has shown this latter group to have reduced glucose metabolism globally and regionally (especially in premotor cortex and superior prefrontal cortex, areas involved in control of attention and motor activity) and MRI in boys has found significant differences from controls in right prefrontal-striatal-pallidal structures. MRI in girls and boys has demonstrated significantly smaller volumes in the posterior-inferior cerebellar vermis. Other MRI research found right-sided grey matter deficits that might underlie attentional network disruption and left-sided white matter deficits that could possibly be due to demyelination. Sowell *et al.* (2003) performed MRI on children and adolescents with ADHD (and controls matched for age and sex) and found morphological abnormalities of frontal cortices and reduced regional brain size mainly involving bilateral inferior prefrontal cortex; brain size was bilaterally smaller in anterior temporal cortex; and there were prominent bilateral increases in gray matter in large parts of the posterior temporal and inferior parietal cortices. Castellanos *et al.* (2003) performed MRI on nine pairs of monozygotic (MZ) twins discordant for ADHD and found affected twins had smaller caudate volumes than did their unaffected co-twins. Qiu *et al.* (2009) used MRI and found that boys had small basal ganglia volumes and volume compression of bilateral caudate head and body, anterior putamen, left anterior globus pallidus, and right ventral putamen, as well as volume expansion in posterior putamen, whereas girls with ADHD had basal ganglia volumes and shapes similar to normal controls. Shaw *et al.* (2009b) prospectively followed children with and without ADHD with MRI. In normal development increased dimensions of right frontal and left occipital cortex emerge in the adult from the reversed pattern of cortical asymmetries in the child. Loss of the prefrontal part of such changes in ADHD is in keeping with disrupted function in that area. McAlonan *et al.* (2009b) found that an ADHD group had difficulty inhibiting a prepotent response and took longer to shift to a new response and these reaction times correlated with fronto-striatal-temporal volumes; these volumes increased with age on MRI and older children improved in terms of reaction speed; in particular, better inhibitory control was associated with larger regional grey matter volumes in bilateral anterior cingulate, right basal ganglia, and left medial temporal circuitry. Biederman *et al.* (2008c) found that ADHD and bipolar disorder independently contributed to volumetric changes of separate brain structures in adults. The pulvinar may be small bilaterally in ADHD but it seems to enlarge if stimulant medication is taken. (Ivanov *et al.*, 2010) The same authors (Ivanov *et al.*, 2010) used MRI and found that 8-to-18-year-olds with ADHD with severe hyperactivity had reduced sizes in right lateral and left posterior thalamic surfaces whereas those with severe inattention had increased sizes of right medial thalamic surfaces. In one controlled fMRI study, (Schulz *et al.*, 2004) adolescents with childhood-onset ADHD showed enhanced responses during inhibition in ventrolateral prefrontal cortical areas that subserve response inhibition, as well as in anterior cingulate and frontopolar regions involved in other executive functions. In an fMRI study employing a task requiring withholding of a triggered motor response (see also Pliszka *et al.*, 2006) medication-naïve adolescents with ADHD demonstrated reduced activation in the right inferior prefrontal cortex during successful motor response inhibition and in the precuneus and posterior cingulate gyrus during inhibition failure. (Rubia *et al.*, 2005) Children with ADHD failed to activate the caudate nucleus in one fMRI study involving tests of interference suppression and response inhibition. (Vaidya *et al.*, 2005) Stevens *et al.* (2007) conducted fMRI during an auditory oddball task (tests the brain's ability to attend to odd or novel environmental stimuli) on boys with combined type ADHD (hyperactive and impulsive) and found deficits in areas involved in orienting attention and processing working memory. During a task that measures the underlying neural control of inhibition and stopping (compared to normal boys) Rubia *et al.* (2008), using fMRI, found that during successful inhibition boys with pure ADHD have relatively less activation in the left dorsolateral prefrontal cortex and, during inhibition failures compared to go responses, boys with either pure ADHD or pure conduct disorder demonstrated underactivation of the posterior cingulate gyrus, and pure conduct disorder was associated with reduced temporoparietal activation bilaterally. An fMRI study (Rubia *et al.*, 2009) of male (aged 9-16 years) pure ADHD, pure conduct disorder, and healthy subjects found

³¹⁴³ E.g. tartrazine, sunset yellow, and carmoisine.

a process-related prefrontal dysfunction in both disorders: attention-related dysfunction in ventrolateral prefrontal cortex in ADHD and reward-related dysfunction in orbitofrontal cortex in conduct disorder. Brotman *et al.* (2010) used fMRI during exposure to neutral faces in children with ADHD, bipolar disorder, and 'severe mood dysregulation', as well as normal controls and found that ADHD subjects demonstrated overactivity of the left amygdala whilst the mood dysregulated group showed under activity. fMRI findings also suggest that methylphenidate may normalise activity in the left ventral basal ganglia. (Shafritz *et al.*, 2004)

An MRS study (Stanley *et al.*, 2008) comparing 6-10-year-old with and without ADHD found lower bilateral membrane phospholipid precursor³¹⁴⁴ levels in the basal ganglia and higher membrane phospholipid precursor levels in the inferior parietal region, suggesting aberrant brain development.

A PET study of never-treated adult ADHD subjects and a non-ADHD comparison group (Volkow *et al.*, 2009) evaluated the brain reward pathway in ADHD. The authors found lower levels of DA receptors and transporters in the nucleus accumbens and midbrain, with the most pronounced cases of ADHD having the lowest levels of these proteins in these brain areas.

Neonatal ultrasound abnormalities suggestive of white matter injury in low-birth-weight babies are associated with increased risk for some psychiatric disorders, especially ADHD, at age 6 years. (Whitaker *et al.*, 1997)

It has been suggested that about 50% of hyperactive children will become hyperactive adults. (Toone *et al.*, 1999; Kooij *et al.*, 2005) Meta-analysis of follow-up studies (Faraone *et al.*, 2006a) found that rates of persistence to age 25 years depended on breadth of diagnostic criteria: 15% for full criteria and 65% for partially remitted cases. Hyperactivity and impulsivity seem to attenuate faster than inattention over time in children with ADHD. (Biederman *et al.*, 2000)

Adult ADHD is an impairing and costly disorder. (Kessler *et al.*, 2009) ADHD affects 0.4% of adults (Kessler *et al.*, 2006) and 4% of adults. (Spencer, 2004) A study in ten countries (Fayyad *et al.*, 2007) found ADHD in 3.4% (range 1.2-7.3% - higher in richer countries) of adults, co-morbidity and disability were common, and patients were more likely to be treated for their other problems than for ADHD. Services for adult ADHD in Britain are patchy. (Edwin & McDonald, 2007) According to Fitzgerald (1998) the core symptoms of ADHD of inattentiveness, impulsivity and hyperactivity affect 0.5-1% of adults. There seem to be deficits in executive function related to spatial working memory but unrelated to age or symptoms. These are not present in those patients on psychostimulants. (Barnett *et al.*, 2001) Co-morbidity is common (Biederman *et al.*, 2006): anxiety, opposition, conduct disorder, antisocial personality disorder, alcohol and substance misuse, and marital/occupational/educational problems. Although Spencer (2004) found that 40% of adults with ADHD may have no comorbid disorder, McGough *et al.* (2005) reported significant lifetime psychiatric comorbidity in adult ADHD. Dalsgaard *et al.* (2002) found that Danish girls with a diagnosis of ADHD had a higher risk of psychiatric admission in adulthood compared with boys with ADHD. Although such girls may be less likely to have comorbid conduct disorder than such boys, the risk of psychiatric admission in adulthood is greatly increased by its presence. McCann *et al.* (2000) found that half of adults with ADHD had a history of psychoactive substance use disorders. Biederman *et al.* (2010) followed up ADHD girls into young adulthood and found that they were at high risk for antisocial³¹⁴⁵, addictive, affective, anxiety, and eating disorders. Developmental coordination disorder (motor coordination problems impacting on daily activity/learning) occurs in a significant number of ADHD children. (Kirby *et al.*, 2007) Biederman *et al.* (2008a) conducted a familial risk analysis and found evidence to suggest that the association between ADHD and drug dependence is likely due to variable expression of a common risk for both disorders, but that the association between ADHD and alcohol dependence results from independent transmission of the two conditions. Biederman *et al.* (2008b) followed up subjects for 10 years (mean age 10.7 to 21.7 years) and found that oppositional defiant disorder was associated with major depression, and oppositional defiant disorder increased the risk for conduct disorder and antisocial personality disorder, but only conduct disorder significantly increased the risk for substance abuse, smoking, and bipolar disorder. The same group (Wozniak *et al.*, 2010) found similar rates of ADHD in the families of ADHD and bipolar I children. Langley *et al.* (2010) examined 5-year outcome for a UK cohort of children diagnosed with and treated for ADHD and found that about 70% still had full ADHD, were known to specialist services, and exhibited

³¹⁴⁴ Phosphomonoesters that are anabolic metabolites of membrane phospholipids.

³¹⁴⁵ Lifetime hazard ratio = 7.2 (95% CI = 4.0-12.7) in comparison to age-matched females.

high levels of antisocial behaviour, criminality and substance use problems; maternal childhood conduct disorder predicted offspring ADHD continuity, and maternal childhood conduct disorder, lower child IQ, and social class predicted conduct disorder symptoms in the children.

Whilst it is stated that ADHD is commonly associated with BAD and both complicates its course and interferes with social adjustment, Santosh et al (2008, p. 783) point out that consensus has yet to be reached on the 'existence and definition of pre-adolescent mania'. The co-association of ADHD and lifetime bipolar affective disorder (BAD) has been examined in a Turkish study of 159 BAD patients. (Tamam et al, 2008) 16.3% of BAD cases had adult ADHD. A different 10.7% were diagnosed with childhood (but not adulthood) ADHD. The authors used the *Wender Utah Rating Scale* and a *Current Symptoms Scale* for ADHD symptoms. Only BAD cases with adult ADHD had higher lifetime Comorbidity rates for Axis I disorders (panic, alcohol, etc) compared to cases without lifetime ADHD. BAD with comorbid adult ADHD did not differ from BAD patients with comorbid childhood ADHD in terms of demographics or clinical variables except for adult ADHD scale scores.

The *Utah criteria* (Wender, 1995; Ward et al, 1993) include inability to relax, dysphoria when inactive, restlessness, distractibility and non-completion of tasks, labile mood, impulsivity, transient temper outbursts, excessive or inappropriate reactions to mundane events, and problems in any life area. However, it is argued that these do not provide a diagnosis in adulthood. (Kirley & Fitzgerald, 2002; McGough & Barkley, 2004) However, Reimherr (2006) defended the criteria, arguing that they focus on recalling easily remembered childhood problem areas. Also, a number of authors (e.g. Tamam et al, 2008) continue to use them for adults.

Utah Criteria for ADHD (Wender, 1995)

Childhood diagnosis: DSM-IV criteria (from parents/older siblings) or hyperactivity + attention deficits and 1 of school behavioural problems/impulsiveness/over-excitable/temper outbursts/combined with *Wender Utah Rating Scale +/- Parents Rating Scale*

Adult characteristics: Motor hyperactivity + attentional problems and 2 or more of affective lability/disorganisation/temper outbursts/over-reactive emotionally/impulsive/other axis I diagnoses excluded

The *Connors Teacher and Parents Rating Scales – Revised* and the *Child Behaviour Checklist* are commonly used scales used to evaluate ADHD symptoms.

Problem arises when ADHD was not diagnosed in childhood and an adult psychiatrist is presented with prominent antisocial personality traits. DSM-IV-TR demanded a childhood history of ADHD in order to entertain the diagnosis in adulthood, and DSM-IV-TR does not permit a separate diagnosis of ADHD in the presence of a pervasive developmental disorder (although the patient may meet the diagnostic criteria). DSM has been challenged as being excessively stringent since cases with very late onset are encountered clinically. (see Faraone et al, 2006b, 2009) Dispute notwithstanding, late diagnosis requires corroboration from as broad a number of sources as is practicable, including the family, general practitioner, any existing childhood and school assessments. (e.g. Rey et al, 2007, p. 407)

'Undiagnosed' adult cases may have an excess of depression, problem drinking, lower educational attainment, and many emotional and interpersonal problems. (Able et al, 2006)

The differential diagnosis of ADHD, which has been called a 'diagnosis of exclusion' by Popper et al, (2003, p. 848) is a broad one.

Differential diagnosis of ADHD

Normality (including attention-seeking behaviour), boredom,

Excess psychosocial stimulation or deprivation

Cerebral trauma

Many psychiatric disorders - including posttraumatic stress disorder, mood disorders, oppositional defiant disorder, and conduct disorder

Child sexual abuse

Hunger, constipation, pain

Thyroid diseases

Various drugs/toxins e.g. pseudoephedrine, caffeine, lead, and theophylline

Hyperactivity confined to school should prompt a search for specific remediable problems such as specific learning disorders. Hyperactivity confined to the home should lead to an evaluation of parenting. (Santosh ea, 2008, p. 783) In such cases there may be no need for drug treatment.

Despite earlier teachings, psychostimulants **do not** have a 'paradoxical' effect in ADHD cases. Similar doses have similar effects on cognition and behaviour in normal boys, hyperactive boys and healthy adults. (Cozza ea, 2003, p. 1405)

Pemoline, formerly used for ADHD was withdrawn because of concerns over hepatic toxicity. (Toone ea, 1999; Kooij ea, 2004) The FDA decided in 2006 to have *Ritalin* and *Concerta* (methylphenidate HCL) and *Adderall* (amphetamine) carry a black box warning due to their tendency to cause raised blood pressure and cause tachycardia, with a resultant potential to increase risk for heart attack, stroke, and sudden death. *Novartis* circulated a warning in the same year to avoid stimulants in the presence of structural heart abnormalities or severe hypertension. Problems with stimulants are summarised in a box.

Stimulants (e.g. Santosh ea, 2008, p. 785)

About one-third of cases fail to respond to or to tolerate stimulants

Avoid in schizophrenia, cardiac arrhythmias/angina pectoris, glaucoma, and hyperthyroidism

Caution advised with young people, depression, high blood pressure, pervasive developmental disorder, severe intellectual disability, tics/Tourette in family, history of drug misuse

Time (weeks) or drop in dose may decrease common side effects such as headache, irritable mood, tummy pain, and anorexia

Mild appetite suppression is usual: take medication after morning and midday meals, use high calorie snacks, and use lower doses at weekends/holidays

Rebound effects (excitable, overactive, irritable, excessively chatty, and poor sleep- the latter may be drug-induced or related to a return/exacerbation of ADHD - adding clonidine before retiring, reducing/bringing forward last stimulant dose, or a change in medication may improve sleep) may occur at day's end or following abrupt cessation of stimulant

Methylphenidate can usually be used in the presence of well controlled epilepsy

Rare stimulant effects include aggressiveness, psychosis, and hypertension

For reasons that are not clear, there may be a tendency to stop prescribing stimulants as patients with ADHD reach late adolescence and early adulthood (McCarthy ea, 2009)

Different authors suggest that stimulants stunt growth or that growth delay is part of ADHD – baseline measurement of height and weight, repeated at intervals, is a wise approach

Concerta XL is prolonged release methylphenidate³¹⁴⁶ taken once daily in the morning whereas *Equasym* is an immediate release form of methylphenidate³¹⁴⁷ that was launched in 2004. Doses of Ritalin over 5 mg daily are given in divided doses. A mixture of amphetamine salts has improved adult ADHD, at least in the short term. Concern has been voiced over a too broad use of stimulants (Rey & Sawyer, 2003) although stimulant treatment for ADHD has been reported to reduce (or not increase or be neutral) the likelihood of substance abuse. (Wilens ea, 2003; Mack ea, 2003, p. 368; Faraone ea, 2007; Biederman ea, 2008a; Mannuzza ea, 2008)

Atomoxetine³¹⁴⁸ (*Strattera* – 10 mg, 18 mg, 25 mg, 40 mg, and 60 mg capsules) is a non-stimulant treatment for ADHD in persons of 6 years of age and older; it may work by selectively inhibiting the presynaptic noradrenaline transporter³¹⁴⁹.

Atomoxetine

³¹⁴⁶ UK guidelines that methylphenidate should be supervised by 'a specialist in childhood or adolescent behavioural disorders' can presumably be translated into 'a specialist in adulthood behavioural disorders' when treating adults!

³¹⁴⁷ 5, 10 and 20 mg tablets.

³¹⁴⁸ Atomoxetine is mainly metabolised by CYP2D6. Atomoxetine is excreted primarily as 4-hydroxyatomoxetine-O-glucuronide, mainly in the urine.

³¹⁴⁹ Lack of cerebral cortical DA terminal DA reuptake sites causes DA to be taken up a noradrenaline reuptake sites, and the resultant increase in prefrontal cortical DA may be the main action of atomoxetine in ADHD.

Take in the morning or, if needed twice daily, a second dose is administered in the late afternoon/early evening

Initial doses for children/adolescents depend on body weight: 0.5 mg/Kg for up to 70 Kg and 40 mg/24 hours if over 70 Kg

Doses in moderate and severe liver insufficiency should be 50% and 25% of usual doses

Dose is not reduced with compromised renal function

Contraindicated for use within 2 weeks of MAOI therapy (or *vice versa*) and in those patients with narrow angle glaucoma³¹⁵⁰

Should be stopped if patient is jaundiced or has abnormal liver tests (rare cases of liver damage reported)

Growth should be monitored, although effects on height are minimal (Crawford ea, 2008, p. 1395)

Possible allergic events – rash (potentially severe), angioneurotic oedema, and urticaria

May get postural hypotension, modest tachycardia and increase in blood pressure, abdominal pain, decreased appetite, early weight loss followed by weight gain, nausea and vomiting, constipation, indigestion, flatulence, flu-like symptoms, rigors, sinus headache, disturbed sleep³¹⁵¹, dizziness, irritability, unstable moods, fatigue/lethargy, decreased libido, hot flushes, dysmenorrhoea, ejaculatory/orgasmic/erectile problems, cold peripheries, urinary retention/hesitancy, and prostatitis

FDA statement, September 2005: 0.4% of children and adolescents on atomoxetine v 0% on placebo experienced suicidal thoughts

Irish Medicines Board statement, October 2006: monitor patients for hostility and emotional lability

Anonymous (2007b): long-term safety not clear; reserve for patients who cannot take or cannot tolerate stimulants

Newcorn ea (2008): atomoxetine (45% response) better than placebo (24%) but not as good as methylphenidate (56%) – however, different people respond better to one or other of the active compounds

Rare: *acute hepatitis*

Co-existing tics are not exacerbated

Action of beta-2 agonists (e.g. salbutamol) on the cardiovascular system may be potentiated by atomoxetine

Drugs affecting noradrenaline³¹⁵² may act synergistically with atomoxetine

Overdose: agitation, hyperactivity, bizarre behaviour, GIT symptoms, mydriasis, tachycardia, and dry mouth

Desipramine³¹⁵³ (> venlafaxine, > other antidepressants) may help, although sudden death has been reported in children³¹⁵⁴. Not all experts believe that TCAs are useful here and some relegate TCAs to second- or third-line status.(Cozza ea, 2003, p. 1413) However, Spencer ea,(2002) in a double-blind placebo-controlled trial in children and adolescents with chronic tic disorder comorbid with ADHD, found desipramine to be well tolerated and to ameliorate both disorders. Fluoxetine may help impulsiveness and aggression if the dose is increased very slowly. Lithium may be used for severe emotional lability or in cases with bipolar affective disorder. Bupropion carries a risk of seizures but does not interact with asthma medications.(Connors ea, 1996) Clonidine and guanfacine (Tenex in USA) may be useful if ADHD is accompanied by tics. Clonidine has also been seen as useful for aggressive symptoms. An ECG is suggested by Hoare (2004, p. 595) because of reports of fatal cardiac arrhythmias. Guanfacine is longer lasting and less sedating than clonidine. Carbamazepine can be useful in resistant cases.(Silva ea, 1996) Adding divalproex to optimised stimulant therapy in children with ADHD and refractory aggression may reduce levels of aggression (Blader ea, 2009) but larger trials are required to determine the size of the reduction.

Behaviour therapy employing contingency principles based on learning theory is advocated although effects may not be sustained once therapy ceases and generalization of learning to new setting may not occur. Cognitive psychotherapy is also advocated but results are contradictory.(Santosh ea, 2008, p. 790) Social skills training works best in peer groups. Parental and teacher psychoeducation and training in

³¹⁵⁰ Increased mydriasis.

³¹⁵¹ EMW and middle insomnia.

³¹⁵² E.g. TCAs, venlafaxine, mirtazepine, pseudoephedrine, and phenylephrine.

³¹⁵³ TCAs in children - monitor for cardiac problems: vital signs and ECGs.

³¹⁵⁴ However, Biederman ea (1995) did **not** find a causal relationship between desipramine and risk of sudden death.

learning theory principles (often modelled by the therapist) may be beneficial. The family might require assistance in changing communication patterns and improving functioning (Barkley et al, 1992) although gains are relatively modest.

Guidance issued by the UK National Institute for Clinical Excellence is summarised in the box.

2008 NICE guidance for ADHD (Kendall et al, 2008)³¹⁵⁵

Diagnosis

Must meet ADHD criteria of DSM-IV or hyperkinetic disorder criteria of ICD-10; impairment is at least of moderate clinical and/or psychosocial significance (taking chronological and mental age into account); symptoms are pervasive (occur in at least two settings); thorough assessment of needs

Treatment

Preschool: offer parents/carers referral to parent training/education programme; drug treatment is not recommended

Teachers of school age children: those trained in ADHD and its management should provide behavioural interventions in class (e.g. token system)

School age child/young person with moderate ADHD: offer parents/carers referral to parent training/education programme (+/- informing school of areas of behavioural management addressed in sessions); offer medication to those who refuse non-drug management or who don't respond to parental/carer training/education programme or group therapy; only a healthcare professional who is appropriately qualified and who is expert in ADHD should start medication (methylphenidate, atomoxetine, or dexamfetamine) although GPs can continue the medication as part of a shared care approach

School age child/young person with severe ADHD: Offer methylphenidate or atomoxetine (only a healthcare professional who is appropriately qualified and who is expert in ADHD should start medication) as part of a comprehensive plan (include psychological, behavioural, and educational advice/intervention)

Dietary advice: elimination of artificial colouring and additives is not generally recommended for children with ADHD

Adults: Offer methylphenidate as first line treatment (only a healthcare professional who is appropriately qualified and who is expert in ADHD should start medication) unless the patient prefers a psychological approach as part of a comprehensive plan (meet psychological, educational, and/or occupational needs)

(Gilles de la) Tourette syndrome (GTS)

GTS³¹⁵⁶ consists of multiple motor tics³¹⁵⁷ and unprovoked loud utterances that may progress to coprolalia³¹⁵⁸ in 30-60% of cases. Copropraxia may also occur. Prevalence is unknown but is probably more common than is thought³¹⁵⁹. DSM-IV requires an onset before 16 years of age. It affects at least 1/2,000 in the USA and 7 men for every 2 females. A MZ concordance rate of 53% contrasts with a DZ concordance rate of 8%, and risk for first- and second-degree relatives of patients with GTS has been estimated at 3.6% compared to 0.029% in the population at large. Spontaneous cases can occur. Polygenetic inheritance with complex input from the environment appears likely. An autosomal dominant gene with incomplete but high penetrance is possible in some cases. Variants in the SLITRK1 gene have been found in about one percent of GTS cases. It has been surmised that GTS, chronic multiple tics, simple

³¹⁵⁵ Thompson (2008) discusses the controversial aspects of this guidance, e.g. the cost (what other services get cut?), specialisation, licensing (methylphenidate not licensed in UK for adults in 2008), low evidence base (for group therapy), and time required involved, not to mention drugs not mentioned.

³¹⁵⁶ Itard first described this syndrome in 1825. Gilles de la Tourette's description came in 1885. Tourette syndrome may not be a single disorder, e.g. Robertson et al (2008) observed 5 factors in symptom data from 410 cases: socially inappropriate behaviours and other complex vocal tics; complex motor tics; simple tics; compulsive behaviours; and touching self. Those with co-morbid ADHD had a clearer relationship with the first and third factors, whereas co-morbid OCD was associated with all 4 factors.

³¹⁵⁷ Tics *per se* are not considered pathological unless they cause significant personal distress or social problems. The tics may persist during sleep and become worse with REM sleep. Exacerbation of tics may follow stress, as when someone relaxes after work or school. Factors that may reduce their intensity include sexual arousal or preoccupation with emotionally neutral material.

³¹⁵⁸ Mental coprolalia, where obscenities are thought but not uttered, may be commoner than the overt form. The former may eventually become overt.

³¹⁵⁹ Estimates of lifetime prevalence vary from 0.1 to 1%. Most cases are probably mild and do not present for medical evaluation.

tics, and OCD disorder are expressions of the same gene, that there is a dopamine transmission problem, and that the site of the lesion is in the limbic forebrain structures, especially cingulate gyrus and basal ganglia. However, not all OCD cases are familial or aetiologically related to GTS.(Eapen ea, 2003, p. 968) Broadly distributed cortical systems are likely to be involved in the pathogenesis of GTS. An MRI study (Peterson ea, 2003) found reduced caudate volumes in children and adult GTS cases (possibly a trait abnormality); smaller lenticular volumes may be a marker for comorbid OCD and for persistence of tics into adult life. A smaller corpus callosum might reduce inhibitory input to the prefrontal cortex.(Plessen ea, 2004) fMRI shows increased frontal cortical and caudate activity³¹⁶⁰ when patients attempt to suppress tics and PET reveals an increase in DA receptor and transporter densities plus increased amphetamine-induced release of DA in the putamen. EEG theta activity is associated with more severe cases. Various studies suggested abnormalities of acetylcholine activity, dopamine receptor sensitivity, platelet MAO concentration, and 5-HT metabolism.

Muller ea (2000) found that the mean level of antistreptolysin O and antideoxyribonuclease B titres were significantly higher in children and adults with GTS compared to age-matched controls and to schizophrenic subjects³¹⁶¹.

ADHD symptoms are commonly comorbid with, and often precede, GTS³¹⁶² and both disorders may respond to the alpha-2 agonists clonidine and guanfacine. Obsessive-compulsive symptoms are common in both patients and their relatives. In fact, it has been stated that if OCD and GTS are lumped together there is a good fit for an autosomal dominant model with a penetrance of 0.88 for both sexes. 50% may have hyperkinetic symptoms. Clinical course is one of waxing and waning of multiple motor and vocal tics. One-third has copro- and echophenomena. Copropraxia refers to the occurrence of complex obscene gestures. According to Popper ea (2003, p. 909) up to half these patients are much better or in remission by age 18 years although the opposite (poor outlook with ADHD, depression, learning problems, and conduct disorder) has been reported by Gorman ea.(2010) GTS has emerged during fluvoxamine treatment of an adolescent with OCD.

Treatment includes butyrophenones³¹⁶³, such as haloperidol (Haldol, Serenace), or pimozide; risperidone, olanzapine, or ziprasidone; habit reversal³¹⁶⁴, massed practice³¹⁶⁵ and encouragement of personal responsibility as part of maturation. Psychoeducation is important.

Psychostimulants³¹⁶⁶, often used for attentional and hyperactivity states, may precipitate motor or vocal tics that may persist after discontinuing the medication. It is suggested that they should therefore only be employed with extreme caution if there is a family history of tics or GTS. Some authors, however, believe that stimulant-induced tic exacerbation is unlikely.(Popper ea, 2003, p. 911; Huffman & Stern, 2008, p. 719) Methylphenidate may be associated with psychotic symptoms.³¹⁶⁷ Hyperkinesia may respond to TCAs.

Most individuals with tics lead reasonably normal lives, and the tics tend to improve during the teens.(Chowdhury & Heyman, 2004) Oesterheld ea (2003, p. 360) caution against stimulant abuse among the relatives of children receiving treatment with such drugs.

Deep brain stimulation (electrodes placed in midline thalamus, nucleus accumbens, or globus pallidus interna) has been used for severe, intractable tics.(e.g. Ackermans ea, 2008) Other treatment approaches include vocal cord injections of botulinum toxin (Porta ea, 2004) for vocal tics and coprolalia. The latter produced hypophonia in 80% of cases.

³¹⁶⁰ With decreased activity of thalamus, globus pallidus, and putamen.

³¹⁶¹ See *PANDAS* - paediatric autoimmune neuropsychiatric disorders associated with streptococcal infection.

³¹⁶² According to a nested case study of children assessed for GTS at specialised clinic (Pringsheim ea, 2009) children with this syndrome are more likely to have comorbid ADHD if their birth weight was low and if their mothers smoked.

³¹⁶³ Chemically related to pethidine.

³¹⁶⁴ Patient learns to recognise (with help from the therapist) and describe tics as well as recognising recurrences and what circumstances may precipitate them. He (or she) re-enacts tics into a mirror. The patient uses competing responses (such as isometric contraction of opposing musculature) when the urge to tic occurs.

³¹⁶⁵ Each tic is repeated voluntarily until it is extinguished.

³¹⁶⁶ E.g. dextroamphetamine, methylphenidate and pemoline – pemoline was withdrawn in UK because of fatal hepatotoxicity, sometimes after many months of use.

³¹⁶⁷ 6% of children in retrospective chart review.(Cherland & Fitzpatrick, 1999)

Kluver-Bucy syndrome

Kluver (or Klüver) and Bucy described this in 1939. Although it has since been diagnosed in man, it was originally described in monkeys following bilateral temporal lobe destruction. Features include the examination of all available objects with the mouth, licking and biting, hypermetamorphosis (nothing ignored and constant exploration), always exploring, placidity, hyperphagia, and hypersexuality (including homosexuality and sexual intercourse with other species). There is psychic blindness (responds in a similar manner to an orange as to a charging bull - able to see but he is unable to meaningfully discriminate between objects). Parts of this syndrome are commonly present in (usually late) AD and are associated with greater temporal lobe atrophy (reduced counts of large neurones in parahippocampal gyrus and parietal neocortex – cortical inhibition with relatively intact subcortical structures?). Again, parts of the syndrome may occur early in the course of frontotemporal dementia.

Diogenes or Plyushkin's syndrome³¹⁶⁸

Diogenes syndrome is named for Diogenes of Sinope, (Wrigley & Cooney, 1992; O'Shea & Falvey, 1997; Cooney, 1997) a Greek cynic philosopher³¹⁶⁹. Clark coined the term in 1975 to describe gross self-neglect in old age and Post called it 'senile recluse'. Plyushkin was a character in Gogol's novel '*Dead Souls*'. The syndrome is found about equally in men and women. Affected persons often refuse help from professionals and they collect all sorts of rubbish (*sylogomania*). About 50% have a formal psychiatric illness at the time of examination, but far fewer have been admitted to psychiatric care. In fact, such patients often flatly refuse to be helped. (Hurley et al, 2000) The most common psychiatric diagnoses are Alzheimer's disease (AD), chronic paranoid schizophrenia, chronic alcoholism, and bipolar affective disorder. The death of a close relative may be a precipitating factor in those with no psychiatric illness. There is a high physical morbidity and mortality. Some cases may have frontal lobe dysfunction. (Sikdar, 1999) Community studies suggest a somewhat different profile for people living in squalor: somewhat younger males of lower social class who are mentally ill and older people who are physically ill. (Halliday et al, 2000) Cases of married couples with so-called 'Diogenes à deux' have been reported. (e.g. Cole et al, 1992) Diogenes syndrome represents a dilemma for psychiatry and for society. Do we let patients live and squalor in case we infringe human rights³¹⁷⁰ ('rotting with their rights on')? Do we insist on doing something because of the danger of infectious disease? The answer is easier when the patient is obviously psychotic.

Sick building syndrome (SBS)

Various uncomfortable or even disabling symptoms and illnesses have been attributed to non-industrial indoor environments, especially schools and (tall) office buildings. (O'Shea, 2002a) Objective physiological abnormalities are uncommon.

Common symptoms in SBS

Irritation of throat and eye
Headache
Fatigue
Diminished concentration
Dyspnoea, wheeze, irritating cough
Skin rash, itch, and dryness

³¹⁶⁸ Other names include *Augean Stables syndrome* and *social breakdown of the elderly syndrome*. The stables in Greek myth belonged to Augeas (Augeias) who was king of Elis. The stables, unclean and housing many cattle, were cleaned by Heracles (Hercules) who achieved his task in a single day by rerouting rivers.

³¹⁶⁹ Diogenes (c. 412 or 404-323 BC) was a native of Sinope, now Sinop in Turkey. A beggar who admired poverty and decried human achievements, he lived in an Athenian tub and ate onions.

³¹⁷⁰ In the UK the provisions of *The National Assistance Act 1948, section 47* are rarely used.

Increased or abnormal odour perception
Visual disturbances

Suggested causes

Air contaminants, e.g. photocopiers, cleaning agents, paints/resins, bacteria
Ventilation

Work organisation – job satisfaction, stress, social factors

Host factors – commoner in females, atopy, airway hyperactivity, and pre-existing disease

“Mass psychogenic illness” – many people within close proximity to one another (e.g. the same building)
develop non-specific symptoms of illness through a process of suggestion

Some trigger may start the condition, such as a disagreeable odour or an unexplained noise. The key to diagnosis is the almost simultaneous development of roughly the same symptoms by a number of people inhabiting the same building. SBS must be distinguished from a non-random collection, e.g. anxious patients in a specialist unit; toxic emissions, e.g. lead, mercury, coal dust; infectious diseases, e.g. influenza, tuberculosis; Gulf War syndrome; fibromyalgia (FMY); chronic fatigue syndrome (CFS); and multiple chemical sensitivity (MCS).

‘Multiple chemical sensitivity’ (MCS) patients often meet diagnostic criteria for the other polysymptomatic syndromes just mentioned viz.: - FMY, CFS, and SBS, and many MCS patients may attribute their symptoms to the toxic environment of a building. Interestingly, many Persian Gulf War veterans who blamed symptoms on toxic exposures have attracted a diagnosis of MCS. Gulf War syndrome (cognitive difficulties, fibromyalgia, depression, anxiety, respiratory problems and chronic fatigue) is not unique to that conflict. Ismail *et al.* (2002) felt that psychiatric disorders did not fully explain self reports of ill health in people with Gulf War syndrome but there is no evidence that it is caused by neurological problems. (Bryant, 2008)

Since the syndrome is poorly understood it is impossible to be dogmatic. One can treat the patient and/or the building. Examples of the latter include improving ventilation systems and reducing any contaminant exposure. There is no evidence for ill effects from fluorescent lighting. The patient may need counselling, medication, career guidance/change/retirement – or whatever is appropriate, keeping in mind the necessity of non-reinforcement. Permanent sequelae appear to be rare.

Humidifier fever is due to contamination of humidifying systems in air conditioners in factories and office blocks with bacteria, thermoactinomyces or amoebae. It may present with the symptoms of extrinsic allergic alveolitis: fever, cough, dyspnoea etc. Management involves sterilising the water used in humidifying plants. Legionnaire’s disease results from contaminated air-conditioning systems.

Whiplash

Whiplash neck injury is the most common injury sustained in road traffic accidents (RTAs). The head is suddenly and unexpectedly jolted whilst the head moves freely, as when one car hits another from behind. The neck is suddenly extended, flexed, or rotated excessively. Soft tissue damage occurs in the cervical area. Claims for persistent symptoms make up a large percentage of all personal injury claims. The history of whiplash is one of acrimony! Are these people physically injured, psychologically traumatised, or ‘on the make’? In the Karlsborg *et al.* (1997) series of 39 patients there are 6 cases of whiplash in females for every 4 cases in males. Mayou and Bryant, (2002) looked at consecutive post-RTA hospital emergency attenders. Moderate to severe pain was reported by 27% of whiplash sufferers at 1 year and by slightly more (30%) at 3 years. Psychiatric sequelae (PTSD, travel anxiety, anxiety, depression) were common but no more so than with other types of injury. Accident-associated and post-accident psychosocial variables predicted pain severity at 12 months. Whilst whiplash was especially associated with compensation seeking, the authors suggested that this was explained by ‘the high proportion of innocent victims, the physical symptoms and the ease of legal definition’. This research was based on case notes and self-reports at follow-up, and response rates declined over the follow-up period. Like Cassidy *et al.* (2000), Thomas (2002) emphasises the potential of litigation (as distinct from no fault compensation) to worsen and prolong suffering and reduce functioning.

Out of body experiences

Out of body experiences are mainly associated with epileptic seizures and migraine. They affect about 10% of the population.(Blanke ea, 2004) They are usually spontaneous, short-lived, and extremely infrequent. However, they may be repetitive. Self or the centre of awareness of oneself is experienced outside of the body. The experience includes the experience of seeing the world (incl. the body) from a position above the body. The underlying pathology is within the temporo-parietal junction. Electrical stimulation of this part of the brain can evoke illusions of elevation, rotation, lightness, flying, and limb shortening or movement.(Blanke ea, 2002)

Dupuytren's contracture

This is a common, usually painless, often bilateral and familial, slowly progressive fibro-proliferation of the superficial palmar fascia leading to pitting and thickening of the skin of the palm with firm, painless nodule fixed to skin and deep structures.(Townley ea, 2006) A cord forms eventually and contracts flexing the finger/s so that they catch in pockets or stick in an eye when washing. Fibrosis may also occur on the soles of the feet (plantar fibromatosis), knuckle pads, and penis (Peyronie's disease). It typically affects older European males, although females by no means immune.

Factors associated with Dupuytren's contracture

Alcohol
Smoking
Anticonvulsant drugs and epilepsy (controversial)
Diabetes mellitus³¹⁷¹
Manual labour/trauma (vibration: disputed in the literature)
Hypercholesterolaemia
HIV infection

Treatment approaches include (injected) collagenase (from *Clostridium histolyticum*: Hurst ea, 2009), fasciectomy, and, for recurrent/aggressive cases, dermofasciectomy. However, many cases do not progress to contracture.

Trace elements

Trace elements occur in living tissues in extremely small quantities. Some are essential for life. The association between trace elements and mental illness is circumstantial at present.

Aluminium: This has been incriminated in associated dialysis encephalopathy³¹⁷². Reducing the amount of aluminium in the water for dialysis prevents this encephalopathy. Contamination of water by huge quantities of aluminium³¹⁷³ may have led to some brain damage. Exposure in the workplace (welders, etc) may lead to tremor, impaired balance, reduced recall memory, and slowing of cognition. Contamination with other substances, such as manganese, must be considered.

Cobalt: Cobalt is found at the centre of the vitamin B12 molecule. Cyanocobalmin (B12) deficiency (most often due to pernicious anaemia with antibodies against parietal cells and intrinsic factor) may cause anaemia, eye problems, spinal cord degeneration³¹⁷⁴, neurasthenia, depression, paranoid psychosis with

³¹⁷¹ May have nodules or skin and knuckle pad thickening.

³¹⁷² Aluminium is also found in Alzheimer lesions.

³¹⁷³ E.g. in Cornwall in 1988.

³¹⁷⁴ Deficiency of B12 may cause demyelination of centrum semiovale as well as the posterior columns and lateral corticospinal tracts.

hallucinations³¹⁷⁵, and delirium or (rarely) dementia. The serum B12 may be low. However, some cases of B12 deficiency, especially older subjects, may have normal B12 levels but elevated methylmalonic acid and homocysteine levels³¹⁷⁶. Always think of B12 deficiency in vegans or in the patient with reduced peripheral vibration sense. In cobalamin deficiency, the EEG is slowed with excess theta waves throughout. Neuroimaging may show involvement of periventricular white matter. B12 deficiency may follow nitrous oxide inhalation.

Copper: This is important in many enzymes and proteins. Hepatolenticular degeneration³¹⁷⁷ is an uncommon inborn error of metabolism of autosomal recessive inheritance (mutations or deletions of ATP7B protein encoded at 13q14.3-q21.1) wherein copper is deposited in various organs, especially the brain and liver. Untreated cases die in adolescence or early adulthood. Successful treatment is now available with chelating agents such as penicillamine. The commonest psychiatric complications are non-specific affective or behaviour disorders, but schizophreniform or bipolar psychoses can also occur. Psychiatric manifestations may precede physical signs.

Menkes' kinky hair syndrome is a rare sex-linked recessive disorder associated with copper malabsorption. The gene ATP7A encodes a copper-transporter ATPase. Infants fail to grow, have intellectually disability, brittle hair, anaemia, neutropaenia, and bone lesions.

Manganese: Manganese is an essential trace element and is plentiful in the environment. It acts as a co-factor of numerous enzymes. It is absorbed via the GIT but in toxic cases the main route into the body is by inhalation. Manganese in toxic doses damages DNA, probably by producing excess free radicals.

Manganese is found in steel castings, ore refineries, dry battery manufacture, bleaching, electro-welding, a fungicide (MANEB), and brick working. Use of an organo-manganese compound (MMT) as an antiknock agent in petrol is not known to humans as yet. An MRI contrast agent (mangafodipir trisodium) may lead to contamination. A high manganese level has been associated with psychosis ('manganese madness'³¹⁷⁸) and Parkinsonism³¹⁷⁹, e.g. in the mining areas of Chile. Manganese is chelated by the phenothiazines. Nocturnal leg cramps are common in manganese poisoning. There is a tentative association with dementia. Some cases may walk with their heels in the air and with their elbows flexed (cock-walk). The patient must be removed from sources of contamination although improvement is not guaranteed. L-DOPA is much less effective than in Parkinson's disease (paralysis agitans).

Manganese deficiency may occur during parenteral feeding.

Lead: Tetraethyl lead in petrol, for example, may cause an encephalopathy. This may present in the adult with delirium and seizures, often with associated hypertension. Chronic encephalopathy is characterised by headache, trembling, impaired memory and concentration, poor hearing, and episodic hemianopia and aphasia. Children are particularly badly affected and may develop coma, pareses, papilloedema, meningism, and compression of medullary centres, and those who survive may be brain damaged or blind. EDTA may be given parenterally. Alternatively, the oral chelating agent meso-2,3-dimercaptosuccinic acid may be used.

Lead poisoning (plumbism)

Sources of lead range from lead toys (common in the author's childhood), retained bullets (especially in a joint space or a pseudocyst), and illegal whiskey (use of old car radiator)

Lethargy

Blue line on gum margins (lead sulphide deposition)

Lead lines on x-rays of long bones in children

Abdominal discomfort or pain, vomiting, constipation

³¹⁷⁵ 'megaloblastic madness'. (Smith, 1960)

³¹⁷⁶ **Methylmalonate** and **homocysteine** are substrates of cobalamin-dependent reactions. They may be more sensitive indicators of tissue B12 deficiency than B12 levels themselves. Folic acid and B12 act as co-factors in re-methylation of homocysteine to methionine, deficiency of either vitamin causing increased homocysteine levels. Homocysteine increases neuronal excitotoxicity by stimulating NMDA receptors. Oxidative stress is increased leading to damage to DNA and apoptosis. Kim et al (2008) suggest that low B12, low folate and raised homocysteine levels may increase risk for late-life depression.

³¹⁷⁷ Kinnier Wilson described hepatolenticular degeneration (Wilson's disease) in 1912.

³¹⁷⁸ Labile moods, inappropriate laughter, aggression, hallucinations, and Parkinsonism.

³¹⁷⁹ Manganese-induced Parkinsonism is associated with damage to the pallidum and striatum whereas the substantia nigra pars compacta bears the brunt in paralysis agitans. Uptake of fluorodopa is normal in manganese-induced Parkinsonism but reduced in paralysis agitans.

Sideroblastic anaemia, mild haemolysis, punctate basophilia³¹⁸⁰
 Encephalopathy (delirium, seizures, coma)
 Peripheral motor neuropathy (foot drop)

Rubidium: Rubidium³¹⁸¹ causes euphoria. Hopes of replacing lithium with rubidium were upset by suggestions of neurotoxicity.

Vanadium³¹⁸²: It is thought that vanadate, the pentavalent ion, inhibits Na-K-ATPase and hence the Na⁺ pump. Vitamin C converts this to the tetravalent ion, vanadyl (methylene blue has the same effect). It has been suggested that vanadium, as vanadate, can cause depression.

Selenium: This is commonly found in skin applications and can cause tremor and loss of appetite if absorbed transcutaneously over a long period of time. Depletion might be a cause of depression and other negative mood states, such as anxiety, confusion and hostility.

Zinc: Zinc is involved in RNA synthesis and RNA is important in memory functions. Low zinc levels have been suggested as a possible cause of dementia. Well recognised symptoms of zinc deficiency include depression and perverted taste and smell. Low zinc levels are associated with poor nutrition and high phytate levels in bread. Zinc deficiency may also occur in malabsorption states, regional enteritis, hepatic failure, kidney disease, certain drugs (e.g. histidine), and diabetes mellitus. Treatment is with zinc sulphate. High zinc levels have been found in multiple sclerosis and in neural tube defects. Zinc (as acetate or sulphate) is used as a copper depleting agent in Wilson's disease. Zinc supplements given to pregnant poor Bangladeshi women did not confer benefit on their infants' mental development (Hamadani *et al.*, 2002) although it does seem to reduce mortality in infants from infectious diseases.

Electrolytes and acid-base balance disorders

Hyponatraemia: symptoms include nausea, vomiting, abdominal pain, anorexia, weakness, dizziness, headache, blurring of vision, sweating, malaise, lassitude, apathy, muscle cramps and twitching, delirium, coma, and hypotension. Various psychotropics (carbamazepine, oxcarbazepine, neuroleptics, TCAs, SSRIs, etc), diuretics, hypoadrenalism, various kidney diseases, and myxoedema may cause hyponatraemia. Patients with psychogenic polydipsia and those with eating disorders who drink water to produce a full feeling are at risk of hyponatraemia. Burn patients, those who sweat excessively in tropical climates, people with GIT diseases (e.g. vomiting, diarrhoea, tube drainage, fistula, etc),

Hyponatraemia in cancer patients can be due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) secondary to paraneoplastic syndrome³¹⁸³. Low sodium (< 125 mmol/L) or a rapid fall in sodium level can lead to agitated delirium whereas more chronic hyponatraemia may be associated with poor attention and falls in older patients. Central pontine myelinolysis is a rare disorder of cerebral white matter and has multiple causes; rapid correction of hyponatraemia (common in beer drinkers, especially when replacing vomited fluids with hypotonic fluids) may be a factor in the aetiology (although not invariably so), the condition presenting a day to a week later.

A low sodium diet may be useful in reducing blood pressure in patients with multiple risk factors for the metabolic syndrome.

Hypernatraemia: either too much water is lost or too little water is taken in; older people are at highest risk; there can be xerostomia, weight loss, grey complexion, lethargy, confusional state/delirium, and muscular hypertonicity; seizures and central pontine myelinolysis may follow over vigorous rehydration; shrinking of the brain may cause bleeding from veins; cerebral sinus thrombosis is a known complication; hypernatraemia may occur with anabolic steroid abuse or in diabetes insipidus.

Hypokalaemia: this may occur in hepatic cirrhosis, metabolic alkalosis, vomiting, or laxative/diuretic/anabolic steroid abuse; there is reduced intake of potassium, a movement of potassium into cells, or excess potassium loss. Clinical findings include lethargy, apathy, anorexia, constipation,

³¹⁸⁰ Punctate basophilia: round, blue particles in red cells represent RNA aggregates in immature red cells.

³¹⁸¹ The bromide of rubidium was in common use in the 19th century for a variety of disorders, e.g. epilepsy.

³¹⁸² Scandinavian goddess Vanadis. Vanadium received wide usage for a variety of problems in the 19th century (e.g. neurasthenia).

³¹⁸³ **SIADH** may be due to small cell carcinoma, mesothelioma, pancreatic or duodenal cancer, brain neoplasm, leukaemia, pulmonary infection, carbamazepine, tranylcypromine, TCAs, SSRIs, or phenothiazines and other antipsychotic drugs.

depression, anxiety, delirium (rarely), paralytic ileus, proximal muscle weakness/myalgia, and EEG changes (flat/inverted T waves, prominent U waves, depressed ST segment, and prolongation of QT interval). When giving potassium with IV fluids normal saline is better than dextrose as the latter increases intracellular shifts in potassium by insulin.

Hyperkalaemia: this is chiefly a problem with kidney failure; clinical features include fatigue, muscle weakness (flaccidity in extreme cases), lethargy, confusion and cardiac arrhythmias (bradycardia due to heart block, ventricular fibrillation/asystole). The classic ECG progression is from normal to tented T waves, small P waves and widened QRS complex, to 'sine wave' pattern, to cardiac arrest.

Calcium: High serum calcium (hyperparathyroidism, cancer) causes depression, anxiety, and delirium; low serum calcium (diet low in calcium or vitamin D, hypoparathyroidism, rhabdomyolysis, kidney/liver disease, anticonvulsant drugs, thyroid/parathyroid surgery) can cause cramps, tetany, and seizures.

Hypophosphataemia: phosphate may move into cells during management of diabetic ketoacidosis or alcoholism; it is also encountered during refeeding of people who have been starving; clinical features may include anxiety, irritability, delirium, ataxia, slurred speech, breathing irregularities, weakness of extraocular muscles, paralysis, areflexia, myoclonus, and paraesthesiae (in hands and feet). Weakness of the diaphragm may make it difficult to stop artificial ventilation. Wernicke's syndrome or Guillain-Barré syndrome may be mimicked in hypophosphataemia.

Magnesium: This is important in neuromuscular transmission. Magnesium reduces neuronal excitability in delirium tremens. Any patient who has fluid and other electrolyte imbalance and who unexpectedly develops neurological problems should have magnesium levels checked.

Hypomagnesaemia is common and is found in association with alcoholism, medication (e.g. loop diuretics, cyclosporine, cisplatin, aminoglycosides) renal, endocrine and GIT disorders. Severe hypomagnesaemia leads to functional underactivity of the parathyroid glands which responds to magnesium replacement. A low magnesium level is found with infantile seizures. Magnesium and calcium concentrations are lowered by neuroleptics. Tetany is a common feature (as with hypocalcaemia). Other potential manifestations include irritability, depression, vertigo, ataxia, muscular weakness/fasciculation, seizures, myoclonus, choreoathetoid movements, and focal symptoms and signs such as dysphasia and hemiparesis. The ECG may show prolongation of the QT interval, T waves that are flat and broad, and there may be shortened ST segments. Affections of consciousness vary from slight confusion via delirium to coma. Treatment is with magnesium sulphate.

Hypermagnesaemia is uncommon (e.g. in renal failure, excess magnesium in dialysate during haemodialysis, or over indulgence in antacids [magnesium trisilicate] or laxatives [magnesium sulphate]) and causes a general depression of the CNS.

Acidosis³¹⁸⁴: reduced level of consciousness and tachypnoea. Examples of drugs that may lead to metabolic acidosis are ethanol, ethylene glycol, diethylene glycol, methyl alcohol, TCAs, topiramate, metformin, calcium channel blocking drugs, iron, paracetamol (acetaminophen), cocaine, CO, and cyanide (hydrogen cyanide = prussic acid).

Alkalosis: apathy, disorientation, delirium, tetany and paraesthesiae.

Endocrinopathies

Due to earlier diagnosis, depression and anxiety are the commonest neuropsychiatric phenomena encountered in this group of disorders. More obviously organic presentations, such as delirium and dementia are associated with longer duration of the endocrinopathies.

Adrenals: Conn's syndrome is associated with severe weakness due to hypokalaemia. In Cushing's disease there are weakness, agitation and depression. The depression may relate to ACTH rather than to glucocorticoids, which might explain the tendency of exogenous steroids to cause euphoria or elation. Hippocampal volume reduction and elevated cortisol levels have been reported in Cushing's disease that are reverse with treatment.(Starkman et al, 1999) Addison's disease causes apathy, depression and loss of libido. A paranoid illness may accompany Cushing's disease and delirium occurs in Addisonian crises.

³¹⁸⁴ Arterial pH is held in the range 7.35-7.45. This is the job of buffering mechanisms, the lungs, and the kidneys.

Adrenal medulla: Phaeochromocytoma (90% in adrenal, 10% in sympathetic chain), which may be episodic or continuous, can be mistaken for anxiety neurosis, hysteria or panic states. TCAs and SSRIs may unmask silent cases and MAOIs may be disastrous. Before and during surgery it is essential to use complete alpha-blockade *followed by*³¹⁸⁵ complete beta-blockade, i.e. phenoxybenzamine first and then add propranolol. This combination is continued if surgery proves to be impossible.

Features of phaeochromocytoma

Apprehensiveness

Headache, dizziness, tremor

Hyperhidrosis, pallor or blushing

Dyspnoea, palpitations, central chest pain

Nausea and vomiting

Glycosuria

Arterial hypertension

Various complications, e.g. myocardial infarction, CVA, papilloedema, haemorrhagic retinitis, convulsions, ventricular fibrillation, and diabetes mellitus

At least annual catecholamine excretion assessments are performed post-operatively as there is at least a 10% recurrence rate

Diagnosis

24 hour urine collection – metanephrines and VMA

Metanephrines are the most sensitive

Urinary VMA can be increased by dietary vanillin (e.g. vanilla extract, citrus foods, bananas, nuts, and coffee)

MRI and (for extra-adrenal tumours) [131I]metaiodobenzylguanidine scan

Factitious phaeochromocytoma

E.g. vanilla extract ingestion

Thyroid: Only 20% of T₃, the active thyroid hormone, is readily produced in the thyroid gland, and the cells of many tissues de-iodinate T₄ to T₃. The liver is a major 'exporter' of T₃.

Thyrotoxicosis must be distinguished from anxiety neurosis, and myxoedema³¹⁸⁶ from melancholia. There were a number of reports of Graves' disease developing following severe stress during the 1914-18 war.

The first description of a treatable dementia was probably a case of hypothyroidism, although unconnected hypothyroidism in dementia is commoner than causative hypothyroidism.

Some chemical causes of myxoedema

Lithium

Carbimazole

Sodium aminosalicylate

Phenylbutazone

Resorcinol ointment

The features are puffy, especially in areas of loose tissue (e.g. under the eyes), there is a non-pitting swelling of the face, limbs and above the clavicles, and the skin is dry. Other features of the condition are lifeless, thinned hair; slow, coarse and monotonous speech; apathetic appearance; angina; bradycardia; anorexia; poor concentration and recent memory; irritability; generalised aches and pains; and dulling of the special senses.

'Polar T₃ syndrome'

Described in persons wintering in Antarctica

³¹⁸⁵ If this sequence is not followed extreme hypertension develops. Sodium nitroprusside is used for sudden extreme hypertension.

³¹⁸⁶ Richard Asher described 'myxoedematous madness' in 1949. There is no consistent picture. It can resemble paranoid schizophrenia, dementia, or depression.

Raised TSH, decreases in total and free T3 and free T4, although levels are still usually within normal limits
Mood changes may occur

Parathyroids: Weakness, depression, delirium, dementia, 'hysteria' and anxiety.

Hypopituitarism: Weakness, depression, delusions, delirium and dementia.

Vitamins in relation to psychiatry³¹⁸⁷

Studies during the 1980s that were conducted among psychiatric and institutional populations found widespread vitamin B deficiency. B group deficiency was strongly linked to endogenous depression and alcoholism. The main drugs associated with avitaminosis were most psychotropic drugs, anticonvulsants, the anovulant pill, antileukaemic agents, antibiotics, and isoniazid. 10-30% of psychiatric patients had folate deficiency (vitamin Bc). According to Carney (1992) depression is the main psychiatric manifestation of folate deficiency. This receives support from work by Sachdev et al. (2005)

Thiamine (B1) deficiency

Failure to convert pyruvate (from glycolysis) to acetyl coenzyme A and, in the citric acid cycle, alpha-ketoglutarate to succinyl coenzyme A

Famine, poverty, alcoholism, malignancy, Hyperemesis gravidarum, AIDS, dialysis, bariatric surgery (Foster et al., 2005)

Commonest form – mixed cerebro-neuropathic-cardiac

Wernicke-Korsakoff syndrome (WKS) including iatrogenic (glucose given in B1 deficiency)

Beriberi - cardiac³¹⁸⁸ (wet) and neurological³¹⁸⁹ (dry) forms +/- WKS³¹⁹⁰

Pyridoxine (B6) deficiency³¹⁹¹

Infantile seizures

Neuropathy

Lethargy

B6-responsive sideroblastic anaemia

MAOIs may cause B6 deficiency, e.g. weakness and paraesthesia

Premenstrual symptoms (?)³¹⁹²

Anovulant-related depression (?)

Nicotinic acid (niacin) deficiency (see discussion of pellagra)

Low serum niacin and 24-hour urinary niacin metabolites

Acute deficiency may lead to an encephalopathic state

Pellagra in subacute cases, preceded by 'neurasthenia'

Pellagra is a rare complication of carcinoid syndrome³¹⁹³

Pellagra may be seen in Hartnup disease³¹⁹⁴

Pantothenic acid deficiency

Sensory neuropathy, 'burning feet' (?)

³¹⁸⁷ Christiaan Eijkman proposed the existence of essential factors in food as a result of his research on beriberi. Casimir Funk used the term 'vitamin' in 1912.

³¹⁸⁸ High output failure with tachycardia, dilated peripheral vasculature, and oedema.

³¹⁸⁹ Peripheral neuropathy (mixed).

³¹⁹⁰ WKS may require a genetically determined transketolase abnormality.

³¹⁹¹ Pyridoxal phosphate is a cofactor in amino acid metabolism. Deficiency may be due to drugs such as isoniazid, penicillamine and hydralazine.

³¹⁹² Do not exceed 10 mg/day. Excessive, prolonged use may lead to a polyneuropathy.

³¹⁹³ A majority of body tryptophan is broken down via a minor pathway.

³¹⁹⁴ Excess excretion of tryptophan via the kidneys and reduced gut absorption of tryptophan.

Decreased vitamin D may be associated with geriatric depression.(Hoogendijk ea, 2008) Vitamin D deficiency is very common in long-stay units where residents do not get outside³¹⁹⁵.(Tiangga ea, 2008) The chief source of vitamin D is UVB. Other sources are fish, eggs, dairy products, and fortified cereals or margarine. Lack of sunlight³¹⁹⁶, malabsorption, liver/kidney dysfunction, phenytoin, carbamazepine, dark skin, and obesity, have been associated with vitamin D deficiency. Alcohol, anticonvulsants, oral contraceptives, methotrexate, pyrimethamine, triamterine, trimethoprim, and sulphasalazine can reduce folate levels, whereas nicotine, H2-blocking drugs, oral contraceptives, zidovudine, metformin, and cholestyramine may lead to B12 deficiency³¹⁹⁷. The effectiveness of phenobarbital, phenytoin, and methotrexate may be reduced by folate.(Reynolds, 2002) There were exaggerated claims in the UK that healthy children would become more intelligent if they consumed extra vitamins.(Dyer, 1992) Also, hypothyroidism and deficiencies of B12 and folate are usually coincidental findings in dementia rather than aetiological factors. Folate, B6 and B12 decrease homocysteine levels, an effect that might reduce the risk for Alzheimer's disease.(Luchsinger ea, 2007) However, Aisen ea (2008) found that high-dose folate, B6 and B12 failed to slow cognitive decline in cases of mild-to-moderate Alzheimer's disease (MMS scores 14-26 inclusive) who had normal folate, B12, and homocysteine levels. Exposure to folic acid antagonists (e.g. anticonvulsants and trimethoprim) during the first trimester of pregnancy increase the risk for congenital defects, especially those affecting the neural tube.(Matok, 2009) Red cell folate is more informative than serum folate about tissue levels over time, whereas serum levels are more immediately affected by changes in diet. Alpha-tocopherol (vitamin E) deficiency may be involved in neurodegeneration.

Agnosia

Inability to recognise and interpret the significance of sensory perceptions³¹⁹⁸; can take many forms.

Anosognosia, denial of illness (a form of hemi-inattention; a left hemiparesis is not acknowledged due to a non-dominant parietal lobe lesion³¹⁹⁹; this causes management problems because the patient does not see why he needs assistance)

The term **disconnection syndrome**³²⁰⁰ suggests an interruption of communication between brain regions in sensory inattention and neglect following a stroke.³²⁰¹

Autopagnosia, denial of body part, e.g. finger³²⁰²

Asomatagnosia, denial of ownership of a paretic limb, sometimes attributing ownership to another person, with a right-sided lesion.³²⁰³

Visual agnosia, inability to recognise objects visually³²⁰⁴, mostly attributable to bilateral (less often right-sided only) medial occipitotemporal lesions.

Auditory agnosia, inability to recognise sounds, everything from a telephone ringing to speech – all is simply noise (usually bitemporal lesions).

Astereognosis, inability to recognise objects by touch.

Topognosia, inability to recognise an object placed on the skin.

Agrophagnosia (agraphaesthesia), inability to recognise numbers or letters written on skin. **Prosopagnosia**, inability to recognise familiar faces.³²⁰⁵

Simultagnosia: inability to recognise more than one element at a time of a visual scene (right temporo-occipital lesion); and, more controversially from the definitional point of view.

Topographagnosia, where patients cannot recognise items like buildings³²⁰⁶.

Alternating sequences: draw a short sequence of alternating squares and triangles and ask patient with frontal lobe pathology to copy the sequence and then continue the pattern; the patient will repeat shapes instead of alternating them.

Aphasia

Aphasia: Broca's area³²⁰⁷ is just below the motor area for the right hand and face. Wernicke's area³²⁰⁸ is in the posterior part of the dominant superior temporal gyrus. The two areas (in most people in the left hemisphere) are joined by the arcuate fasciculus that passes through the angular gyrus. Cerebral dominance is not well established in very young children.

Dysphasia (the complete form being aphasia) is an organic impairment of language and communication.

Receptive (sensory, fluent, jargon) aphasia - patient hears but cannot understand (lesion in Wernicke's area³²⁰⁹; speech is fluid and spontaneous but incoherent and nonsensical) and is unaware of the problem; motor function is normal
