Expressive (motor, non-fluent) aphasia (lesion in Broca's area) - patient understands others but cannot express himself normally: speech is halting, laborious, inaccurate, inarticulate, telegraphic, sparse, or even absent - in the lesser, *dysphasic* form the appropriate words cannot be found despite knowing what it is one wants to say; right hemiplegia common

Global (total) aphasia - combination of (a) and (b) - speech is non-fluent and the patient shows by his emotional reaction that he is unaware that there is a problem; may be mute; variable right hemiplegia

Conduction aphasia - similar to sensory/fluent aphasia but with understanding and awareness of deficits, the latter leading to frustration; there is selective impairment of repetition

Nominal dysphasia (anomia, amnesic aphasia) - inability to find words or name objects that patient should know (e.g. a pen or a watch) - tested for in detail by asking the patient to (1) name 12 familiar (e.g. a cup) and unfamiliar (e.g. examination couch; teeth of a comb) objects while he handles each in turn, and (2) name as many members of stated categories (e.g. flowers or animals) as can be recalled

Patients with Broca's dysphasia are frustrated: **emotional speech** is found in such patients: they may utter words or sentences when experiencing great emotion that they would otherwise be unable to produce. The acute onset of abnormal speech in a middle-aged person is almost always diagnostic of a fluent aphasia. (Geschwind, 1971) **Fluent dysphasia** may be misdiagnosed because many

³¹⁹⁸ *Gnosis*: ability to recognise objects, faces, sounds, or body parts.

³¹⁹⁹ Other authorities point to the right frontal cortex.

³²⁰⁰ Term coined by Norman Geschwind in 1965.

³²⁰¹ Neglect can be visual, wherein a clock is drawn with figures bunched to one side, or motor, as when only one hand is used to carry out a task without any neurological finding by way of explanation. The negation of hemi-neglect by the application of transcranial magnetic stimulation to the intact hemisphere (Oliveri et al, 1999) suggests that it is interhemispheric imbalance rather than damage to the other hemisphere that leads to hemi-neglect.

³²⁰² Tests for finger agnosia: recognise/name individual fingers; name finger being touched whilst patient keeps eyes closed.

³²⁰³ Usually parietal but can be internal capsule, striatum, or thalamus.

³²⁰⁴ In contrast, *deep dyslexia* refers to an ability to read the sense of a word but a word with similar meaning is substituted consciously, e.g. 'terminal' for 'ending' – a form of adaptation to neural damage.

³²⁰⁵ Same areas are affected as in visual agnosia; may occur as part of simple partial seizure, when it is of brief duration.

³²⁰⁶ Alternatively defined as a loss of sense of direction – see 'geographical disorientation'.

³²⁰⁷ Posterior part of inferior frontal gyrus of dominant hemisphere, i.e. Brodmann's areas 44 and 45.

³²⁰⁸ Discovered in 1874 by Carl Wernicke (1848-1905): worked with Heinrich Neumann (1814-1884) in Breslau and succeeded him as professor of psychiatry and neurology in 1885; professor of psychiatry in Halle from 1904. Also known for idea of loosened continuity of nerve fibres in psychosis ('sejunction' theory).

³²⁰⁹ Can be due to diffuse disorders like Alzheimer's disease but vascular causes are more common, e.g. vascular dementia due to CVA affecting temporal or parietal lobes.

doctors are unaware of the frequency of aphasia without a hemiplegia. The patient may be mislabelled as ‘psychotic’ or ‘confused’, especially when there is a rapid outpouring of abnormal speech. In practice, the differential diagnosis is not always straightforward.

Nominal dysphasia, unlike primary motor aphasia, may be commoner in diffuse rather than focal brain dysfunction (e.g. Alzheimer’s disease), and it is often accompanied by **acalculia** (inability to do simple arithmetical calculations; tested for by ‘serial 7s’ – this, or **dyscalculia** (dysarithmetria), a lesser form, may be acquired or developmental). People with nominal dysphasia are aware of the deficit. A temporary inability to remember a proper noun or name, a universal experience, is called **lethologica**.

A lesion of the angular gyrus leads to loss of ability to read and write (speech, both in terms of production and understanding, is normal), the two kinds of visually mediated language. **Alexia**³²¹⁰ is loss of ability to grasp the meaning of written or printed words or sentences. *Dyslexia* includes word blindness and a tendency to reverse read or written letters and words.

There may be associated neurological deficits in dysphasic patients, e.g. right hemiplegia (Broca’s aphasia), hemianaesthesia and hemianopsia (Wernicke’s), or all of these (global).

Attention

The ability to focus in a sustained way on the matter in hand.

Concentration is the ability to hold that focus.

Latent inhibition refers to the situation wherein a person becomes used to ignoring a stimulus because of its irrelevance, but when its once again becomes relevant the subject finds it difficult to learn its significance³²¹¹.

Terminology around the subject of attention varies somewhat. Krabbendam and Jolles (2002) define attention as a multifactorial construct that includes the capacity to remain alert, orient to new stimuli, to filter what is relevant, and to rapidly discriminate stimuli; sustained attention allows one to be ready to respond to small environmental changes; and sustained attention allows one to focus on the relevant, ignoring the irrelevant. Sustained attention (vigilance) is often measured with the *Continuous Performance Test*³²¹² (CPT). The *Stroop Colour-Word Test* (reading words, naming colours, and an interference condition of names printed in conflicting colours, e.g. ‘**BLUE**’ written in red) is often used to assess selective attention.

The related concept of **alertness** has been divided into *phasic* (a warning stimulus raises the level of attention), *divided* (ability to attend to more than one stimulus simultaneously and to react to whatever is relevant), and *sustained or vigilant* (maintaining attention on a task over a long period of time). Whilst focal brain damage may selectively impair one of these subtypes, mixed patterns of different degrees of severity are common.

Consciousness

A state of mind which refers to the nature of a person’s mental experience at a given moment in time; to be conscious is to be aware of oneself and one’s environment; consciousness may be clouded, that is incomplete or diminished; preoccupation may narrow consciousness so that elements foreign to the preoccupation are excluded from consideration; the lay use of consciousness refers to an awareness, e.g. ‘I was conscious of your dilemma’. From a biological viewpoint, consciousness is a product of tegmental nuclei of the brainstem reticular activating system; diffuse projections go to the forebrain and diencephalon.

Torpor: A state of abnormal drowsiness – patient is sleepy, everything is slowed down³²¹³, perception is diminished in range, concentration requires great effort, and, unlike in functional stupor, amnesia often occurs following resolution of torpor.

Dysarthria

Speech disorder caused by mechanical problems with anatomical structures necessary for articulation of speech. Cerebellar speech involves fluctuations in rate, volume and tone, giving the false impression of intoxication.

Dyspraxia (apraxia)

Absence of praxis.

Motor dyspraxia (lesion of dominant premotor frontal cortex or anterior corpus callosum, or diffuse cortical disease) – ask patient to mime simple tasks such as brushing teeth or copy unusual hand postures demonstrated by examiner.

Constructional dyspraxia (especially lesions of non-dominant hemisphere) – inability to construct shapes, by drawing or other means, either on request or when asked to copy a particular design such as a three-dimensional cube, a clock face, or a bicycle; ask patient to light a match (a complex task) to test for ideomotor/ideational dyspraxia (Q.V.).

Buccofacial apraxia: patient unable to execute the normal facial, lip, and tongue movements, and the problem is not simply due to paresis; severe cases may be almost mute (*aphaemia*).

Ideomotor dyspraxia: the patient cannot mime an action (e.g. hair combing, using scissors, or lighting a cigarette) but can carry out the action when given the actual implements (like a comb)

In **ideational dyspraxia**, on the other hand, there is defective carrying out of both actions (miming and real).

In **dressing dyspraxia**, the patient has difficulty putting on clothing (e.g. puts on garments backwards or puts arm in wrong sleeve).

³²¹⁰ The lesser form is called *dyslexia*.

³²¹¹ This phenomenon is lacking to a significant extent in people with schizophrenia. The latter may be less influenced by prior experience, a phenomenon that might have some relevance for the genesis of hallucinations.

³²¹² Letters or digits are presented singly in random order and subject must respond when a designated target stimulus appears, although there are variations in practice.

³²¹³ Incl. thinking.

Foreign accent syndrome

A rare disorder in people with lesions of the left frontal cortex: speech is otherwise normal but begins to speak with an accent associated with a country to which he or she has no connection. (see, e.g., Seliger et al., 1992)

Euphoria

Unjustified non-infectious happiness, contentment and unconcern; associated with frontal lobe damage or other organic states.

Ecstasy: rare; extreme well being usually kept private, without overactivity; may feel in communion with God; found in epilepsy, mania, and schizophrenia.

Elation: increased mood that is infectious to others, as in many cases of mania: 'infectious jollity'.

Hypergraphia

Uncontrolled excess writing that is correct from a linguistic viewpoint but is nevertheless semantically loose. Causes include CVA, epilepsy, brain tumours, and CJD.

Logoclonia

Spastic repetition of terminal syllable: 'I'm going to the circus, cus, cus, cus.' Found in Parkinson's disease.

Memory

There are 3 functions of memory that are routinely tested by psychiatrists: immediate (primary), recent (secondary), and remote (tertiary).

Testing Memory						
Function	Accessibility	Capacity	Duration	Site of damage	Function	Test
Immediate	Rapid	Limited	Up to 1 minute	RAS*	Register new information	Repeat string of numbers
Recent	Slower	Larger	Mins/years	Limbic	Retention/recall	Repeat 3 objects**
Remote	Slow	Immense	Permanent	AC***	Crucial+	E.g. wars, childhood, jobs

*RAS, reticular activating system. **After 3-5 minutes of distraction. ***Association cortex. +Personal significance of information influences ability to remember.

Palilalia

Repetitions of one's own words, as distinct from *echolalia*, the repetition of the words of other people and *coprolalia*, the uttering of obscenities. However, palilalia is often used to mean repetition of the last uttered word or phrase uttered by others. (Sanchez-Ramos, 2004, p. 296)

Perseveration

Same answer is repeatedly given to different questions, or same non-verbal response is given for different stimuli; common in dementia and frontal lobe syndrome; includes palilalia and logoclonia. A patient may never get dressed because he keeps opening buttons each time he closes them!

Pleiotropy

A single cause can lead to a wide range of behaviours; a gene can manifest different phenotypes, as in Marfan's syndrome.

Reduplicative paramnesia

A (variously defined) delusional belief that one is somewhere other than where one objectively is or, whilst incorrectly describing their true locality, patients hold that a familiar place has many copies in different localities; the actual place where the person is may be novel to that person; described by Pick in 1903; often associated with neurological deficit, e.g. head injury or stroke, especially involving both frontal lobes.

Subtypes of reduplicative paramnesia:

- (a) **Place reduplication** – 2 identical places exist to which the patient gives the same name, but the places are situated at a distance from one another
- (b) **Chimeric assimilation** – 2 places become one, as when a patient believes that home and hospital are one
- (c) **Extravagant spatial localisation** – belief that one is in another place, often one that one knows well

Wada test

Inject sodium amytal directly into each carotid artery: when dominant hemisphere is perfused the patient becomes briefly aphasic.

Witzelsucht

Silly, loud humour, pranks and punning; indicates organic cause, e.g. frontal lobe disease; *moria* is childish excitement or silliness in frontal lobe disease.

Lesions

Hirano bodies: small, eosinophilic rod- or carrot-shaped bodies; may be found in/close to hippocampal pyramidal neurones; contain microfilament protein actin; numerous in AD.

Lewy bodies: laminated intracytoplasmic inclusion bodies in melanin-containing neurones of substantia nigra; derived from neuronal cytoskeleton; are often seen in surviving substantia nigra cells in Parkinson's disease; also found in pigmented cells of locus coeruleus, dorsal vagal nucleus and reticular formation; with development of concept of Lewy body dementia, it became clear that these eosinophilic intraneuronal inclusion bodies have a core of phosphorylated and non-phosphorylated neurofilament protein, microtubule protein, the protein ubiquitin and tau protein and can be found in cerebral cortex³²¹⁴. Antibodies to ubiquitin and alpha-synuclein can be used in postmortem tissue as a method of detecting Lewy bodies. The first genetic cause of Parkinson's disease was reported in 1997: a mis-sense mutation altering fifty-third amino acid of the alpha-synuclein protein (A53T). Shortly thereafter, alpha-synuclein was found in Lewy bodies. Discovery of another mutation (A30P) followed. Genetic triplication³²¹⁵ is associated with onset of Parkinson's disease and dementia with Lewy bodies in the mid-thirties. Genetic duplication³²¹⁶ also leads to disease in some European families. Triplication is far more likely to be associated with dementia than is duplication.

Neurofibrillary tangles (NT) appear as coils of argentophilic tangled bundles. On electronmicroscopy, they are made up of paired helical filaments. The tangle is formed from tau protein itself derived from microtubules. Tau protein in AD is abnormally phosphorylated by protein kinases, less soluble than normal, and unable to bind to microtubules. Glycogen synthase kinase-3 (GSK-3) is an important enzyme in this phosphorylation process. Such abnormal phosphorylation of tau causes neurofilaments to become cross linked and hence form insoluble complexes. Heavily phosphorylated tau does not bind to microtubules, leading the latter to collapse. Many affected neurones die and disappear in the latter stages of Alzheimer's disease, leaving *ghost tangles*³²¹⁷. NTs are usually confined to the hippocampi in normal ageing, whereas in dementia they are more widespread and prevalent. NTs are found in almost every person surviving to the tenth decade.

Pick bodies: rounded, perinuclear condensations of straight (contrasting with helical Alzheimer) filaments found in cortical neurones; contain cytoskeletal elements that bind polyclonal antibodies against neurotubules and a monoclonal antibody against neurofilaments.

Pick cells: cortical neurones that have been expanded and enlarged (ballooned) by argyrophilic bundles of neurofilaments.

Senile plaques (SP): group of abnormal argyrophilic neuritic processes together with reactive microglia and astrocytes arranged in roughly spherical formation, with (mature SP) or without (immature SP) extracellular amyloid core; this amyloid is amyloid beta-protein, derived from a precursor, amyloid precursor protein; gene for amyloid precursor protein (APP) is on chromosome 21.³²¹⁸ Amyloid beta-protein is a normal physiological product. It is hypothesised that amyloid beta-protein deposition leads to tau phosphorylation, tangle formation and cell death (amyloid cascade). Also been suggested that amyloid precursor protein gene mutations alone can account for all pathology found in AD. SP occur in 75% of people who reach their ninetieth birthday.

I am delighted to welcome publication of the Old Age Psychiatry section, edited by Dr Henry O'Connell. It is very much a practical and clinically oriented document, written by Clinicians for Clinicians. It covers the core clinical areas covered by all jobbing Old Age Psychiatrists in urban and rural settings, and serves as a useful framework for Medical students, Psychiatrists in Training as well as all members of our Multidisciplinary Teams. I particularly welcome the development of this textbook geared for an Irish setting. The section on Delirium by Professor Dave Meagher is particularly relevant in view of the large Liaison Psychiatry component to our clinical work. In addition, with the expected silver tsunami and expansion in our older population, the concomitant increase in cases with Dementia will be particularly challenging for all of us working in the field. A clear overview of this topic is extremely helpful. The sections covering "functional" illnesses depression and psychoses includes a welcome section on Anxiety disorders and a very relevant chapter on Alcohol Use Disorders. The inclusion of chapters on Psychotherapies, Pharmacotherapy and Capacity highlights the breadth of Clinical work for this important specialty. I hope all will find this a practical aide memoire both in the clinic and in the community.

Dr Geraldine McCarthy

MD DCH MRCPsych CAT Practitioner

Consultant in Psychiatry of Old Age,

Honorary Senior Lecturer NUI Galway and Dean of Medical Education, Sligo Medical Academy

Chair Faculty of Psychiatry of Old Age, College of Psychiatry of Ireland

February 2012

933
Introduction

Henry O'Connell

The complexities and co-morbidities associated with dementia and other mental health problems in older people means that the Old Age Psychiatrist is unique among clinicians in having a vital role in all clinical contexts, including acute psychiatric inpatient care, extended and long-term psychiatric care, nursing-home care, Consultation-Liaison Psychiatry on acute Medical and Surgical wards and in the provision of Day Hospital and home-based assessment and treatment. Older people with mental health problems often present with atypical features requiring specialist assessment and diagnosis and treatment is further complicated by comorbid medical illness and frailty, complex social problems and emerging cognitive impairment and dementia. Dementia itself is a devastating and ultimately terminal condition with wide-ranging cognitive, psychological, social and physical impacts on the individual sufferer, their family and carers and wider society. The practice of Old Age Psychiatry is, therefore, complex and challenging, requiring wide-ranging clinical skills and experience. Furthermore, the Old Age Psychiatrist must constantly advocate for individual older people and for the development of services for older people both locally and nationally. The ageing of populations worldwide means that the absolute number of older people with mental health problems and dementia is expected to rise exponentially in the coming years. All of these factors combine to make Old Age Psychiatry not only a core psychiatric speciality but one of most important of all medical specialities.

Old Age Psychiatry began as a speciality in the United Kingdom and subsequently in Ireland in the late 1980s, in an effort to address the complex needs of older people with dementia and other mental health problems. Older people were, and continue to be, liable to a 'double-whammy' of problems, associated with stigmatised attitudes towards people with mental health problems that is further complicated by problems related to ageism. Even within mental health services, the specific needs of older people are frequently ignored.

There are now approximately thirty public Old Age Psychiatry services in Ireland, covering most geographical regions and at various stages of development, with some private services. However, there is still only limited or no Old Age Psychiatry service available in significant tracts of the country.

This chapter is written by clinicians and for clinicians. The chapter reflects the clinical practice of Old Age Psychiatry, with the first half relating to dementia and delirium and the second half relating to 'functional' mental disorders.

I would like to take this opportunity to thank most sincerely all of the contributors for giving of their time and effort to make this chapter possible.

Dementia

Walter Enudi

Diagnosis and clinical evaluation

Dementia is divided into cortical and subcortical types, based on the site of the primary pathology. The clinical features of cortical and subcortical dementia are shown below in Table 1;

Table 1

Cortical dementia	Subcortical dementia
Early deterioration of memory (amnesia)	Slowing of thought
Early deterioration of language (aphasia)	Relative sparing of memory and language
Early deterioration of visuospatial ability (apraxia)	Difficulty with complex tasks

Early deterioration of face and object recognition (agnosia)	Apathy
	Impaired coordination

The patterns of cognitive deficits in dementia have helped in correlating brain structure and function. The relative preservation of episodic learning often discriminates between Alzheimer's disease and other dementias like Vascular Dementia, with patients having better verbal recall and better contextual verbal delayed recall in Dementia with Lewy body (DLB) and better multimodal retention in Frontotemporal Dementia (FTD).

Diagnosis

A detailed history is an important part of the assessment and emphasis should be placed on the mode of onset, course of progression, pattern of cognitive impairment and presence of non-cognitive symptoms such as behavioural disturbance, hallucinations and delusions. A good collateral history from a relative or carer is also essential as dementia patients may not be able to give a reliable history. The diagnostic criteria for probable Alzheimer's disease using the DSM-IV or ICD-10 have good diagnostic accuracy with a sensitivity of up to 80%. The National Institute of Neurologic, Communicative Disorders and Stroke-Alzheimer's Disease and Related Disorder Association group (NINCDS-ADRDA) criteria for probable Alzheimer's disease is also widely used. However, there are few studies looking at the diagnostic accuracy of criteria for Vascular Dementia compared to Alzheimer's disease. This is further complicated by the fact that patients often present with mixed pathology of Vascular Dementia and Alzheimer's disease, and available diagnostic criteria are inadequate in identifying patients with this mixed picture.

The diagnostic criteria in ICD-10 Alzheimer's disease are summarised below

- Presence of dementia
- Insidious onset usually with slow deterioration
- No clinical evidence of systemic or other brain disease which can induce dementia
- Absence of sudden onset or focal neurological signs

DSM IV criteria for dementia of the Alzheimer's type

- Impaired ability to learn new information or to recall previously learned information
- One or more of the following: aphasia, apraxia, agnosia, disturbance in executive functioning
- Significant impairment in social and occupational functioning
- Gradual onset and continuing cognitive decline
- Absence of systemic, neurological or substance induced conditions

The clinical features of Vascular Dementia are variable depending on the underlying pathology and the common presenting features are

- Abrupt onset or step wise deterioration
- Fluctuating course
- Preservation of insight and judgement
- History of stroke
- Focal neurological symptoms or signs
- Depression or emotional lability

The diagnostic criteria for Vascular Dementia using ICD-10 and DSM-IV are summarised below:

ICD-10 criteria for vascular dementia

- Uneven impairment of cognitive function
- Clinical evidence of focal brain damage, manifest as at least one of the following:
 - (1) Unilateral spastic weakness of the limbs
 - (2) Unilaterally increased tendon reflexes
 - (3) Extended plantar response
 - (4) Pseudobulbar palsy

Evidence of significant cerebrovascular disease which may reasonably be judged to be aetiologically related to the dementia

DSM-IV criteria for vascular dementia

- Memory impairment
- One or more of the following cognitive disturbances
 - (a) Aphasia (language disturbance)
 - (b) Apraxia (impaired ability to carry out motor activities despite intact motor function)
 - (c) Agnosia (failure to recognise or identify objects despite intact sensory function)
 - (d) Disturbance in executive function
- Symptoms cause significant impairment in social or occupational functioning
- Evidence that cerebrovascular disease has caused these deficits

Dementia with Lewy Bodies

There are no ICD-10 or DSM-IV diagnostic criteria for Dementia with Lewy bodies (DLB) but there is a consensus criteria proposed by McKeith *et al* (2006) for the diagnosis of DLB which are summarised below:

Core features

Two of the following core features are essential for a diagnosis of probable DLB and one is essential for possible DLB. Deficits on tests of attention and/or of frontal sub-cortical skills and visuospatial ability may be especially prominent.

- Progressive cognitive decline of sufficient magnitude with interference of normal social or occupational function
- Fluctuating cognition
- Visual hallucinations
- Spontaneous motor features of Parkinsonism

Supportive features

- Repeated falls/syncope
- Transient loss of consciousness
- Autonomic dysfunction
- Systematised delusions

Suggestive features

- REM sleep behaviour disorder
- Severe neuroleptic sensitivity
- Low dopamine transporter uptake in basal ganglia on Positron Emission Tomography (PET) or Single Photon Emission Computerised Tomography (SPECT)

Frontotemporal Dementia

As with DLB there is a consensus guideline, the Lund-Manchester guidelines (Lund and Manchester group, 1994), for the clinical diagnosis of Frontotemporal Dementia and these are also summarised below;

Core features

- Insidious onset and gradual progression
- Early decline in social interpersonal conduct
- Early emotional blunting
- Early impairment in regulation of personal conduct

- Early loss of insight

Supportive features

Behavioural disorder

- Decline in personal hygiene and grooming
- Mental rigidity and inflexibility
- Hyperorality
- Perseverative and stereotyped behaviour
- Utilisation behaviour

Speech and language

- Altered speech output
- Echolalia
- Perseveration
- Late mutism
- Stereotypy of speech

Physical signs

- Incontinence
- Primitive reflexes
- Rigidity, akinesia and tremor
- Low and labile blood pressure

Investigations

- Significant impairment on frontal lobe tests in the absence of severe amnesia, aphasia or perceptuospatial disorder.
- Brain imaging: predominant frontal and/or anterior temporal abnormality.

Clinical examination in Dementia

Full physical including neurological examination is essential in the evaluation of patients with dementia. Conducting a physical examination is essential in also ruling out reversible medical causes of cognitive deficits such as hypothyroidism. The presence of gait abnormalities might be suggestive of normal pressure hydrocephalus.

A detailed mental state examination is paramount in the overall assessment of patients with dementia. Appearance and behaviour give an idea of the severity of the dementia and raises safety concerns. The presence of speech problems such as hesitancy and word-finding difficulties are common. Disturbances in mood are common in dementia and one must also

assess for suicidal thoughts and ideas of harm to others. The presence of visual hallucinations early in the condition and parkinsonism may suggest DLB.

Cognitive Assessment

There are various tools used in the cognitive assessment and the extent to which clinicians assess cognitive function varies widely. The *Mini-Mental State Examination* (MMSE) developed by Folstein et al (1975) as a screening instrument for dementia is widely used. The limitation of the MMSE is its inability to detect very mild dementia, especially with subcortical features. The MMSE results in superficial assessment of memory, language and visuospatial function. Executive functions are not tested and in such cases the Montreal Cognitive Assessment (MOCA, Nasreddine et al, 2005) is more appropriate.

The *Addenbrooke's Cognitive Examination* (ACE) is a more comprehensive measure of cognitive function that incorporates the MMSE. The MMSE should be used in the diagnosis of dementia in individuals with suspected cognitive impairment and the assessment can be improved by the use of *Addenbrooke's Cognitive Examination* or the MOCA. The *Informant Questionnaire on Cognitive Decline in the Elderly* (IQCODE) is a short questionnaire completed by someone who knows the patient and can be a useful adjunct to direct cognitive testing.

Functional Assessment

Diagnosis of dementia invariably affects the individual's daily living skills and ability to perform activities of daily living (ADL) such as feeding, toileting and grooming. Instrumental ADLs (IADLs) include complex activities such as meal preparation, banking and driving. These changes in functional abilities correlate with cognitive deficits and also impact on carer burden that in turn impacts on the risk of institutionalisation. Tools such as the *Bristol Activities of Daily Living* tools are used to assess level of functional impairment. Patients could also be referred to Occupational Therapy for more detailed functional assessment where tools such as the *Assessment of Motor and Processing Skills* (AMPS) are commonly used.

Investigations

Reversible causes of cognitive impairment such as hypothyroidism and vitamin B₁₂ deficiency are rare but must be screened for in each individual assessment. Routine dementia screen involves:

- ✓ Full Blood Count
- ✓ Urea and electrolytes
- ✓ Liver function tests
- ✓ Thyroid function tests
- ✓ Vitamin B₁₂
- ✓ Folate
- ✓ Fasting glucose
- ✓ ESR
- ✓ CRP
- ✓ Urine microscopy, culture and sensitivity
- ✓ CT/MRI brain

Neuroimaging

Brain imaging can be used to detect reversible causes of cognitive impairment and to aid in the differential diagnosis of dementia. Structural imaging should form part of the diagnostic workup of patients with suspected dementia. The choice of imaging technique varies widely and includes Computed Tomography (CT), Magnetic Resonance Imaging (MRI), Single Photon Emission Computed Tomography (SPECT) and Positron Emission Tomography (PET). SPECT may be used in combination with CT to aid the differential diagnosis of dementia if the diagnosis is in doubt.

CT/MRI Neuroimaging findings in dementia:

Alzheimer's disease	Generalised cerebral atrophy, ventricular enlargement, widened sulci (MRI/CT) Hippocampal atrophy (MRI)
Vascular dementia	Variable depending on pathologies. Single infarct or multiple cortical lesions. Periventricular and deep subcortical lesions and/or lacunae in basal ganglia in subcortical ischaemic vascular disease
Dementia with Lewy bodies	Generalised cerebral atrophy. Relative sparing of medial temporal lobes (MRI)
Frontotemporal Dementia	Focal frontal/temporal atrophy that can be asymmetrical. Knife edge atrophy (MRI)

Management

Treatment of dementia requires a multi-disciplinary approach addressing four core areas; treating the disease, treating the symptoms, supporting the patient and the caregiver. The currently available anti-dementia drugs are not disease modifying but the management of dementia presently is aimed primarily at managing the cognitive and neuropsychiatric symptoms associated with dementia. The treatment involves pharmacological and non-pharmacological treatment, and using both treatment modalities has been found to have better outcomes than either alone.

Pharmacological Intervention

It is important to consider certain factors when starting medication in the elderly. It is well known that older people are more prone to adverse effects of drugs and this is due to the pharmacokinetic changes (e.g. decreased renal clearance and slowed hepatic metabolism) along with higher levels of comorbid medical illness and higher levels of polypharmacy. Therefore, it is advisable to consider these factors when starting medication in the elderly and to start at low doses and go slowly as tolerated.

Acetylcholinesterase Inhibitors:

In Alzheimer's disease (AD), abnormalities in cholinergic neurones are among the prominent neuropathological changes, leading to a cholinergic deficit. Therefore, inhibiting the enzymatic breakdown of acetylcholine should reduce the impact of these abnormalities. A meta-analysis comparing the tolerability and effect on cognition of the three acetylcholinesterase inhibitors, Donepezil, Galantamine and Rivastigmine in people with dementia indicated that there is no difference in efficacy among the three drugs but that Donepezil is better tolerated at therapeutic doses.

Donepezil: Evidence supports the use of Donepezil in people with mild to moderate Alzheimer's disease. There are some benefits for the use of Donepezil in people with Vascular Dementia of mild to moderate severity as revealed by a systematic review. It has also been shown that Donepezil is effective in reducing psychotic symptoms and a limited number of behavioural problems in people with mild to moderate dementia.

Galantamine: Galantamine is effective for the maintenance of cognition in people with mild to moderate Alzheimer's disease. There is also evidence of some benefits in people with mixed Alzheimer's and Vascular Dementia. Higher doses of Galantamine are more effective than lower doses but no added benefit is seen at doses above 24mg daily.

Rivastigmine: Rivastigmine has been shown to have benefits on cognition and global function in people with mild to moderately severe Alzheimer's disease. It is also effective in treating people with Dementia with Lewy Bodies and effective in reducing anxiety and hallucinations.

The doses and common side effects of acetylcholinesterase inhibitors are shown in the table below;

Drug	Dosing	Common side effects
Donepezil	Start 5mg daily then increase to 10mg in 4 weeks	Nausea, headache, diarrhoea
Rivastigmine	Start 1.5 mg twice daily, increase by 1.5mg bd every 2 weeks to maximum dose of 6 mg twice daily. Also available as topical preparation: 4.6mg once daily for 4 weeks increased to 9.5mg once daily thereafter.	Nausea, vomiting, diarrhoea, dizziness Nausea, vomiting, diarrhoea
Galantamine	Start 4mg bd (or 8mg XL daily), increase by 4mg bd every 4 weeks to maximum of 12mg bd (or 24mg XL daily)	

Memantine

Memantine is licensed for the treatment of moderately severe to severe Alzheimer's disease. It acts as an antagonist at N-Methyl-D-Aspartate (NMDA) receptors, which may be neuroprotective and disease modifying. The starting dose is 5mg daily and this should be increased by 5mg weekly to maximum dose of 20 mg daily. Common side effects are headache, dizziness and somnolence.

Non-pharmacological intervention

A wide range of non-pharmacological interventions should be considered in the management of dementia. Behavioural therapy using Antecedent-Behaviour- Consequence (ABC) assessment has been shown to improve behaviour which is sustained. Other therapies that have been used are music therapy, multi-sensory stimulation, reality orientation and validation therapy. There is little evidence that they work and they are often difficult to implement in real-world settings, which may lead to an over reliance on medications.

Caregiver intervention programmes, ranging from simple reassurance to comprehensive caregiver support packages have been shown to delay institutionalisation.

Behavioural and Psychological Symptoms of Dementia (BPSD)

This is a term used to describe a wide range of psychological reactions, psychiatric symptoms and behaviours seen in people with dementia.

Behavioural disturbances

Agitation
 Aggression
 Sleep disturbance
 Inappropriate sexual behaviour
 Hyperorality
 Wandering
 Repetitive behaviours

Psychological symptoms

Depression
 Anxiety
 Misidentification
 Reduplications
 Paranoia
 Delusions
 Hallucinations

These symptoms are usually more distressing to those who care for people with dementia compared to the cognitive features and are often the reason for referral to psychiatric services. Evidence has shown that paranoia and aggressive behaviour is predictive of institutionalisation. In assessing people with BPSD, pharmacological treatment is usually not the first option. It is important to establish the nature and frequency of the symptoms as well as behavioural analysis looking at the antecedents, the context in which the behaviours occur and the consequences. Before considering any intervention, assess for risk to self and others and establish why the behaviour is a problem. In the absence of the above factors, intervention may not be necessary. Some of the non-pharmacological interventions have already been mentioned above, though for some, therapies are limited.

Pharmacological management of BPSD Clusters

BPSD can be conceptualised to comprise of three main clusters of symptoms: psychomotor agitation; aggression and psychosis. Although there is limited evidence supporting the use of medication in the management of BPSD, it is still usually considered as the last option especially if risk to self or others is an issue, and to reduce the level of distress to people with dementia.

- **Psychomotor agitation, including pacing, walking aimlessly, restlessness, repetitive actions, sleep disturbance.**

Trazadone has been found to be useful especially if agitation is associated with depressive symptoms. It also increases slow wave sleep (SWS) and therefore might benefit those with sleep disturbance.

Low dose Lorazepam (0.5mg) is also found to be useful but only in the short term because of the risk of tolerance, dependence and falls. Lorazepam may also cause paradoxical reactions in the elderly.

- **Aggression including verbal and physical aggression especially with high likelihood of risk to self and others and failed non-pharmacological treatment.**

Choice of medication is an atypical antipsychotic, either Olanzapine or Risperidone, but both are associated with increased risk of stroke. Note that all antipsychotics are associated with increased risk of stroke in people with dementia especially in those with vascular risk factors. Avoid using neuroleptics in dementia with Lewy bodies: if necessary, then Quetiapine may be the best choice.

- **Psychosis: hallucinations, delusions and misidentification**

Atypical antipsychotics are the treatment of choice and the above concerns regarding treatment with antipsychotics should be taken into consideration. The lowest possible dose should be used and the need for continued use should be checked regularly, especially after a sustained period of stability.

Course and prognosis

The median survival from diagnosis for AD is about 6 years, which is similar for Vascular Dementia. Neuropsychiatric features and behavioural disturbance become more frequent as the disease progresses.

DEMENTIA

Chidinma Anamah

Introduction

In dementia there is a decline of higher mental function and previously held abilities. Memory, judgement, thinking, planning and general processing of information are affected.

It is usually regarded as an acquired disorder of the elderly but in 1 in 1000 people symptoms start before age 65. This deterioration according to the WHO should be present for at least 6 months. It should also be severe enough to affect functioning. This is as opposed to Mild Cognitive Impairment (MCI) in which the individual has a measurable deficit in cognition in the absence of dementia and the cognitive deficits do not affect functioning.

Epidemiology

According to the Alzheimer's Society 1 in 1000 people younger than 65yrs has a dementia but by age 80 the rate increases to 1 in 5.

The table below shows the projected prevalence of dementia in Ireland.

YEAR	PERSONS WITH DEMENTIA
2006	37,746
2011	42,441
2016	49,153
2021	58,044
2026	70,115
2031	85,847
2036	103,998

Classification

Dementia can be classified based on age at onset and pathology and aetiology.

Age at onset

Dementia occurring before age 65 is termed Presenile or Early Onset Dementia with aetiological causes of which are more varied and in some cases potentially reversible. Late onset dementia occurs after age 65 and causes are mainly degenerative.

Pathological changes

- Cortical- Alzheimer's disease, Frontotemporal dementia and Creutzfeldt-Jacob disease
- Subcortical- Parkinson's disease, Huntington's disease, Normal pressure hydrocephalus, Multiple Sclerosis
- Mixed-Dementia with Lewy Bodies, Vascular dementia, Corticobasal Degeneration and Neurosyphilis

Aetiology

Degeneration	<ul style="list-style-type: none"> • Alzheimer's disease • Frontotemporal Lobar degeneration • Dementia with Lewy bodies • Parkinson's disorder related dementia • Huntington's disorder
Vascular	<ul style="list-style-type: none"> • Single or multi-infarcts • Cerebral haemorrhage • Binswanger's disease • Vasculitides with CNS involvement • Cardiac disorders
Infections	<ul style="list-style-type: none"> • Syphilis • HIV • TB • CJD
Nutritional deficiencies	<ul style="list-style-type: none"> • Vitamin B12 • Folate
Metabolic, endocrine & inflammatory	<ul style="list-style-type: none"> • Cushing's syndrome • Hypo/hyperthyroidism • SLE • Sustained uraemia • Parathyroidism • Multiple Sclerosis • Sarcoidosis
Toxins	<ul style="list-style-type: none"> • Carbon monoxide • Lead • Arsenic
Others	<ul style="list-style-type: none"> • Normal Pressure Hydrocephalus • Trauma- severe or repeated head injury e.g. in boxers. • Alcohol

Causes of dementia include:

1. Degeneration

The vast majority of dementia is caused by degenerative changes to the brain. These include Alzheimer's Dementia (AD), Frontotemporal Lobar Degeneration, Dementia with Lewy bodies (DLB), Parkinson's disorder related dementia and Huntington's disorder.

Alzheimer's dementia is the commonest cause of dementia at older age, less prevalent before age 65, but still the most common cause of Early Onset Dementia. There is general decrease in the brain weight with atrophic changes. These changes are as a result of abnormal deposits of amyloid proteins and tau proteins in the form of neurofibrillary tangles which release neurotoxic substances that are neurotoxic. The amyloid deposits in AD are composed of beta amyloid proteins. Most cases occur sporadically but rare cases of early onset dementia are inherited as an autosomal dominant disorder that causes mutations in the Amyloid Precursor Protein, Presenilin 1 and Presenilin 2 genes. These genes are located on chromosomes 21, 14 and 1 respectively.

In DLB there is the presence of Lewy bodies which are abnormal proteinaceous cytoplasmic inclusions throughout the brain. In addition to deterioration in memory and other cognitive functions, DLB is also associated with frequent falls, motor features of parkinsonism and well-formed detailed visual hallucinations.

Degenerative changes localised to mainly the frontal and temporal lobes cause Frontotemporal Lobar degeneration. This can occur with or without the presence of Picks bodies (Pick's disease). This disorder is associated with early changes in personality and behavioural difficulties. It occurs more commonly in early onset dementia than with the elderly.

Huntington's chorea is a rare disorder that has autosomal dominant inheritance with complete penetrance. There is atrophy of the caudate and onset of symptoms could be as early as in adolescence. It is associated with choreiform movements and schizophrenia like features in addition to cognitive decline.

Other degenerative causes include corticobasal degeneration and progressive supranuclear palsy.

2. Vascular

These could arise from a single or multi-infarcts, cerebral haemorrhage, vasculitides with CNS involvement, cardiac disorders and Binswanger's disease. Cognitive deterioration in vascular dementia occurs in a step-wise manner i.e. symptoms remain the same for a period of time with intermittent rapid periods of decline.

3. Trauma

Subdural haemorrhages and other traumata to the brain increase the potential for developing dementia.

4. Infections

Infections associated with the development of dementia include syphilis, HIV and TB. A less common infectious cause of dementia is Creutzfeldt Jacob disease, a prion disorder. There are spongiform changes to the brain tissue. Amyloid deposits here are made up from infectious prion protein.

5. Nutritional deficiencies

Decrease in folate and vitamin B12 can cause dementia.

6. Metabolic, endocrine and inflammatory conditions

Metabolic, endocrine and inflammatory causes of dementia are potentially reversible.

7. Toxins

Carbon monoxide, chronic exposure to lead, arsenic and other such toxins are potential causes of dementia.

8. Alcohol

Prolonged heavy use of alcohol and periods of alcohol withdrawal increase glutaminergic neurotransmission in the CNS which is neurotoxic.

9. Other causes

Include normal pressure hydrocephalus (potentially reversible).

Clinical features

People with dementia may present with any combination of behavioural, emotional and psychiatric difficulties as a result of their cognitive decline. This in turn will affect their functioning and ability to carry out activities of daily living.

Onset of difficulties for degenerative causes of dementia could be insidious and family members may report minor changes over months. An acute or subacute onset would suggest a metabolic disorder, toxins or hydrocephalus. A stepwise deterioration is suggestive of vascular type cause.

History

Symptoms may include

1. Deterioration in memory with family members reporting person being more forgetful, losing things, forgetting conversations and asking questions over and over again.
2. There may be complaints of reduced attention, concentration and generally becoming more distractible.
3. Difficulty carrying out and completing tasks. This could be from complex tasks to patients requiring assistance with day to day tasks like cooking, dressing, meals shopping etc. Decline in memory, judgement and general slowing of thought processing can pose potential risks to the patient e.g. leaving a gas cooker on, operating machinery, driving, handling finances.
4. Neuropsychiatric symptoms: depression, anxiety, emotional lability, paranoia, hallucinations and delusions. These symptoms occur intermittently and can lead to agitation and aggressive behaviours. Whilst hallucinations are less common than delusions, visual hallucinations occur early in Dementia with Lewy Bodies.
5. Behavioural symptoms: family may report intermittent periods of agitation and aggression. This could result from the patient's paranoia, anxiety, depression or confusion. Frustration arising from word finding and speech difficulties can also lead to agitation. Wandering behaviour can also arise from increased restlessness. Disinhibition and inappropriate sexualised behaviours occurs in a small percentage of people with dementia. Behaviours reported include making sexualised comments even to strangers, openly masturbating and inappropriately touching people. Compulsive behaviours and rituals have also been reported e.g. turning on and off light switches, constantly going to the bathroom, gathering and collecting certain items, setting fires, cutting things etc. These behaviours can sometimes reflect previous occupations, hobbies and premorbid personality.
6. Personality changes: persons have been described by family as not being their usual selves e.g. becoming more irritable, suspicious, constantly needing reassurance.
7. Speech/language difficulties-word finding difficulties, difficulty naming objects, receptive and expressive language difficulties.
8. Difficulty recognising familiar places and faces.
9. Confusing dates and time
10. Symptoms associated with possible aetiology e.g. family history, medical history of hypertension, strokes, Parkinson's disease, coronary artery disease history of excessive alcohol use, head injury etc.

Physical Examination

Clinical features on physical examination are usually non-specific but could also point to the aetiological cause of the dementia. Tremors, bradykinesia and rigidity could be seen in DLB and features of raised blood pressure and hemiparesis from a previous cerebrovascular accident could indicate a vascular dementia.

Neurological examination may show ataxia, nystagmus and ophthalmoplegia with excessive alcohol related cognitive impairment, such as the Wernicke-Korsakoff syndrome. Gait abnormalities and urinary incontinence could be seen in Normal Pressure Hydrocephalus. As causes of dementia could be mixed, the findings on physical examination could also be varied.

Delirium

David Meagher

Introduction

Delirium is an acute complex neuropsychiatric syndrome that is characterised by generalised disturbance of brain function occurring in the context of physical illness. The term has subsumed a range of synonyms that (e.g. acute confusional state, brain failure, toxic encephalopathy, intensive care psychosis) that reflect delirium occurring in particular patient groups or treatment settings.

It is estimated that around 10-15% of general hospital patients have delirium upon admission with a further 10-40% developing delirium during hospitalisation. Overall frequency is estimated at 11-42% (Siddiqi ea, 2006), with the clinical rule of thumb that one in five general hospital in-patients experience delirium at some time during hospitalisation. Delirium is especially common in the elderly, those with pre-existing cognitive problems and those receiving intensive care or in hospice and nursing homes.

Symptoms and differential diagnosis

During the 20th century, delirium was described as a 'clouding of consciousness' but this rather nebulous concept has been replaced by the recognition that delirium involves a disproportionate disturbance of attentional processes, diminished grasp of the surrounding environment, and

impaired higher order thinking reflected in disorganised or illogical thought processes and impaired abstraction and comprehension.

Delirium involves generalised disturbance of cognitive functioning and include problems with orientation, visuospatial function, short and long-term memory but attention is disproportionately affected and considered the cardinal cognitive disturbance of delirium. Inattention includes distractibility, reduced vigilance or concentration, and impaired environmental awareness. This contrasts with dementia where memory deficits are cardinal.

Thought process abnormalities in delirium include loosened associations, circumstantiality and tangentiality and result in disorganised thinking. This can be elicited through general observation during the interview and/or proverb interpretation. Disruptions of sleep-wake cycle are a core element of delirium and often predate the appearance of a full-blown episode. These involve sleep fragmentation or even complete sleep-wake cycle reversal and thus are more severe than the insomnia that is a common problem in hospitalised patients. Similarly, alterations in patterns of motor activity are also very common and are used to define clinical subtypes (hypoactive, hyperactive, mixed) (Meagher, 2009). Hypoactive cases are especially prone to non-detection or misdiagnosis as depression. Agitated depression or severe mania can mimic hyperactive delirium but the affective lability of delirium contrast with more sustained alterations in mood and affect in major mood disorders. Psychotic symptoms occur in approximately 50% of delirious patients. Delusions are typically poorly-formed and usually relate to persecutory themes of impending danger or threat in the immediate environment (e.g. being poisoned by nurses) rather than the more complex stereotyped delusions of functional psychosis and dementia. Hallucinations commonly involve the visual modality whereas auditory modalities tend to dominate in mood and functional psychotic disorders.

Delirium onset may be abrupt as with concussion, drug intoxication or stroke, or can be preceded by a prodromal period characterised by anxiety, sleep disturbance, cognitive impairments and increased levels of perceived distress (Gupta et al, 2008).

Diagnosis and detection

ICD-10 and DSM-IV share key features used to diagnose delirium (i.e. acute onset, fluctuating course, inattention, and disorganised thinking). DSM IV is more inclusive and preferred in research studies. Delirium is poorly detected in clinical practice with more than 50% of cases missed, misdiagnosed, or diagnosed late. This reflects the complex and fluctuating nature of delirium symptoms, inadequate education and interview skills of non-psychiatrists, under-appreciation of the prognostic significance of delirium, and inadequate routine cognitive screening in real world practice. Delirium does not have a pathognomonic feature but the range of symptoms (cognition, thought, language, sleep-wake cycle, perception, affect, and motor behaviour) and their pattern over time (acute onset with fluctuating course) are highly characteristic. Delirium diagnosis is also complicated by comorbidity, where over 50% of cases are superimposed on dementia or other pre-existing cognitive impairments. Distinguishing delirium from the neuropsychiatric symptoms of dementia can be challenging but acute onset, fluctuating course, temporal relationship to an identifiable physical precipitant, prominent inattention and altered level of consciousness usually allow differentiation. Third party informants and previous medical charts can clarify baseline cognitive functioning. Studies comparing symptoms of delirium and dementia indicate that where they co-exist, delirium symptoms dominate the clinical picture.

More consistent detection of delirium can be achieved with regular monitoring for any acute deterioration from baseline function coupled with regular formal assessment with simple cognitive tests such as the digit span, reciting the months of year backwards, serial sevens test or clock drawing (Meagher & Leonard, 2008). The *Confusion Assessment Method* (CAM) (Inouye et al, 1990) is a screening tool to assess for four key diagnostic features of delirium. Psychiatrists and delirium specialists use more detailed instruments (e.g. the *Delirium Rating Scale-Revised-98* (DRS-R98) (Trzepacz et al, 2001) and the *Memorial Delirium Rating Scale* (MDAS) (Breitbart et al, 1997) that have specific cut-off scores to identify delirium. In clinically challenging situations,

generalised slowing of the dominant posterior rhythm on the EEG can be used to help differentiate delirium from other neuropsychiatric disorders.

Delirium can be the first indicator of serious physical morbidity (e.g. stroke) and represents a medical emergency. It is not surprising therefore that non-detection is associated with poorer outcomes that include elevated mortality (Kakuma *et al*, 2003). Given the poor prognostic implications of delirium, a possible diagnosis of delirium assumes diagnostic precedence over other neuropsychiatric disorders and the clinical rule of thumb is that suspicious presentations should be considered to be delirium until proven otherwise.

Risk Factors

Delirium is a multifactorial condition where the cumulative effects of predisposing risk factors, individual patient vulnerabilities, and precipitating aetiological insults result in an episode of delirium. A wide range of patient, illness, and treatment variables increase the likelihood of developing delirium but pre-existing cognitive impairment, age extremes, and exposure to particular medications are particularly robust predictors of delirium across populations. The interaction between predisposition (baseline vulnerability) and precipitating insults account for delirium incidence. Inouye and Charpentier (1996) developed a model of 4 common predisposing and 5 precipitating factors that predicted a 17-fold variation in delirium risk in elderly medical patients. Baseline vulnerability is especially important such that minor insults can precipitate delirium in those with multiple predisposing factors.

Aetiology

Single-aetiology delirium is the exception with typically 3-4 significant causative factors relevant over the course of any single episode. It is thus important to remain vigilant to the possibility of multiple aetiological factors and to constantly re-evaluate throughout a delirium episode.

Neuropathogenesis

Delirium reflects generalised disturbance of brain function as evidenced by the broad range of neuropsychiatric symptoms, diffuse slowing on EEG, and widespread alterations in cerebral blood flow. Despite the many possible aetiological factors that contribute to delirium, the clinical presentation is remarkably consistent suggesting that delirium is a unitary syndrome reflecting a final common neural pathway for multiple diverse causes and pathophysiologies (Trzepacz *et al*, 2007).

The prevailing neurochemical theory for delirium posits a relative imbalance of dopaminergic and cholinergic systems and is supported by evidence from preclinical studies, causation of delirium by agents that impact upon these neurochemical systems, and evidence for the effectiveness of dopamine blockers in delirium treatment. Other neurochemical systems (e.g. serotonergic, glutamatergic, GABAergic, noradrenergic) are also implicated in delirium due to particular aetiologies, perhaps through their interactions with dopaminergic and cholinergic systems. Current research is increasingly focusing upon inflammatory mechanisms, disruptions to the stress axis and disturbed oxidative metabolism as possible mechanisms in delirium pathogenesis (Trzepacz *et al*, 2007).

Course and outcomes

The course of delirium is highly variable reflecting the heterogeneity of aetiology and patient populations in which delirium occurs, with many recent studies emphasizing that it is frequently not the benign and transient condition that was previously thought. While in many cases delirium is brief (hours to days), represents a transitional state from unconsciousness or is a benign reaction to treatment exposures, in other cases it can be more prolonged or associated with serious complications and persistent cognitive difficulties where differentiation from dementia becomes difficult (MacLulich *et al*, 2009).

Delirium episodes are associated with elevated morbidity, longer hospital stays, greater costs of care, and higher frequency of complications (NICE, 2010). Moreover, in the elderly, reduced post

hospital independence and elevated 1-year mortality rates occur. A recent study found that the risk of mortality increased by 11% for each additional 48 hours of active delirium (González *et al.*, 2009). Other work has highlighted how experiencing an episode of delirium can accelerate the course of a pre-existing dementia (Fong *et al.*, 2009). Importantly, these adverse outcomes are independent of factors such as age and severity of physical morbidity and are predicted by the presence and severity of delirium itself.

Management

The multifactorial nature of delirium means that optimal management requires the collaborative efforts of primary treating physicians and nursing staff with delirium specialists. Treatment is focused upon addressing the underlying aetiological causes as well as controlling delirium symptoms. Family and loved ones can assist in detection of changes in behaviour and mental state ('not themselves') and provide information about baseline cognitive and adaptive functioning and risk factor exposure.

Delirium can be prevented by multi-component interventions that address modifiable risk factors in elderly medical and post-operative populations (NICE, 2010). Common elements include elimination of unnecessary medications, careful attention to hydration and nutritional status, pain relief, correction of sensory deficits, sleep enhancement, early mobilisation, and cognitive stimulation. Careful attention to reorientation strategies (e.g. clearly visible clock/calendar), safety in immediate surroundings and optimal level of environmental stimulation (e.g. natural levels of diurnal lighting) are fundamental to the management of delirium across treatment settings and populations (Meagher, 2001).

Recent studies of pharmacological prophylaxis of delirium indicate that use of small doses of haloperidol (Kalisvaart *et al.*, 2005), olanzapine (Larsen *et al.*, 2007), risperidone (Prakanrattana & Prapaitrakool, 2007) and melatonin (Al-Aama *et al.*, 2010) can reduce the incidence of delirium in high risk populations.

The pharmacological management of delirium has been poorly studied and although there are over 20 prospective studies of antipsychotic agents, well designed placebo-controlled studies remain lacking. Existing evidence suggests that more than two-thirds of treated delirious patients experience clinical improvement, typically within a week (Meagher & Leonard, 2008). There is little evidence to suggest differences in effectiveness for typical vs atypical agents (Hua *et al.*, 2006), although the few randomised placebo-controlled trials have focused on the use of quetiapine (Tahir *et al.*, 2010; Devlin *et al.*, 2010). Treatment response includes improved cognitive and non-cognitive symptoms of delirium and does not appear to be closely linked to antipsychotic effect or sedative action.

Benzodiazepines are first line treatment for delirium related to sedative and alcohol-withdrawal or seizures but can aggravate mental state (Breitbart *et al.*, 1996) and increase delirium risk in ICU (Pandharipande *et al.*, 2006) and cancer patients (Gaudreau *et al.*, 2005). Judicious use is thus required. The few studies of pro-cholinergic agents do not suggest significant benefits either in prophylaxis or treatment of incident delirium (NICE, 2010) but further work is warranted.

Both pharmacological and non-pharmacological strategies appear less effective in patients with concomitant dementia perhaps reflecting the inherently poor outcome of elderly demented populations with high physical comorbidity. There are concerns regarding the small but increased risk of cerebrovascular events in demented patients chronically receiving neuroleptics, but the relative risks of short-term use in delirium must be proportionalised against potential benefits.

Differential diagnosis of delirium vs. other common neuropsychiatric conditions

Factors associated with an increased risk for delirium

	Delirium	Dementia	Depression	Schizophrenia
Onset	Acute	Insidious*	Variable	Variable
Course	Fluctuating	Often progressive	Diurnal variation	Variable
Reversibility	Frequently	Not usually	Usually but can be recurrent	Chronic relapsing and remitting course typical
Level of consciousness	Impaired	Unimpaired until late stages	Generally unimpaired	Unimpaired (perplexity in acute stage)
Attention/memory	Inattention is primary with poor memory	Poor memory without marked inattention except in end-stage illness	Mild attention problems, inconsistent pattern – depressive pseudodementia, memory intact with formal testing	Poor attention, inconsistent pattern, memory intact
Affect	Lability	No clear pattern	Flattening	Incongruity
Hallucinations	Usually visual; can be auditory, tactile, gustatory, olfactory	Can be visual or auditory	Usually auditory	Usually auditory
Delusions	Fleeting, fragmented, and usually persecutory often relate to immediate environment or impending danger	Paranoid, often fixed, relate to misconceptions	Complex and mood congruent e.g. themes of guilt or nihilism	Frequent, complex, systematized, and often paranoid

*Except for Vascular and Lewy Body Dementia which can be acute/subacute.

1. Patient vulnerabilities
Age extremes
Pre-existing cognitive impairment e.g. dementia,
CNS disorder
Genetic factors e.g. APOE genotype
Visual deficit
Hearing deficits
Poor nutritional status
Previous episode of delirium
2. Environmental
Social isolation
Sensory extremes
Immobility
Novel environment
Stress
Use of restraints
ICU stay
3. Medical

Severe medical illness Burns HIV / AIDS Organ insufficiency Infection (eg,UTI) Hypoxemia Fracture Hypothermia / fever Metabolic disturbances Dehydration Elevated BUN Low serum albumin Nicotine withdrawal Increased blood-brain barrier permeability Uncontrolled pain
4. Procedure-related Peri-operative Type of surgery (e.g. hip) Emergency procedure Duration of operation Urinary Catheterization Artificial respiration
5. Drug-related Polypharmacy Drug / alcohol dependence Psychoactive drug use Specific agents (e.g. anticholinergics / opiates/ benzodiazepines)

Examples of different aetiologies for delirium and a variety of pathophysiological mechanisms that can then alter brain function. The neuropathogenesis of delirium involves dysfunction of brain regions and circuitry which may ultimately result in characteristic symptoms of delirium despite a wide variety of aetiologies and pathophysiological insults to the brain.

MOOD DISORDERS

Oliaku Eneh

Depression

Definition

Depression is a mood disorder that is characterized by persistent sadness that has gone beyond the normal every day fluctuations in mood and adversely affects one's view of self, the world and the future and can infringe on the individual's level of functioning, depending on the severity. It is often recurrent but the first episode is likely to be associated with a stressful life event.

Depression is common in the elderly. However, it is not recognized frequently nor treated adequately in this age group and the clinical picture may vary to a greater or lesser extent from that seen in younger adults and is often complicated by co-morbid dementia and physical illness. In addition, the loneliness associated with loss of a spouse and other social difficulties contribute in making elderly people more vulnerable to depression.

Epidemiology

According to the DSM-IV criteria for major depression, community prevalence is up to 9.4%, higher in hospitals (approximately 12%) and nursing homes (approximately 42%) and doubles after the age of 70 with a male: female ratio of approximately 1:2 (Rodda ea, 2008).

Aetiology

In most cases it is difficult to isolate a single cause as many factors come into play to determine a person's susceptibility for depression. Therefore, the term risk factors are used to describe some situations that could predispose a person to develop depression in later life. The most important risk factors for depression in later life are (Rodda et al, 2008):

1. Genetic predisposition: though it remains somewhat significant, the genetic risk of developing depression in later life is thought to be less than that of adolescents or younger adults.

2. Physical illness: This accounts for a large proportion of depression in the elderly. The risk of depression increases with severity of medical problems. Although there are certain diseases that are known to be associated with an increased risk, any debilitating illness can lead to the development of depression in older persons. The disease conditions with the greatest risk of depression include:

- Cardiovascular disease, mainly myocardial infarction (25% have minor depression and 25% have major depression) and hypertension.
- Cerebrovascular disease: mainly ischaemic stroke (Vascular Depression)
- Carcinoma (25-38% of cancer patients suffer from depression)
- Endocrine disorder, mainly thyroid and parathyroid disorders, adrenocortical insufficiency or hyperactivity, Cushing's disease and Diabetes mellitus (the prevalence of depression in diabetic patients is 20%).
- Parkinson's disease (50% of patients with Parkinson's disease have depressive symptoms)
- Malnutrition.
- Nutritional deficiency e.g Vitamin B12.
- Dementia.
- Infection

3. Neurotransmitter theory: there is evidence to show that depression is closely linked to depletion of neurotransmitters such as serotonin and noradrenaline.

4. Social isolation, deprivation and stressful life event: loneliness and lack of companionship especially that of a confiding one possibly due to bereavement is significantly associated with late onset depression. Low socioeconomic status, role transition like retirement and increased dependency due to frailty and poor physical health are also contributory factors.

5. Vulnerable Personality: anxious and dependent personality disorders increase the vulnerability of certain elderly people to depression and are also poor prognostic indicators.

6. Drug induced: steroids, hormones, antihypertensives (clonidine, methyldopa, beta-blockers, calcium channel blockers, ACE inhibitors, reserpine), statins, H2 receptor antagonists like cimetidine, drugs used in oncology like tamoxifen, vinblastine and vincristine, analgesics like NSAIDs, antiparkinsonian drugs, some antibiotics, alcohol and illicit substances.

Clinical Features and Diagnosis

According to the ICD-10 diagnostic criteria (WHO, 1992), key clinical features include:

- Low mood which may be worse in the mornings*
- Loss of interest and enjoyment, also called anhedonia.*
- Reduced energy levels leading to increased fatigability and diminished activity.

The above are the 3 major symptoms that are usually present.

Other associated symptoms which may be present depending on the severity include:

- altered sleep pattern leading to early morning waking (>2 hours before normal)*
- reduced appetite sometimes leading to weight loss of up to 5% or more body weight in past month*
- diminished concentration and attention
- low self-esteem and self confidence
- feelings of guilt and worthlessness
- negative view of the future which may sometimes border on hopelessness
- anxiety and irritability
- loss of libido*
- motor agitation or retardation*
- decreased emotional reactivity*
- thoughts of self harm, passive death wish or active suicidal ideation.

Co-occurrence of up to 4 of the symptoms marked with asterisk constitutes a somatic syndrome. These symptoms should be present for at least two weeks to warrant a diagnosis for all degrees of severity but a shorter duration may suffice if the symptoms are exceptionally severe. This description is valid for all age groups including the elderly.

Depressive episodes can be sub-divided into 3 varieties: mild, moderate and severe, each of which presents with varying degrees of the symptoms mentioned above.

A **mild depressive episode** consists of 2 or more major symptoms plus at least 2 other symptoms with or without somatic syndrome. There is usually preservation of normal function.

A **moderate depressive episode** consists of 2 or more major symptoms plus at least 3 or 4 other symptoms with or without somatic syndrome. There is considerable reduction in normal function.

A **severe depressive episode** consists of all 3 major symptoms plus at least 4 other symptoms including prominent feelings of guilt, futility and low self esteem in addition to passive death wish or active suicidal ideation with or without psychotic features.

If the depressive episode recurs, then the term **recurrent** is used to describe it. If the depressed mood becomes chronic lasting for several years but is too mild in severity and too short in duration to fulfil the criteria for any of the categories listed above then the term **dysthymia** is used.

In the elderly, somatic complaints, reversible cognitive impairment (the so-called 'pseudo-dementia'), anxiety, psychomotor agitation and psychotic symptoms (delusions of guilt, nihilism, persecution, hypochondriasis) may be the prominent symptoms.

It is important to recognize pseudo-dementia, which presents with definite onset and short duration of memory impairment. Low mood precedes the onset of subjective memory impairment, insight into memory difficulties is well preserved, patient's may be unwilling to answer questions on cognitive testing, often saying, with frequent 'I don't know' or 'I can't' type answers.

Neuropathological changes

In late life, as a result of vascular disease there are ischaemic and inflammatory changes in key brain areas especially the dorsolateral, prefrontal cortex leading to increase in glia and astrocyte activity in addition to MRI signal hyperintensities in the deep white matter in contrast to younger adults where there seems to be glial reduction³.

Abnormalities of frontostriatal circuitry, amygdala and hippocampus, which may be related to both aging and hypercortisolaemia are also noted (Rodda et al, 2008).

Management

After a thorough history, mental state and cognitive function examination, any underlying physical illness should be detected and treated with review of current medications. The general model for treatment follows the same principle as in younger adults and includes the following types of intervention:

- Pharmacological/biological** (antidepressants)
- Psychological** (cognitive behavioural therapy, interpersonal therapy and problem-solving therapy)
- Social** (welfare benefits, housing issues, joining groups for social interaction and support, etc.)

The psychological and social interventions require input from other allied healthcare professionals (Psychologist, Social Worker and Occupational Therapist) and lend a holistic approach to the treatment.

In mild depression and dysthymia, 'watchful waiting' is appropriate unless symptoms persist for longer than two to three months, when treatment should be started using the model above.

In moderate and severe depression, immediate treatment is indicated also using the above model, inpatient admission may be required especially if thoughts of suicide are prominent and switching to or combining with a different class of antidepressant, augmentation using lithium or electroconvulsive therapy (ECT) may become necessary if there is inadequate response. If psychotic features are part of the presenting symptoms of depression, an atypical antipsychotic or ECT may be used in addition.

The choice of antidepressants is clearly at the discretion of the treating psychiatrist but NICE guidelines recommend selective serotonin reuptake inhibitors (SSRIs) as first line because of their safer side effect profile, they are safer in over-dose and can cause nausea and other gastrointestinal symptoms but are relatively free of cardiotoxicity, postural hypotension and anticholinergic side effects seen with Tricyclic antidepressants. Venlafaxine and Mirtazapine are second line drugs while the Tricyclic antidepressants and Moclobemide (Mono-amine Oxidase Inhibitor) are third line and side effects must be carefully considered before prescribing. The elderly are likely to be on several medications due to concurrent illnesses so the risk of drug interactions and drug induced problems are high. The general rule is to start at a low dose and increase very gradually if necessary ('start low and go slow').

The duration of treatment should be for at least one year after resolution of symptoms and, if the condition is recurrent, treatment may be further prolonged and in some cases may be lifelong.

Prognosis

In determining the long term outcome of late life depression, the confounding effects of physical illness, cognitive impairment, social stressors, long term mental illness and different management approaches should be borne in mind. There is evidence to suggest that 21% of elderly patients with depression will have died and almost 50% will still have depression.

The highest risk of completed suicide worldwide is among the elderly and up to 83% of elderly suicides have a diagnosis of depression. Therefore, enquiring about thoughts of self harm and suicide is a crucial part of mental state examination in this age group and must not be overlooked. There is evidence to show that depression also increases the non-suicide related mortality in elderly patients.

Bipolar Affective Disorder

Definition

Bipolar affective disorder (BPAD) is a mood disorder that manifests with repeated periods of low mood alternating with periods of elevated mood and, in between these two phases, there are intervening periods of completely normal mood during which the individual maintains optimal function.

Onset of mania after the age is 65 is relatively rare and is often associated with an organic or neurological illness, less likely associated with a positive family history of affective disorder and is classified as secondary mania. In the majority of elderly patients with BPAD, the onset is usually in young adulthood. As with depression, the management of BPAD in the elderly is similar to that of younger adults.

Epidemiology

Data regarding incidence and prevalence of mania in the elderly shows some trends (Shulman, 1993). The incidence, as measured by first admission rates to hospital, increases with age even in the extremes of old age. However, the community prevalence decreases with age. The one year prevalence rate of BPAD decreases with age: prevalence is about 1.4% in those aged 18-44, 0.4% in those aged 45-64 and 0.1% in those aged 65 and over. Only 10% of all cases of BPAD present after the age of 50 and male: female ratio in the elderly is 2:1. Mania represents up to 12% of all affective disorders treated on specialized psychiatric geriatric units and average age of onset is 55 years, often preceded by repeated episodes of depression by up to 16 years.

Aetiology

As with unipolar depression, the aetiological factors for BPAD in the elderly are multiple and include:

1. Genetic predisposition: first degree relatives of patients with BPAD have 25-50% increased chance of developing the illness. Earlier age of onset is associated with a positive family history while co-morbid neurological disorder has lower genetic predisposition
2. Organic or neurological disease (secondary mania) - the likelihood of an organic aetiology increases with age. The prevalence of organic brain disease in mania ranges from 20-40% with significant increase in cognitive impairment and cerebral atrophy noted on CT scan. Cerebrovascular disorders, chronic alcoholism, head injury and right sided brain lesions are the most common brain diseases associated with secondary mania
3. Substance misuse
4. Personality traits (Cyclothymic personality)
5. Social deprivation
6. Adverse life events, especially loss events
7. Neurotransmitter theory (serotonin, noradrenalin and dopamine have been implicated).
8. Drug induced- antidepressants, antiparkinsonian drugs (levodopa, bromocriptine, amantadine), steroids, cardiovascular drugs (captopril, methyldopa, clonidine, propranolol, digoxin, diltiazem), antibiotics (clarithromycin and drugs used in tuberculosis), analgesics (opiates, tramadol, buprenorphine, indomethacin), antiemetics (cyclizine and metoclopramide), H2 receptor antagonists (cimetidine, ranitidine), others (baclofen, chloroquine, interferon, cyclosporine)

Clinical Features and Diagnosis

The cardinal features of mania as stated in the ICD-10 diagnostic guidelines are (WHO, 1992)

- Elevated mood (elation or euphoria)

- Increase in the quantity and speed of physical (energy) and mental activity (racing thoughts and flight of ideas)
- Other associated symptoms are
 - increased sociability
 - talkativeness (pressure of speech)
 - overfamiliarity
 - increased sexual energy with disinhibited behaviour
 - decreased need for sleep
 - poor financial judgement leading to overspending
 - irritability
 - distractibility
 - conceit
 - ill-mannered behaviour
 - impaired concentration and attention
 - inflated sense of self importance (grandiosity) which may lead to the undertaking of unrealistic new ventures and reckless behaviour
 - possession of special talents or powers
 - exaggerated optimism and self esteem

Mania can occur with or without psychotic features depending on the severity and is usually associated with severe or complete disruption of work or other social activities. The most severe form of mania is associated with psychotic features which are mainly mood congruent in the form of grandiose delusions and hallucinatory experiences in the auditory modality specifically in the context of voices talking about the patient's special powers.

The mildest form of mania in which abnormalities of mood and behaviour are too persistent and marked to be classified as cyclothymia is called **hypomania**. In this variety there are no psychotic features, the symptom profile is milder and there is considerable but not severe disruption of work or other social activities with preservation of some degree of functioning.

Cyclothymia is a persistent instability of mood, involving numerous periods of mild depression and mild elation that develops in early adult life and pursues a chronic course. None of the episodes of depression or elation are sufficiently severe or prolonged to fulfil the criteria for BPAD.

In BPAD, the individual suffers from two or more episodes of affective disturbance, either:

- episodes of depression alternating with either mania or hypomania
- or repeated episodes of mania or hypomania

The episodes must last at least one week to warrant a diagnosis.

Rapid cycling bipolar illness is associated with 4 or more affective episodes in a year. It is less responsive to medications and has a poorer prognosis.

Mixed affective state is characterized by a mixture of both manic and depressive symptoms occurring concurrently. Elderly patients present more frequently with mixed affective symptoms. It is treated in the same way as mania.

Neuropathological changes

Neuroimaging studies have confirmed an increase in sub-cortical hyperintensities. Also MRI scans in elderly patients with mania show a high prevalence of deep white matter and sub-cortical ischaemic changes, which may be of aetiological importance.

Management

This follows the same principles as for depression. It is important to investigate thoroughly any elderly patient with first episode mania, looking out for underlying organic or neurological diseases. Neuroimaging techniques like positron emission tomography (PET scan), single photon emission tomography (SPECT) and magnetic resonance imaging (MRI scan) may facilitate the identification of neurological diseases. The interventions include:

-Pharmacological/Biological: evidence is limited regarding the treatment of mania in the elderly.

Lithium retains an important first line role in the acute treatment and prophylaxis of mania and depression in the elderly but beware of increased risk of neurotoxicity. Renal function is compromised in the elderly so 'start low and go slow' applies in relation to initial and subsequent dose administration. Careful blood monitoring is required and target serum level is lower than for younger adults. Treatment is initiated and maintained at approximately half the dose of younger adults.

Anticonvulsants **Sodium Valproate** and **Carbamazepine** are widely used in the acute treatment and prophylaxis of mania and depression due to their mood stabilizing properties. Valproate is an enzyme inhibitor and this may lead to interactions with hepatically metabolised drugs Valproate is not superior to Lithium but it has a better side effect profile and is used as an adjunct in lithium therapy. It is useful in treating rapid cycling illness and secondary mania. A combination of Lithium and Sodium Valproate is more superior than using either drug alone. Carbamazepine is less effective than either Lithium or Valproate and is a liver enzyme inducer, therefore it interferes with the metabolism of other drugs. It has a worse side effect profile than Valproate with potential to cause agranulocytosis, cardiotoxicity and neurotoxicity.

Lamotrigine is effective in treating bipolar depression. Evidence is limited for the use of **Gabapentin** and **Topiramate**.

Antipsychotics like Olanzapine, Risperidone, Quetiapine and Aripiprazole appear to be effective in treating mania but their use in the elderly manic patients is limited by side effects such as extrapyramidal with potential for worsening of parkinsonism, hypotension, sedation, weight gain and diabetes and precipitation of depressive symptoms. Quetiapine seems to have lesser potential for inducing extrapyramidal side effects.

Benzodiazepines are effective in lessening agitation and behavioural disturbances. However, in the elderly their use should be restricted to severe cases because of adverse effects such as sedation, hypotension, falls and paradoxical agitation and confusion.

Antidepressants are effective in alleviating depressive episodes but caution should be exercised because of their potential to induce mania. The protective effect of a mood stabilizer is required before using an antidepressant and as soon as the depressive episode resolves, the antidepressant is usually withdrawn.

After recovery from an acute affective episode in BPAD, prophylactic treatment is continued long-term in elderly patients. The exact duration is not clear but the NICE guidelines recommend a period of two to five years in young adults.

In very severe manic or depressive symptoms, where the patient is either stuporous, has psychotic symptoms, fails to eat or drink, or is not responding to other treatments, **ECT** is valuable.

-Psychological interventions include Cognitive Behavioural Therapy and family interventions. These are helpful as adjuncts to pharmacological treatment.

-Social interventions like resolving housing and financial issues and improving social interactions and vocational involvements are also important.

Prognosis

After accounting for some confounding factors like brain disease, evidence suggests that 34-50% of elderly manic patient will die on long term follow up as against 20% of elderly patients with unipolar depression. Also, 32% will suffer significant cognitive decline, as measured by a score of less than 24 on Mini-Mental State Examination. This suggests that mania has a poorer prognosis and represents a more severe disruption of the central nervous system function.

Anxiety Disorders

Oliaku Eneh

Definition

The psychological symptoms of anxiety comprise of fear, worry, nervousness, tension, apprehension, irritability, difficulty concentrating and insomnia. The physical symptoms include increased heart rate resulting in palpitations, breathlessness, light headedness and dizziness, nausea, tremor, dry mouth, sweating, abdominal discomfort that may progress to diarrhoea and frequent micturition. Patients may have a tendency to alleviate their symptoms by abusing alcohol and prescribed medications, especially benzodiazepines.

Most psychiatric disorders in the elderly have co-morbid anxiety and many elderly people get very anxious about the multiple health conditions they are faced with, resulting in the under-recognition and under-treatment of primary anxiety disorders.

Classification

According to the ICD-10 diagnostic guidelines, anxiety disorders include the following common disorders

- Phobic disorders
- Panic disorder
- Generalized anxiety disorder
- Mixed anxiety and depressive disorder
- Obsessive-Compulsive disorder
- Post-traumatic stress disorder
- Acute stress reaction
- Adjustment disorders
- Dissociative disorders
- Somatoform disorders

There is considerable co-morbidity within these disorders and between anxiety disorders and depression.

Epidemiology

The prevalence of most anxiety disorders falls with age and is higher in women than in men. This gender difference is less pronounced in the elderly and the majority of cases are longstanding with onset in young adulthood and middle age. However, a significant minority have their onset in old age. Overall prevalence in the elderly ranges from 5-10%, the highest rates are found in the community with phobic disorders presenting the most while panic disorders present the least.

Aetiology

As with other psychiatric disorders, many factors come to play in the development of anxiety disorders in the elderly. They include

1. **Physical illness-** there is an association between anxiety disorders and increased mortality and physical morbidity from cardiovascular, respiratory and gastrointestinal complaints. This is further confounded by the physical symptoms of anxiety with some important physical disorders presenting with anxiety symptoms and vice versa. In the majority of elderly people, the investigations and treatment of physical illness is frightening and may provoke anxiety disorder in vulnerable individuals. The following are some of the physical causes of anxiety in the elderly
 - Cardiovascular (myocardial infarction, cardiac arrhythmias, postural hypotension, mitral valve prolapse, heart failure)
 - Respiratory (pneumonia, pulmonary embolism, COPD)
 - Endocrine (hypo/hyperthyroidism, hypo/hypercalcaemia, hypo/hyperkalaemia, hypoglycaemia, hypothermia, pheochromocytoma, insulinoma, Cushing's disease and carcinoid syndrome).
 - Neurological (dementia, head injury, cerebral tumour, delirium, epilepsy, demyelinating disease)
 - Dietary and medication related (vitamin deficiencies, caffeine, digoxin toxicity, corticosteroids, dopamine agonists, sympathomimetics, akathisia, fluoxetine)
2. **Psychosocial stressors-** evidence shows that anxiety is associated with low socioeconomic status. Adverse life events especially if they are threatening in nature are known to precipitate anxiety. In addition, individuals may also develop late life vulnerability to anxiety when faced with challenges if they were previously exposed to early adverse experience such as parental loss. Anxiety essentially results from inability to utilize effective coping skills. In contrast to late life depression, phobic disorders in the elderly are not associated with the lack of confiding relationships; rather it is believed that in some cases the presence of close relationships may maintain phobic avoidance (Lindesay, 1996) because in a bid to protect and support the patient, families and other home based services invariably encourage the housebound approach and may thereby worsen the situation.
3. **Drug induced-** A variety of drugs have been implicated in the onset of anxiety symptoms. They include:
 - Thyroxine
 - Antidepressants
 - Anticholinergics
 - Sympathomimetics

- Steroids
- Alcohol
- Caffeine

In addition, withdrawal symptoms from psychotropic medications can also precipitate anxiety symptoms (Rodda et al, 2008).

4. Co-morbidity with other psychiatric illness-

- High levels of anxiety are often found in elderly patients in the early stages of dementia.
- Symptoms of anxiety are often associated with depression and when both conditions coexist in elderly people, there is a greater severity of depressive symptoms, an increased likelihood of suicidal ideation, lower social functioning and a negative impact on remission of depressive symptoms (Rodda et al, 2008).

5. **Genetic predisposition-** may contribute to the development of anxiety disorders. Recent studies revealed that different genes showed evidence for association with specific types of anxiety disorders, such as panic disorder, social phobias or generalised anxiety disorder (Academy of Finland, 2008). However this finding is more robust in adult onset anxiety disorders.

Specific anxiety disorders and their clinical features

Phobic disorder

Phobia occurs commonly in the elderly with increasing frailty and prevalence ranges from 0.7 to 13.4% (Rodda et al, 2008). Phobia arises due to irrational fears about specific objects or situations. These disorders provoke clinically significant levels of distress and disability due to high levels of anxiety. They are usually heralded by a traumatic event usually of a physical nature and may have had a public manifestation. However, in spite of the complete resolution of the physical event, the psychological impairment persists.

There are 3 main types of phobia:

Agoraphobia- prevalence in the elderly is estimated to range from 1.4 to 7.9% (Rodda et al, 2008) and according to the ICD-10 criteria, this consists of significant and consistent fear of two or more of the following (WHO, 1992):

- leaving home
- entering shops, crowds and public places
- travelling alone in trains, buses or planes.

These individuals may be rendered housebound because many are terrified by the thought of collapsing and being left helpless in public. It can occur with or without panic attacks but always causes anxiety symptoms during the situation. This fear may spiral out of control if there is no obvious escape route and embarrassment is perceived. Consequently the individual learns to avoid these situations and this avoidance in turn reinforces the fear. Fear can also occur merely in anticipation of the anxiety-provoking situation and symptoms are not better explained by another mental or physical disorder.

Social phobia- onset is usually in adolescence and runs a chronic course. According to the ICD-10 criteria, this consists of:

- significant and consistent fear of scrutiny by other people and being an object of ridicule as a result of negative public evaluation, usually in the context of behaving in an embarrassing and shameful manner. It occurs in the context of small groups rather than crowds.
- experience of general symptoms of anxiety in social situations in addition to either tremors, blushing, fear of vomiting or micturition.
- avoidance of social situations which in turn reinforces this fear and may lead to complete social isolation.

Fear can also occur merely in anticipation of social situations. Symptoms are not better explained by another mental or physical disorder.

Specific phobias- fear is experienced only in the presence of a particular object or situation. Onset is usually in childhood and prevalence in the elderly is estimated to range from 3.1 to 12%. Examples in the elderly include phobia for height, lightning and flying. Anxiety is restricted to the presence of the specific phobic object or situation, all other diagnostic criteria are similar to those of social phobia.

Panic disorder

Panic attacks and panic disorder are rare and symptomatically less severe in the elderly, estimates of prevalence ranges from 0.1-1%. However, the prominent physical symptoms of panic disorder may result in patients being referred instead to cardiologists, neurologists and gastroenterologists. In one study of cardiology patients with chest pain and no coronary disease, one third of those aged 65 and over met the criteria for panic disorder. It is a chronic condition with a relapsing and remitting course.

According to the ICD-10, the diagnostic criteria for panic disorder includes:

- recurrent attacks of extreme anxiety which develop rapidly and resolve spontaneously after a few minutes.
- attacks occur spontaneously in situations with no obvious danger, are not confined to a particular situation with anxiety free periods in between attacks.

Several attacks occur within a period of one month and symptoms are not better explained by another psychiatric or physical disorder.

Panic attacks are often co-morbid with other psychiatric disorders, particularly depression, and it may be severe enough to mask depressive features.

Generalised anxiety disorder (GAD)

GAD is very common and has a community prevalence of 1.9-7.3% in the elderly. It is more common in women than in men. In 50% of patients, onset is in early adulthood.

According to the ICD 10 criteria, there should be at least six months duration of

- prominent and excessive tension, worry and apprehension about normal everyday issues on most days, not limited to any one object, subject or situation and enough to cause distress and impair function.
- at least four associated psychological and physical symptoms of anxiety resulting from autonomic arousal.

In addition the condition should not meet the criteria for other anxiety disorders, psychiatric or physical disorders.

Obsessive Compulsive Disorder (OCD)

OCD is a distinct disorder involving the orbitofrontal cortex, basal ganglia, substantia nigra and ventrolateral pallidum. It is the most persistent and stable of all the specific anxiety disorders.

Onset in old age is rare, the majority starting before the age of 25 and usually running a chronic fluctuating course into old age especially if left untreated.

Obsessional symptoms may appear at any age following head injury or cerebral tumour.

According to the ICD 10 criteria, obsessions are unpleasant, persistent and intrusive ideas, images or desires that dominate a person's thoughts. The individual recognizes them as originating from his own mind but is unable to resist them despite repeated attempts at doing so. Compulsion is the irresistible urge to perform an act repeatedly despite the futility of that action. The underlying motivation is to prevent a perceived adverse event from happening. Insight is usually fully intact and the patients usually regard these symptoms as unreasonable and are distressed by them so much so that their functioning is impaired to a greater or lesser degree. Obsessions and or compulsions should last at least two weeks and not arise as a result of another mental disorder.

OCD is highly co-morbid with other anxiety disorders, depression, schizophrenia Parkinson's disease and dementia.

Common examples of OCD presentations are cleaning, checking, symmetry, contamination, doubting, and violent thoughts that sometimes have a sexual undertone.

Post traumatic stress disorder (PTSD)

In PTSD, anxiety symptoms are preceded by an event that is exceptionally traumatic and disastrous in nature. The experience of the event is sometimes regarded as "near death" for the individual and might actually have involved the death of another person. Symptoms begin within six months of the event and should be present for more than a month, are severe enough to cause distress and impair functioning. According to the ICD 10 criteria, it involves the following:

- repetitive and intrusive recollection or reliving of the event (flashbacks) with associated recurring nightmares.
- avoidance of situations or places that are reminiscent of the trauma
- and one or more of
 1. Inability to remember certain aspects of the event
 2. Heightened emotional arousal in the form of exaggerated startle response, hypervigilance, emotional numbness, insomnia, irritability and poor concentration that were not there prior to the incident.

Older persons who are frail have a greater tendency to feel threatened than their younger counterparts.

Acute stress reaction

This happens when symptoms of anxiety occur in response to extreme physical or psychological trauma. The risk of developing this disorder is increased if physical exhaustion or organic factors are also present as in the elderly. It is usually of brief duration, onset is within a few hours and it lasts only hours or days. Patient is initially 'dazed' with associated reduction in attention and consciousness, inability to comprehend stimuli and disorientation. This is followed by either withdrawal from the situation or agitation and severe distress, depression, anger and despair.

Symptoms of autonomic arousal are often present.

Supportive counselling is the treatment of choice.

Adjustment disorders

These are similar to an acute stress reaction. The preceding event is a life changing one that is associated with significant subjective distress and emotional disturbance. The major difference is that the anxiety that follows lasts longer and emanates from difficulty in adjusting to the prevailing situation. Onset of symptoms is within one month of the event and duration is usually less than six months. Brief (< one month) or prolonged mild depressive reaction might accompany the anxiety symptoms. Symptoms may impair functioning but do not meet the criteria for another psychiatric diagnosis.

Community prevalence is about 5% and in the elderly, an adjustment disorder often follows physical illness or disability, moving into a residential or nursing home and bereavement.

Supportive psychotherapy, social and occupational support are the mainstay of treatment.

Medications may be necessary for symptoms of anxiety and depression.

Management

Summary of NICE guidelines (Taylor et al., 2007) for the treatment of anxiety disorders:

1. Psychological therapy is more effective than pharmacological therapy and should be used as first line where possible.

This includes Cognitive Behavioural Therapy (CBT) with anxiety management for most anxiety disorders, graded exposure to feared situation with relaxation (systematic desensitization) for phobic disorders, exposure and response prevention for OCD, eye movement desensitization and reprocessing (EMDR) and trauma focussed psychological treatment for PTSD.

Self-help (based on CBT principles) should also be encouraged.

2. Pharmacological therapy is also effective but should be used as second line for most anxiety disorders. Most evidence supports the use of SSRI antidepressants for all anxiety disorders.

Panic disorders

Benzodiazepines should be avoided.

If SSRIs are contraindicated or ineffective, Imipramine or Clomipramine can be used but be mindful of the anticholinergic and arrhythmogenic side effects in the elderly. It is imperative to recognize and treat any underlying co-morbid conditions.

GAD

Benzodiazepines should not be used beyond 2-4 weeks. More recent evidence suggests the use of Pregabalin for GAD in the elderly.

OCD

Combination of SSRI and intensive CBT is highly advocated. Use Clomipramine if SSRIs fail and if response is suboptimal, add an antipsychotic or combine Citalopram and Clomipramine. High doses of medication are often required and there may be delay in onset of action of up to 12 weeks.

PTSD

In addition to SSRIs, Tricyclic Antidepressants and Mirtazapine are useful.

Psychosis

Oliaku Eneh

Definition

The psychoses include disorders which distort the individual's perception and interpretation of reality in combination with inappropriate affect and they are referred to as late paraphrenia if onset is in old age. Sensorium remains intact but deficits in cognitive function may manifest over time. The individual loses their sense of uniqueness and individuality with a persistent feeling that their innermost thoughts and ideas are being infiltrated upon and hijacked by others, with their actions and impulses under bizarre external influences and belief in the validity of these experiences may grow to become unwavering.

There may be perceptual disturbances in terms of delusions and hallucinatory experiences most especially in the auditory modality. Hallucinations in other modalities like olfactory and gustatory may also occur. However, visual hallucinations are often indicative of an organic pathology.

Classification

The major disorders in this category include:

- Schizophrenia
- Schizoaffective disorder
- Delusional disorder

Furthermore, according to the International Late-Onset Schizophrenia Group publication in 2000 there are three groups based on age of onset:

- Early Onset Schizophrenia like illness (EOS) depicts onset before the age of 40.
- Late-Onset Schizophrenia like illness (LOS) depicts onset between the age of 40 and 60
- Very Late Onset Schizophrenia like illness (VLOS) depicts onset after the age of 60 and this is rare.

Epidemiology

Data is scarce but one-year prevalence of LOS is 0.6% and of VLOSP is 0.4%. Community prevalence of VLOSP is 0.1-0.5%.

Aetiology

Risk factors for late onset psychosis include:

1. Female gender
2. Abnormal pre-morbid personality (schizoid and paranoid personality traits)
3. Poor pre-morbid social functioning
4. Social isolation
5. Sensory impairment (mainly deafness)

Genetic predisposition and neurodevelopmental factors have lesser impact than in earlier onset psychosis.

Clinical features

Schizophrenia

The symptoms of schizophrenia are divided into positive (symptoms that are typical only to schizophrenia, they include the group listed 1 to 5 below) and negative (symptoms that are

not typically found only in schizophrenia but may be found in other disorders, they are the symptoms listed on number 6 below).

1. Auditory hallucinations- running commentary, 2nd (includes command hallucinations) and 3rd person or other hallucinatory voices coming from some part of the body.
2. Delusions of control, influence, or passivity, clearly referred to body or limb movements or specific thoughts, actions or sensations; delusional perception.
3. Persistent delusions that are culturally inappropriate and completely impossible.
4. Thought echo, thought insertion or withdrawal, thought broadcasting.
5. Thought disorder- breaks in the train of thought resulting in incoherent or irrelevant speech or neologisms.
6. Negative symptoms such as flat or blunted affect (apathy), poverty of thought and speech (alogia), inability to experience pleasure (anhedonia), lack of desire to form relationships (asociality), lack of motivation (amotivation). They should not be due to depression or neuroleptic medication.
7. Persistent hallucinations in other modality (olfactory and gustatory hallucinations) when accompanied by delusions without clear affective component, persistent overvalued ideas, occurrence every day for months on end.
8. Catatonia (stupor, excitement, waxy flexibility, negativism, mutism and posturing).

According to the ICD-10 diagnostic criteria, at least the following must be present most of the time for one month to warrant a diagnosis

- a minimum of one very clear symptom in the group listed 1 to 4 above OR
- at least two symptoms from the group listed 5 to 8 above.

The diagnosis of schizophrenia should not be made if depressive or manic symptoms are prominent and extensive unless it is clear that psychotic symptoms predate the affective disturbance.

If both psychotic and affective symptoms develop at the same time, then a diagnosis of schizoaffective disorder should be made.

If affective symptoms predate the psychotic symptoms, then a diagnosis of either mania with psychotic symptoms or depression with psychotic symptoms should be made.

Other associated symptoms are depression, agitation, cognitive impairment and soft neurological signs.

With ageing, there are certain changes that occur in early onset schizophrenia. New positive symptoms rarely develop in old age, but old hallucinations and delusions may persist.

Individuals are often well adjusted to their illness by the time they are older.

Onset in old age

- Thought disorder and negative symptoms are relatively rare.
- Delusions are almost always systematized and mainly of a persecutory and referential nature and often in the context of invasion of privacy by unwanted visitors and neighbours through structural barriers like walls, ceilings and floors (partition delusions). Other common delusions are theft, jealousy, and disease infestation.
- Hallucinations may include auditory, visual, tactile and gustatory.

Early onset

- Thought disorder and negative symptoms are common.
- Delusions can be systematised or non-systematised.
- Hallucinations are almost always auditory.

Neuropathological changes

Findings are similar to those of early onset schizophrenia.

On CT brain scan there is

- Increased ventricle-to-brain volume ratio
- Third ventricle enlargement
- Reduced frontal and temporal lobe or superior temporal gyrus volume

Management

Forming a good therapeutic relationship is imperative and can go a long way in improving medication compliance. Members of the Community Mental Health team should bear this in mind. Patients may require inpatient admission if distress is high and medication compliance is an issue.

1. **Pharmacological treatment-** Atypical antipsychotics are first-line, mainly Olanzapine and Risperidone. The required doses are much lower than for younger adults, as low as one tenth of the standard dose because the elderly are at a greater risk of developing extrapyramidal and other adverse effects, and 'starting low and going slow' is strongly advised.
2. **Psychological treatment-** e.g. Cognitive Behavioural Therapy.
3. **Social interventions-** Day centre and day hospital attendance helps to mitigate social isolation. Treating hearing loss and visual impairment can help reduce sensory deprivation, which in itself can be an aetiological factor.

Prognosis

Late onset schizophrenia may have a better prognosis and response to treatment than early onset schizophrenia. Compliance with medication and good social support are among the predictors of good response. Remission rates of up to 48-61% have been reported.

Schizoaffective disorder

If both schizophrenic and affective symptoms develop simultaneously and are evenly balanced, the diagnosis of schizoaffective disorder should be made even if the schizophrenic symptoms by themselves would have justified the diagnosis of schizophrenia.

Management is similar to that of schizophrenia; however the mood symptoms may need to be treated with antidepressants and/or mood stabilizer medication.

Delusional disorder

This disorder is characterized by the development of either a single delusion or a set of related delusions which are usually persistent and sometimes lifelong. The delusions are often persecutory, hypochondriacal, or grandiose but they may be concerned with litigation, jealousy, or express a conviction that the individual's body is misshapen, or that others think he or she smells. According to the ICD-10, the delusions must be present for at least three months with no persistent hallucinations in any modality. The general criteria for schizophrenia are not fulfilled and the delusions are not typically schizophrenic.

The condition should not be due to other medical or psychiatric disorder and depressive symptoms may be present at other times.

Management involves the use of atypical antipsychotics and CBT focused on the delusional belief.

Prognosis

In general, there is complete remission in 33-50%, noted improvement in 10% and persisting delusions in 33-50%. Acute onset is associated with better prognosis and presence of symptoms for more than six months is associated with poorer prognosis. Long-term treatment is necessary in many cases.

Alcohol Use Disorders (AUDs) and Illicit Drug Use in Older People

Henry O'Connell

Alcohol Use Disorders (AUDs) is a general term used to describe the wide spectrum of health problems associated with alcohol use, ranging from excessive alcohol consumption above recommended levels through to alcohol abuse and alcohol dependence syndrome.

AUDs in older people tend not to receive as much attention as in younger people for a number of reasons. AUDs in older people are often more clinically silent than in younger people with less obvious social disruption for the individual and society generally (O'Connell ea, 2003; Dar, 2006).

As with many other mental disorders in older people, AUDs in older people may present atypically, thus leading to problems with under-detection and misdiagnosis. Furthermore, when detected, AUDs in older people may not be treated aggressively, because of ageist and therapeutically pessimistic assumptions.

Screening and diagnostic criteria for AUDs may be inappropriate for older people, and recommended levels of intake for the general population may be inappropriately high for older people.

There are few systematic studies that have examined the prevalence of alcohol abuse/dependence in people over the age of 65. A recent study (Blazer & Wu, 2011) examining the prevalence of alcohol abuse, dependence and subthreshold dependence among middle-aged and elderly persons in the United States found that about 6.7% (dependence 0.6%, abuse 0.9% and subthreshold dependence 5.2%) of those older than 65 reported alcohol abuse, dependence or dependence symptoms. Among past-year alcohol users, 15.4% (dependence 1.3%, abuse

2.1% and subthreshold dependence 12.0%) of those older than 65 endorsed alcohol abuse or dependence symptoms. 'Tolerance' (48%) and 'time spent using' (37%) were the two symptoms most frequently endorsed by the subthreshold group.

AUDs in older people are associated with multiple associations and risk factors (see Table 1), and clinical effects are wide-ranging, affecting practically all organ systems (Table 2).

Table 1: Risk factors for substance abuse in the elderly (from Atkinson RM, *Psychiatry in the Elderly*, 2001)

Predisposing factors
Family history (alcohol)
Previous substance abuse
Previous pattern of substance consumption (individual and cohort effects)
Personality traits (sedative-hypnotics, anxiolytics)
Factors that may increase substance exposure and consumption level
Gender (men-alcohol, illicit drugs; women-sedative-hypnotics, anxiolytics)
Chronic illness associated with pain (opioid analgesics), insomnia (hypnotic drugs), or anxiety (anxiolytic)
Long-term prescribing (sedative-hypnotics, anxiolytics)
Caregiver overuse of 'as needed, medication (institutionalized elderly)
Life stress, loss, social isolation
Negative affects (depression, grief, demoralization, anger) (alcohol)
Family collusion and drinking partners (alcohol)
Discretionary time, money (alcohol)
Factors that may increase the effects and abuse potential of substances
Age-associated drug sensitivity (pharmacokinetic, pharmacodynamic factors)
Chronic medical illnesses
Other medications (alcohol-drug, drug-drug interactions)

Table 2: Physical, neuropsychiatric and sociodemographic aspects of AUDs in older people

<p><u>Gastrointestinal:</u> Hepatic problems: elevated liver enzymes; fatty liver; alcoholic hepatitis; cirrhosis; malignancy <i>Gastritis, peptic ulcer disease and bleeding</i> Oesophageal varices Acute and chronic pancreatitis</p> <p><u>Malignancies:</u> mouth, pharynx, larynx, oesophagus, hepatic, colorectal, pancreatic</p> <p><u>Cardiovascular:</u> Ischaemic heart disease <i>Hypertension</i> <i>Alcohol induced arrhythmias</i> Congestive heart failure Alcoholic cardiomyopathy</p> <p><u>Haematological:</u> Macrocytosis (acute effect of alcohol intake and due to Vitamin B12 and Folate deficiency in chronic AUD) Anaemia (due to gastrointestinal problems)</p> <p><u>Musculoskeletal:</u> Falls and fractures Reduced bone density Myopathy</p> <p><u>Metabolic:</u> Hypoglycaemia Hyperuricaemia Elevated lipids Diabetes more difficult to control</p> <p><u>Neuropsychiatric:</u> Cognitive impairment and dementia Frontal lobe impairment Wernicke-Korsakoff syndrome Cerebellar cortical degeneration Central pontine myelinosis Marchiafava-Bignami disease Depression Psychosis Intoxication <i>Withdrawal syndrome (may be more difficult to treat in older people)</i> Suicide</p> <p><u>Other:</u></p>
Alcohol-drug interactions
Aspiration pneumonia Road traffic and other accidents

Sociodemographic:

Male gender

Divorced, widowed and single status

Social isolation

Upper and lower ends of socio-economic spectrum

Prevention and Treatment of AUDs in Older People

Primary prevention measures focus on preventing the development of *de novo* AUDs in the general population and in older people. Measures such as increasing alcohol cost through taxation and restricting accessing through licensing laws have significant impacts on overall consumption and the level of AUDs in a population. Specifically in older people, clinicians should be vigilant for the development of an AUD in the context of any of the risk factors outlined in Table 1.

Treatment modalities for AUDs in older people can be divided into biological/medical, social and psychological. Biological/medical treatments are most important in the acute setting, where detoxification may be required. In view of increased physical frailty and evidence for more severe alcohol withdrawals in older people (Brower et al, 1994), medical admission is advised for detoxification in older people. Fluid and electrolyte imbalances should be corrected and cognitive state should be monitored regularly in view of the risk of developing delirium.

Care should be taken with benzodiazepine-assisted withdrawal in older people, in view of the elevated risk of over-sedation, confusion and falls. Use of an objective measure of alcohol withdrawal such as the Clinical Institute Withdrawal Assessment for Alcohol-Revised Version (CIWA-Ar) is advisable in defining the severity of alcohol withdrawal and monitoring clinical course, although this scale is not elderly-specific and areas such as 'orientation and clouding of sensorium' may be disproportionately affected in older people, especially if cognitive impairment is present (Naranjo & Sellers, 1986 and see Table 3).

Table 3. The Clinical Institute Withdrawal Assessment for Alcohol-Revised Version (CIWA-Ar) (from The South London and Maudsley NHS Trust Prescribing Guidelines, 2005-2006)

(Items 1-9 are scored from 0-7 and item 10 from 0-4. Maximum possible score is 67).

1. Nausea and vomiting
2. Tremor
3. Paroxysmal sweats
4. Anxiety
5. Agitation
6. Tactile disturbances

- | |
|---|
| 7. Auditory disturbances |
| 8. Visual disturbances |
| 9. Headaches and fullness in head |
| 10. Orientation and clouding of sensorium |

Severity of alcohol withdrawal

Mild:	<10
Moderate:	10-20
Severe:	20+

Parenteral or oral thiamine should be given to prevent development of the Wernicke-Korsakoff syndrome.

There is limited evidence available on the use of abstinence medications such as Disulfiram, Naltrexone and Acamprosate in older people, and they are probably best avoided in view of elevated risk of adverse effects. However, there is some evidence that Naltrexone may be safe and effective in treating AUDs in older people (Oslin *ea*, 1997a and 1997b).

Psychological treatments include specific psychotherapies focussing on AUDs (e.g. motivational interviewing, addiction counselling) and psychotherapies aimed at comorbid psychiatric disorders. There is some evidence that older people may respond better to psychotherapy in same-age settings, i.e. among other older people (Schonfeld & Dupree, 1995; Kofoed *ea*, 1987), presumably because of a shared experience of the elderly-specific aspects of AUDs. Social aspects of treatment include identifying and addressing problems with personal finances, housing levels of social contacts, as problems in these areas may serve to perpetuate the AUD.

Illicit Drug Use in Older People

*Generations of people reaching old age in the coming decades will carry with them higher levels of illicit drug use than current and past generations of older people (Dowling *ea*, 2008; Patterson & Jeste, 1999).*

As with AUDs in older people, lower levels of drug intake are required to cause harm and presentation may be atypical and thus go undetected.

ICD-10 defines specific diagnostic criteria for intoxication, harmful use, dependence and withdrawal state for a wide range of illegal substances, including opioids (heroin), cannabinoids, cocaine, other stimulants including caffeine, hallucinogens, tobacco and volatile solvents. However, there are no elderly-specific diagnostic criteria.

In the recent NSDUH Report from the USA, the past year non-medical use of prescription drugs was more common than marijuana use among those over age 65 years (0.8% versus 0.4%; Office of Applied Studies, 2009); however, the rates of marijuana use for 'baby-boomers' (those over age 50 years) was much higher at 4.2% and we can therefore expect a rise in the incidence and prevalence of illicit drug use in older people by 2020 as this population ages.

The findings of Amdt et al (2011) demonstrating that the proportion of older adults (defined as 55 years or over in the study) attending for substance use treatment is increasing relative to younger adults, with an increasing illicit drug involvement (cocaine and heroin) in older adult admissions is consistent with a cohort effect of 'Baby-boomers'.

There is currently a dearth of information on clinical features and comorbidity of illicit substance use in older people. Such features will also vary widely depending on the drug in question and the mode of administration.

A thorough history of any current or past use of illicit drugs should be recorded, along with mental state and physical examinations and collateral history, if available. Further investigations will be directed by the type of drug or drugs used, the route of administration and the clinical findings.

It is predicted that by 2020, the number of people over the age of 50 needing substance abuse treatment will double (Han et al, 2009). The ageing 'baby-boom' generation in the US has been cited as a potential source of older illegal drug users (Patterson & Jester, 1999) and so clinical experience in this area and the need for primary prevention strategies and age-specific treatment programmes will be needed.

Prescribing in the Elderly

Nola Greene

Age-related changes have profound impacts on pharmacokinetic and pharmacodynamic factors, thus impacting on prescribing practices in older people.

Changes:

Central Nervous System

1. Older people have impaired postural reflexes and increased sway with an associated increased risk of falls.
2. Increased frequency of oral dyskinesias and tremors.
3. Neuronal loss especially in the Cerebellum and Substantia Nigra (gait disturbance) and the Locus Ceruleus (sleep disturbance).
4. Visual and Hearing deficits (difficulty in medication management)
5. Cognitive difficulties (medication management)
6. Sleep changes with ageing include reduced continuity of sleep (frequent awakenings), reduced Stage 4 (slow wave) sleep, phase advancement (earlier REM).

Cardiac

1. Increased systolic blood pressure.
2. Reduced early diastolic filling.
3. Increased susceptibility to heart failure if heart rate increased (c.f. drugs with anticholinergic side effects or those that increase heart rate can lead to heart failure).

Respiratory

1. Increased residual volume.
2. Reduced FEV.
3. Reduced Vital capacity.
4. Reduced pulmonary defence mechanisms (e.g. increased susceptibility to pneumonia in depressed patients who stay in bed).
5. Reduced arterial pO₂ (increased susceptibility to delirium).

Endocrine

1. Increased insulin resistance
2. Slight increase in TSH

Sexual/gender-related

1. In men erections are less firm
2. Increased risk of osteoporosis in post-menopausal women (therefore increased risk of fractures with falls)

Specific changes of ageing affecting psychotropic prescribing:

1. Reduction in renal clearance affecting excretion of e.g. Lithium, Gabapentin, Memantine.
2. Reduction in hepatic blood flow and oxidising systems slowing drug metabolism resulting in increased half life of most psychotropic drugs such as benzodiazepines, antidepressants and antipsychotics.
3. Reduced capacity to conserve sodium can result in hyponatremia, especially with SSRIs.
4. Increase in Fat/Muscle ratio resulting in the accumulation of liposoluble drugs.
5. Reduction in albumin levels resulting in increase in the free fraction of protein-bound drugs.

Overall there is increased heterogeneity apparent, i.e. there is more variety in presentation of illness and in response to drug treatment.

The elderly respond differently than others to physical illness and have easily impaired homeostasis, with less pronounced signs of illness. For example, pneumonia can be present without fever.

The importance of taking a thorough medical history and physical examination cannot be over emphasised.

1. Prescription drugs (enquire about multiple sources such as multiple GP's, hospital specialists) especially analgesics, anxiolytics and sedative hypnotics. Take note of medication with particular neurological or psychiatric side-effects such as anticholinergic drugs, Beta blockers, drugs for Parkinson's disease. Check medication list at each encounter and ascertain what is actually being consumed, which may be different to that which is being prescribed. Always include topical eye drops, often containing anticholinergic and Beta blocking agents.
2. Over the Counter drugs including those with codeine and caffeine. Non-Steroidal Anti-Inflammatory drugs. Laxatives.
3. Herbal, homeopathic medication, vitamins, nutraceuticals, home remedies and other substances sourced from alternative practitioners and 'Health Food' shops.
4. Medication taken on advice from family and neighbours.
5. Consumer direct marketed medication (Internet, mail order)
6. Latterly, the introduction of Nurse prescribed medication.
7. Substance abuse history to include alcohol, Illicit substances (remember middle aged drug addicts become older drug addicts), caffeine, codeine and nicotine abuse.

Those over age 65 years are the greatest consumers of prescribed medication. In the US, in a study of a community dwelling population of older people, 29% took ≥ 5 prescribed medications, 42% took ≥ 1 over the counter medication and 49% took ≥ 1 dietary supplements. The average intake was 5 prescription drugs and 3 non-prescription drugs. (Kennerfalk *et al*, 2002; Everitt, 1986) Byrne *et al* (2011) found that long-term residents of Irish nursing homes took a median of eleven medications.

Risk for drug interaction increases with the number of drugs ingested, with an interaction rate of 13% with 2 drugs up to a rate of 82% with 7 or more drugs taken.

Co-morbid disease will influence prescribing not only due to the impact of the disease in addition to the normal physiological changes of ageing, but also by forcing consideration of drug interactions with the medication already prescribed or sourced for these conditions by the patient. Possessing ≥ 3 co-morbidities increases the risk of an adverse drug event (ADE) by three to twelve-fold. (Evans *et al*, 2005)

Inappropriate prescribing is highly prevalent in older patients, (60% in Irish nursing homes: O'Mahony EUGMS 2010), 73% in Irish long stay facilities for the elderly, and may be even higher in patients attending Psychiatry of Later life services (Greene *et al*, *in press*).

Potentially inappropriate medications (PIMs) are defined as drugs that pose more risk than benefit particularly where safer alternatives exist, and includes drugs prescribed at inappropriate dosages or for inappropriate duration or where there are clinically significant drug-drug or drug-disease interactions (Gallagher & O'Mahony, 2008).

PIMs are associated with increased risk of ADE's, and increased morbidity, mortality and health care utilisation. (Hamilton *et al*, 2009).

Drug Utilisation Review Tools used when documenting medication can be useful in detecting PIMs. The best known ones are *Beers' criteria* (US), *Medication Appropriateness Index* (MAI: US), *IPET* (Canada)) and *Screening Tool of Older Persons' Potentially inappropriate Prescriptions* (STOPP) criteria (Ireland, UK and Europe).

Potentially inappropriate medication prescription may initially present to the psychiatrist acutely as Delirium or as Cognitive impairment.

Apparent treatment resistant depression can be due to ongoing alcohol dependence. Caffeine withdrawal causes recurrent headaches and Anxiety. Without a thorough medication and substance use history, prescription of psychotropic drugs can become part of a treatment cascade whereby increasing amounts of inappropriate medication are prescribed to treat the side effects of previously prescribed medication. The elderly are particularly vulnerable to Medication errors at so called 'transitions of Care', such as on admission and discharge from hospital or nursing homes. Many older people residing at home need supervision or administration of medication either due to psychiatric illness or cognitive impairment. Those who are disorientated in day and time will not be able to manage even with the assistance of 'pill-pot' daily packaging of medication. In summary, the elderly psychiatric patient carries prescribing risks associated with the pharmacokinetics of the ageing body. In addition, older patients more often have multiple co-morbidities and associated increased prescribing from multiple prescribers and are at increased risk of PIMs. Heterogeneity of psychotropic pharmacodynamics in this population demands caution both in initiation and monitoring of drug dosages.

Psychological interventions in Old Age Psychiatry

Marcel Steenkist

'... Near or above the age of fifty the elasticity of the mental processes on which treatment depends is as a rule lacking – old people are no longer educable...' (Freud, 1905).

It is rather ironic those comments of Freud, then already at the age of 49, having this view on older people. Nevertheless this negative view of age has continued into recent times. This therapeutic nihilism has had a profound effect on the development of both psychotherapy theory and services for older people. Psychotherapy theory has tended to focus on childhood development and the developmental stages of infant, child and early-adult life, with later life being neglected as a developmental phase.

Currently 'Late life' or 'The Third Age' is viewed as an important developmental period that can significantly add to a life well lived, if approached as an important period of growth and psychological development. We may experience a time of vitality during which individuals can expect to explore and develop their potentials. Society makes available social services and living options that did not exist a few decades ago. (Zarit & Knight, 1996).

My aim here is to give readers a brief overview of the psychological therapies that may be used when working with older people. Psychological therapies with older people have traditionally held a low position in Old Age Psychiatry and in psychotherapy generally, mainly due to ageism and negative stereotyping about treatability, especially around the impact of cognitive decline on older people.

With the current high demand on Old Age Psychiatry services for the assessment and treatment of early dementia, depression and anxiety, developments in services are focusing on biological models of illness and pharmacological treatments, again at the expense of psychological therapies. Psychotherapeutic interventions require specific additional skills of the clinician and are not always on hand. Secondly, the psychotherapeutic process may not yield immediate

responses and is more time consuming and labour intensive. Many of our clients still want a quick fix. Beck (1976) argued that the combination of a biological approach with a psychotherapy approach yields better results than either of those therapies alone.

While there is no systematic research to suggest that psychotherapies must be adapted for older populations, most experts in psychotherapy with older populations believe that, for older adults to benefit from psychotherapy, the interventions must be modified to accommodate age-related changes in learning, information processing, and health status.

In addition, cohort-related beliefs about mental health and psychotherapy should also be considered. Thus, adaptations made to psychotherapy for older populations include time to socialize older adults to the process of psychotherapy, adjusting the pace of the psychotherapy to account for age-related changes in information processing, and allowing flexibility in the delivery of psychotherapy to overcome medical and physical barriers to care.

Some of the psychotherapeutic interventions are listed below:

Cognitive–Behavioural Therapy (CBT) is the form of psychotherapy most often used with older people. CBT is the evidence-based treatment of choice for several psychiatric disorders, and it is agreed that a person's age should not preclude them from psychological therapies (Department of Health, 2002).

At the same time, older adults with mental health problems should have access to the same range of therapies as those under the age of 65 (Department of Health, 2001).

In controlled clinical studies it has been shown to be efficacious in the treatment of depression, anxiety and problematic behaviours in the context of dementia. For reviews of this literature see Teri (1994) and Wilkinson (2002).

Cognitive Analytic Therapy (CAT) represents a modern integration of analytic (object relations theory) and cognitive psychotherapy traditions to provide a brief, structured and collaborative therapeutic journey from past trauma into reconnection with dialogue and meaning. In existence for less than 20 years, the evidence base, although in progress, is yet to be established, but there is interest in applying the model to older people and potential for the development of a therapy that truly speaks to later life through its emphasis on shared meaning in the context of the client's life story and the recognised importance of the 'dialogue', both cathartic and reparative, in the therapeutic relationship (Hepple, 2002).

Psychodynamic therapy: this broad range of therapies, stemming largely from the work of Freud, Klein and Jung, has been discussed widely in relation to later life. For reviews, see Garner (2002) and Arden (2002). Some empirical evidence exists to suggest that psychodynamic work with older people is at least as effective as CBT in dealing with depression (Thompson et al, 1987).

Interpersonal therapy is a practical, focused, brief manual-based therapy that can be applied by a range of professionals after a period of basic training.

Its accessibility has generated considerable interest in its use with older people, and a reasonable evidence base exists to support its efficacy in the treatment of depression in older people, both in the acute phase and in relapse prevention (Reynolds et al, 1999).

The aim of this brief outline was to give some overview on the therapeutic interventions available and to give some consideration on how to apply them successfully to the older patient group.

If we are really serious about implementing a bio-psycho-social or holistic model, psychotherapy sits comfortably within this model, in whatever shape or form.

Capacity

Colin Fernandez and Miriam Kennedy

Prior to examining and commencing treatment on a patient, a healthcare professional must obtain valid consent. This respects a patient's autonomy to make an informed decision about their care without coercion. In order to make an informed decision, there is a presumption that an individual possesses the mental 'capacity' or 'competence' to make a decision. In a medical context and for the purpose of this chapter, 'capacity' is referred to and defined as (Leonard P & McLoughlin, 2009):

- The ability to understand the information that is relevant to the decision.
- The ability to retain the information long enough to make a decision.
- The ability to use or weigh up the information to make a decision.
- The ability to communicate the decision. (Includes talking, sign language and simple motor movements such as blinking or hand squeezing to communicate).

In certain mental states such as severe mental illness, dementia, learning disability, brain damage, terminal illnesses or altered consciousness, one's ability to make a decision may be affected. This is referred to as a lack of 'capacity'. A patient lacking in capacity will not be able to give valid consent. Valid consent is both a legal and ethical requirement prior to examination or commencing treatment. Failure to obtain valid consent on the part of a healthcare professional may lead to serious legal consequences such as charges of negligence and assault. Capacity may be temporarily impaired due to various factors such as altered consciousness, intoxication or heightened emotional distress and may return following resolution of these states. The assessment of capacity therefore should be repeated as required during the course of treatment if there is any doubt of a patient's capacity.

The principle function of capacity is to safeguard a patient's autonomy. In the presence of capacity, a patient retains the overriding right to consent or refuse treatment or care even if this may seem unwise or go against clinical advice. This emphasizes the core issue in balancing a person's right to autonomy in decision-making with a professional and ethical duty to protect them from harm.

A **functional approach** is recommended when assessing capacity (Arscott, 1997). This involves assessing a specific choice at a specific point in time. The person's functional abilities are assessed in relation to the skills required for decision-making. Judgment is then made as to whether or not the person's abilities meet the demands of the decision in question. The functional approach brings the advantages of greater reliability, acknowledgement of the fluctuating nature

of capacity and therefore a requirement for repeat assessment as required and the possibility of improving an individual's relevant functional abilities (Arscott, 1997).

At present there is no legislation pertaining to capacity in Ireland. There is a move towards a change following an expansion on a template set out by the Law Reform Commission Ireland (Law Reform Commission, 2006) in the form of the publication of the *Mental Capacity and Guardianship Bill* in 2008 and the *Scheme of Mental Capacity Bill* 2008. The Bill proposes a substitute decision-making process for those without capacity through the establishment of a Guardianship Board, an Office of the Public Guardian and appointment of Personal Guardians to assist in decision-making (*Mental Capacity and Guardianship Bill*, 2008; *Scheme of Mental Capacity Bill*, 2008).

Until this new legislation comes into effect in Ireland, the Wardship system (*Lunacy Regulations (Ireland) Act, 1871*) is the only option for substitute decision-making in Ireland. According to this system, an adult who lacks decision making power can be made a Ward of Court whereby the President of the High Court will make decisions on the said adult's care. This system has its limitations in that it does not provide easy access to immediate decisions regarding day-to-day clinical care. This renders clinicians in Ireland without a legal framework to guide their decisions. In the absence of legal protection, clinicians often resort to making decisions either with the involvement of spouses, relatives, next of kin and appointed carers (Irish Medical Council, 2009). This approach is advised by the Irish Medical Council in the absence of someone who has legal authority over decisions made.

Capacity in clinical practice

In day-to-day clinical practice, issues pertaining to assessing a patient's capacity feature in several different settings. A few examples of scenarios that are commonly encountered are assessing capacity to consent to treatment, assessing testamentary capacity, capacity to manage one's financial affairs and domiciliary arrangements and assessment of one's fitness to plead. The recommended approach to this is always a functional approach. Below is a general guideline on key points that are worth considering when assessing capacity in these scenarios.

Consent to treatment

Consent to treatment refers to one's ability to accept or refuse medical treatment. To illustrate an example: in Liaison Psychiatry, an opinion may be sought by the surgical team on an elderly man with a psychotic depression regarding his capacity to consent to a proposed gastroscopy. Key points to take into account in this setting are:

- The ability to understand and appreciate the information that is relevant to the procedure/proposed treatment.
- The ability to retain the information and repeat it back.
- The ability to understand and appreciate the risks versus benefits of the proposed procedure/treatment.
- The ability to communicate a choice.
- Sequence of decision making should reflect logical consistency.

Fitness to plead

At times a clinician may be called upon to assess a patient's competence to stand trial following a charge. This is a unique setting where a more focused approach in assessing capacity should be utilized. This criteria is based on *Rex v. Prichard* (Prichard, 1836) .

The accused is unfit to stand trial if he cannot fulfil any of the below:

- | |
|---|
| <ul style="list-style-type: none"> • Understand the nature of the charge. • Understand the difference between pleading guilty and not guilty. |
|---|

- Instruct counsel.
- Challenge jurors.
- Follow evidence presented in court.

Testamentary Capacity and capacity to manage one's financial affairs

Testamentary capacity refers to one's ability to make a will. It begins with the presumption that capacity is present. The onus lies on those challenging the will to prove that the testator lacks testamentary capacity. The legal test implies challenger is a disgruntled would-be heir. You must assess whether the person making the will is aware of:

- What a will is and when it comes into effect.
- The extent and value of their property (does not have to be exact but a reasonable idea of the extent is sufficient).
- Who has a reasonable claim to their assets.
- The disposition of assets (who receives what).
- Presence of any psychopathology impacting on this decision.
- Seek collateral where possible to confirm the accuracy of knowledge surrounding assets, reasonable claims and disposition. Family, friends, carers, General Practitioners and previous wills are good sources.

In certain scenarios, especially in later life, the ability to manage one's financial affairs may be compromised due to illness. There are several legal avenues that are present that may help in this regard. However, each avenue has its own limitations. Power of attorney refers to a legal document that allows a person (the donor) to allow another (the attorney) to act in their place on legal decisions usually referring to management of finances and assets. It can be limited to specific situations or general. This terminates if the donor becomes mentally incapacitated and can become a problem as people often do not realise that Power of Attorney will not apply once they become incapacitated.

Another variation of this document is an Enduring Power of Attorney (EPA) that allows an appointed individual to act on an individual's behalf if the individual is mentally incapacitated. A clinician's role is limited to assessing whether the patient:

- Has the mental capacity to understand the EPA
- Understands the effect of creating the EPA
- Does not nominate an unsuitable person as attorney (bankrupts, carers in nursing home/hospital, convicted fraudsters, etc.)

Quite often if an EPA is not secured before a person becomes incapacitated and in the current absence of capacity legislation, appointing someone a Ward of Court is the only avenue for surrogate decision-making. This involves a court-appointed individual/committee to manage the patient's affairs in their best interests. It requires assessments to be conducted by two doctors regarding the individual's mental capacity.

Domiciliary arrangements

In the care of incapacitated individuals, a clinician's opinion may be sought to decide if a patient has the ability to make a decision regarding where they choose to be domicile. This is an important aspect in the care of the elderly where a seemingly simple decision such as where a person chooses to live may in fact be hampered by a cognitive/ physical disability and a lack of clear understanding and appreciation of the nature of their physical and mental health that may impact on their ability to live either independently or with support. Levels of support may range from a few hours a day of home help to the need for full-time care.

As an example, an elderly person with a high risk of falls may in fact be able to choose to live independently but may not truly appreciate the risks and impact should they have a fall. The overall decision should ideally respect a patient's autonomy but also offer objective management of any risks or limitations that may be involved in someone choosing to pursue independent living in the later years of their life.

It is often useful to involve the expertise of members of allied health professionals such as Occupational Therapists, Psychologists and Social Workers that may be able to offer their input to facilitating a person's decision to live independently. Inputs such as optimizing a person's home with ease of access such as ramps, safety alarms and hand-rails could protect from the risk of falling. The consistent assessment of capacity in this regard and efforts to facilitate a patient's decision is fundamental to protect their autonomy and best interests.

Psychiatric Services

Brian O'Shea

'The biggest problem, as always, is money'. (Coid, 1991)

'...psychiatrists should be aware of and concerned with the equitable allocation of health resources'. (World Psychiatric Association, 1996)

'...the major reason why community care has been promoted in psychiatry is that it is considerably cheaper than hospital care'. (Tyrer, 2001)

'The negative voice of experience is often at a disadvantage against the siren voice of hope. (Shephard, 2002)

'Community psychiatry from its inception has been as much an ideology as a scientific endeavour'. (Mechanic, 2001)

'Investment in mental health is an investment that no country, however rich, however poor, can afford not to make'. (Rutz, 2003)

'Populations with high rates of socioeconomic deprivation have the highest need for mental health care, but the lowest access to it'. (Saxena ea, 2007)

'People with psychiatric illness are not like you and me – they are you and me'. (Yawar, 2008a)

Mental health is a costly business (Secretary of State for Health, 1991; Knapp, 2001; Walsh, 2007a; Levinson ea, 2010) and professional mental health workers, service users and families must fight for a fair share of the total health expenditure on behalf of a relatively helpless section of society. (Lancet Global Mental Health Group, 2007) Across the income spectrum, despite often greater disability, mental disorders are often undertreated compared to physical disorders. (Ormel ea, 2008) Promises of better services are often made by politicians as funding continues to fall. (Okasha, 2002; Expert Group on Mental Health Policy, 2006, p. 178; Barry ea, 2008; Walsh, 2009) Closure of large mental hospitals in the US had actually led to increased care costs because of acute admissions. (Rothbard ea, 1998) Ireland has traditionally relied heavily on admission to hospital in the care of people with psychiatric disorder. The fact that over 13% of total Irish psychiatric admissions are aged 65 years and over speaks to the need to further develop old age psychiatry services. (Dixit, 2008) The great majority of persons employed in the modern health service have no immediate role in treatment. Administrative numbers expand with increasing bureaucratisation of health services.

Glossary

Access – ability of person to get a service when required within a reasonable time frame³²¹⁹

Approved centre – treatment/care facility registered pursuant to current mental health legislation and approved by Mental Health Commission (MHC) in Ireland

Choice – retaining control over one's own life, including choice of treatment, access to relevant information, being seen as a participant, and having access to staff and advocates³²²⁰

Clinical governance – a way of improving clinical standards (includes audit, education, R & D, risk management, etc)

Risk – the chance of an event occurring that might impact on objectives of a system

Risk management – aspects of a service directed towards reducing the likelihood of adverse outcomes and managing those that occur

Background³²²¹

³²¹⁹ Alonso ea (2007) estimated that 3.1% of adults in 6 European countries had unmet mental healthcare needs.

³²²⁰ A **mental health advocate** is defined (MHC, 2009c) as someone acting for a psychiatric patient, e.g. advising and defending, or, more widely, involved in planning, delivery and evaluating services.

The move towards the community antedated modern political activity. Most psychiatric patients have been treated outside hospital since the 1950s. The advent of ECT and effective drug therapies provided a strong impetus for communitisation of psychiatric practice. The advent of voluntary admissions increased the expectation of discharges. Other factors promoting discharge included state payments for the unemployed, public housing, and the development of primary care. (Rose, 2001)

The exodus of patients into the community increased re-admissions and pushed total admissions ever upwards. It also influenced number of involuntary admissions, with an upward trend despite less available beds. (O'Doherty, 1998; Hotopf *et al*, 2000; Muijen *et al*, 2003, p. 693; Salize & Dressing, 2004) Among EU states during the period 1998-2000 that had available information, involuntary admission rates were highest in Finland at 218/1000,000 of the population³²²². 'Revolving door' and 'new longstay' replaced terms like 'open door'.³²²³ We must achieve a selfless balance to avoid returning to the equivalent of the Victorian buildings that were built when labour and life were relatively cheap. Understimulating hospital environments in the UK (Wing & Brown, 1970) and elsewhere (Oshima *et al*, 2003) have been found to correlate with institutionalisation. However, an institutional basis for negative symptoms (clinical poverty syndrome) is questioned by findings that such symptoms persist for at least nine years after post-discharge. (Johnstone *et al*, 1981) This is not to say that psychiatric wards can be very non-stimulating environments³²²⁴. (Goffman, 1991; Radcliffe & Smith, 2007; Yawar, 2008a) Enoch Powell (Minister of Health, UK) told the National Association of Mental Health in 1961 that the following 15 years would see a halving of mental illness inpatient places and the closure of most mental hospitals. Tooth and Brooke (1961) predicted that of all the longstay patients in 1954 none would remain by 1970. They also said that all the needs of the mentally ill (except the mentally retarded) could be provided for with a bed ratio of 180/100,000 population.

Day services

1942 - first day care program established in Russia
 1946 - first program in an English-speaking country starts in Montreal
 1946 - Marlborough Day Hospital opens in London, England
 1947 - Menninger Clinic (Kansas) starts 'day hospital'
 1949 - Yale University sets up similar 'day care clinic'
 1957 - Carse starts the 'Worthing Experiment'; range of services, including domiciliary visits, reduces admissions from Worthing by 59%
 1958 - day care geriatric service starts in Oxford
 1963 - formal US policy of community care dates from *Community Mental Health Centres Act*

British DHSS³²²⁵ recommendations during the 1970s for population of 100,000

50 beds and 25 day places for adult mentally ill
 30-40 beds and 10-20 day places for elderly severely demented
 Local authorities should provide 20-30 hostel places and 60 day centre places for those with social handicaps but not needing continuous medical and nursing care
 Units on a regional or sub-regional basis should be provided for special groups³²²⁶

³²²¹ In 1744, King George II amended the *Vagrancy Act* and ensured the care of lunatics. Private registered homes, wherein the mentally ill discharged from hospital may be placed, were likened to the original private madhouses.

³²²² Followed by Austria, Germany, and Sweden.

³²²³ Revolving door patients show an excess of alcohol and substance misuse as well as non-adherence with prescribed management. (Turner *et al*, 1999) In fact, a small number of such patients may make up an inordinate percentage of total inpatient length of stay figures. (O'Shea *et al*, 1996) A 5-year follow-up (2001-5) in Ireland found that severe psychotic illness (hard to avoid) and alcohol-related disorders (despite exhortations to treat in the community) were important causes of re-admission. (Daly *et al*, 2007a)

³²²⁴ England's mental health wards were criticised in 2008 for having high levels of violence, overcrowding, impersonal care, and for the high numbers of detained patients absconding for days at a time. (Cole, 2008)

³²²⁵ Dept. of Health & Social Services

³²²⁶ Children, adolescents, alcoholics, drug addicts, and secure units.

By 2001 the situation was that provision of secure forensic psychiatry services was uncoordinated, under-provided, and tended to prioritise offender patients and not to support local psychiatric services.(Coid ea, 2001) In Ireland *The Psychiatric Service - Planning for the Future* (1984) set out the requirements of a comprehensive community-based psychiatric service.

Planning for the Future planning norms (Trant Report)

Sector size: 25-30,000

Day care places: 0.75/1,000

Community residential accommodation: 60/100,000

Short to medium stay inpatient places: 0.5/1,000

New longstay inpatient places for < 65s: 0.2/1,000 under 65s

New longstay inpatient places for > 65s: 5/1,000 over 65s

'Ideal' admission rate would to be 5/1,000.

Actual Irish provisions

2001 - 42.5 day hospital places/100,000 in 63 centres (2002 - 32.4) and 92.7 day centre places/100,000 in 104 centres (81.2 in 2002)

3,077 places in 404 community residences (low, medium and high support)(3,136 in 2002)

1987 - 233 community residences (1,625 places)(418 [3,210] in 2003)

Excluding residences exclusively for intellectual disability, there were 1,412 people (M>F, majority with schizophrenia) living in 113 'high support community residences' (rate: 46.6/100,000 population aged at least 16 years) on 31.03.2006.(Doherty ea, 2007)

The recommended number of day care places per 1,000 of the population varies from 0.75 in *Planning for the Future* to 1.88 in Hickey ea (2003) with the Inspector of Mental Hospitals (Department of Health and Children, 2001) recommending 1-1.5.

Hickey ea (2003) recommendations

66 day care places per 35,000 of the population, 11 being day hospital places and 55 being day centre places

There is great variation in the provision of both day hospital and day centre places across Ireland, some areas providing services way below the optimum.(Kelly, 2004) The same observation applies to residential accommodation in the community.(Mulholland, 2010)

3 main obstacles to better mental health (Saxena ea, 2007)

- Scarce resources
- Unequal resource distribution
- Inefficient use of resources

A Vision for Change (Expert Group on Mental Health Policy, 2006; see also Anonymous, 2006) makes a number of recommendations: service user/carer involvement in service development/delivery; mental health promotion (enhance and decrease protective and risk factors respectively); establishment of comprehensive community mental health teams (CMHTs); multidisciplinary home-based and assertive outreach services offering a full range of relevant interventions; a recovery orientation; links with primary care and voluntary groups; catchment areas serving 250,000-400,000³²²⁷ run by local mental health catchment area management teams with a national mental health service directorate that works directly

³²²⁷ Regional catchments are required to allow consultant to undertake some degree of special interest work.(see Walsh, 2009)

with the Health Service Executive (HSE); prioritisation of those in greatest need; annual evaluation of services; close all psychiatric hospitals and use the released resources for the new service; local data collection and funding of research; centralised planning and funding of education/training of mental health professionals; the national mental health service directorate should put a plan in place for multi-professional manpower; an implementation review committee to oversee this policy; substantial extra funding adjusted for inflation; and acceptance/implementation of the complete plan. Under a proposed 7-10 year plan, provision of CMHTs should receive priority in order to allow acute beds in psychiatric hospitals are to be phased out.

A Vision for Change (Expert Group on Mental Health Policy, 2006) recommendations

Child and adolescent mental health services - each catchment area to have 6 CMHTs for people up to age 18 years; extra CMHT for paediatric liaison; 1 day hospital/catchment area; nationally, 5 inpatient units of 20 beds apiece

Each adult CMHT for 18-64 year olds/population of 50,000, with 2 consultants (mainly employing home-based treatment); 1 acute inpatient unit of 35 beds and 1 crisis house with 10 places/catchment area; 2 high support intensive care residences (10 places each)/HSE region³²²⁸; 2 pilot early intervention services 'Recovery and rehabilitation' services³²²⁹ for severe/enduring illness: 1 CMHT/100,000 population: assessment, treatment, care assertive outreach, etc; 3 community residences (10 places/100,000); 1-2 day centres (30 places)/300,000; 1 service user-provided support centre/social club/100,000

Older people served by one team/100,000 and 8 inpatient beds; 1 day hospital (25 places)/300,000; unit (30 beds/300,000) for continuing care/challenging behaviour

1 and 2 CMHTs for intellectually disabled children/adolescents and adults/catchment area, respectively
Forensic: 2 teams for children/adolescents nationally³²³⁰ and 1 secure national (adult) unit, and a similarly sized unit for intellectually disabled people who become severely disturbed in context of criminal justice system; court diversion and work with police and other mental health services

Homeless: 2 CMHTs in Dublin, a crisis house (10 beds), local psychiatric acute beds, 2 day centres and 1 day hospital

Substance misuse (i.e. comorbidity of 'a complex or severe substance misuse problem' with mental illness): 1 CMHT/catchment area and expanded services for adolescents

Eating disorders: 4 regional CMHTs and a national tertiary referral centre for children/adolescents

Liaison: 1 team per regional hospital/catchment area (13 nationally)

Neuropsychiatry: 2 national teams (1 unit of 6-10 beds)

Perinatal psychiatric: based in a national maternity hospital

Acute in-patient care based in a regional hospital (50 beds/hospital: 35 for acute adult, 8 for elderly, 5 for intellectual disability, 2 beds for eating disorders)

One 10-bedded crisis house/300,000

4 intensive care rehabilitation units (30 beds in each HSE region³²³¹)

Two 10-place high support intensive care residences/HSE region

One 30-bed continuing care/challenging behaviour unit for elderly

10 rehabilitation beds in approved intellectual disability residential centres

100 beds nationally for 0-18 year olds (5 units of 20 beds each)

10-bed national secure unit for children/adolescents and similar unit for the intellectually disabled

Transinstitutionalisation³²³² refers to the phenomenon of discharged chronic patients ending up in prison or other (unsatisfactory) places. Homelessness has become a major problem in the Western World. Hostels for the homeless may become repositories for unmedicated actively psychotic patients. The fact of being ill

³²²⁸ 4 regions, 8 residences, 80 places nationally.

³²²⁹ See Tedstone Doherty et al. (2007)

³²³⁰ One in a 10-bedded secure unit and one in the community.

³²³¹ The HSE is to create 4 regional health boards by January 2010.

³²³² Or reinstitutionalisation. **Penrose's Law** (after Lionel Penrose who discussed this phenomenon in 1939) = as number of psychiatric inpatients fall, number of prisoners rises. There is some evidence for this in Ireland. (Kelly, 2007) The US saw a 95% decrease in public psychiatric beds since the 1950s and reports from that country suggest that Penrose was correct: vagrancy, crime, imprisonment and neglect. (Weich, 2008)

may have more to do with reported criminality in schizophrenia than any genetic endowment. The move from asylum care has expanded the range of social ills viewed as being 'psychiatric'. (Rose, 2001) It seems probable that many people that once would have been warehoused in psychiatric asylums are now been diverted to forensic units, prisons, and supported housing. (Priebe *ea*, 2005) Despite there being over 3,000 extramural residential places in the Republic of Ireland, and low provision on the part of local authorities, the Expert Group on Mental Health Policy (2006, p. 253) placed responsibility for shelter on scarce mental health treatment facilities, suggesting that discharged persons who remain homeless be returned to 'their parent service'.

Some of the resistance to decentralising mental health services comes from hospital-bound staff.³²³³ Chlorpromazine became available in 1953. Within two years the population of mental hospital began to fall after rising steadily in most industrial countries for 150 years.

Bed usage (psychiatry)

USA - 450/100,000 in 1955 → 110/100,000 in 1981
 Italy - 210/100,000 in 1970 → 75/100,000 in 1985³²³⁴
 England - peaked at 148,000 in 1954 → 45,000 by 1992 → 42,000 by 1994
 Scotland - 319 inpatients/100,000 in 1985
 Ireland - 930/100,000 in 1999 → 907/100,000³²³⁵

The number of residents in English mental illness and 'mental handicap' hospitals fell from 143,547 and 50,515 respectively in 1954 to 56,900 and 24,909 respectively in 1990. The English hospitalisation rate in 1986 was 128/100,000 and the number of beds was reckoned to be dropping by about 4,000 per annum in early 1993. The Irish hospitalisation rates in 1999 and 2001 were 930 and 907/100,000.

Comparative number of psychiatric beds per 1,000 population (Walsh & Daly, 2004)

	1961	2001
Republic of Ireland	7.3	1.5
Sweden	4.8	0.6
Japan	1.1	2.8

Republic of Ireland v England and Wales 2006³²³⁶ (Walsh, 2007b)

	Inpatients	Rate/100,000	Involuntary admissions
Rep of Ireland	3389	86.5	15%
E & W	32023	52.8	40%

There were 4,321 inpatients in Irish psychiatric facilities in the 2001 census, (Daly & Walsh, 2002, 2003a; cf. also their 2001 publication) a rate of 160.3/100,000 population aged 16 years and over, falls of 78% and 47% from 1963 and 1991 respectively. 3,891 patients resided in such facilities in 2002. (Daly & Walsh, 2003b) In 2001, 55% were male, 38% were at least 65 years old, 69% were single, 17% were involuntary (rate = 26.7/100,000 pop.), 37% had schizophrenia, 18% had depressive states, 14% were intellectually disabled, 54% were longstay (> 1 year) and 36%³²³⁷ were old longstay (> 5 years). High rates were also associated with old age, single male and unskilled worker status. One-quarter of alcohol- and the same fraction of substance-dependence admissions were for less than 7 days, whereas as the same fraction of depressives were in hospital for 1-3 months. There was a large disparity in rates of bed/100,000 in 2001 between different health board areas (range 271.7 in South-Eastern Health Board v 40.0 in South-Western

³²³³ See Saraceno *ea* (2007) for a discussion of this and related problems in poorer countries.

³²³⁴ Italy (minus Sicily) has 4,108 public beds (0.78/10,000) and 4,862 private beds (0.94/10,000). (De Girolamo *ea*, 2007) The Netherlands had 135 beds/100,000 population in 2001. (Weich, 2008)

³²³⁵ People aged 16 and over respectively.

³²³⁶ 53% and 1% of involuntary patients in Ireland during 2007 had admissions lasting less than 21 days and over 1 year respectively. (MHC, 2008)

³²³⁷ Another figure from the same authors is 42%!

Area Health Board). The average length of stay³²³⁸ in 2001 was 26.2 days, the shortest average stay by diagnostic grouping being for alcohol-related conditions (13.7 days); organic psychoses stayed longest (37.1 days – 40.4 days in 2002), followed by schizophrenia (35.6 days). 46%, a quarter, and a fifth of patients with alcohol-related conditions, depression, and schizophrenia were discharged within a week. General hospital psychiatric units developed slowly in Ireland³²³⁹. However, admissions to such units increased from 4.4% of psychiatric admissions in 1991 to 14.2% in 2001. For the first time, 2003 saw admissions to general hospital psychiatric units (44%) surpass those to psychiatric hospitals (38%).(Daly et al, 2004)

General hospital psychiatric units may have problems dealing with disturbed patients (Farnham & James, 2000) and with heavy liaison commitments,(McGennis, 1992) although some of the resistance may come from within the medical profession itself.(Walsh, 1993)

Ireland, traditionally a culture of exodus, is experiencing the influx of foreign ethnic groups in large numbers. Britain, especially its cities, has had to deal with culturally diverse groups presenting with psychiatric difficulties for much longer. Among the reasons cited for such high bed occupancy rates (125% in 1997) in London are concentrations of ethnic minorities with a high incidence of psychosis, unemployment, social isolation and deprivation, and homelessness.

There is a great need to develop readily accessible interpretation services (incl. sign language for the deaf: Du Feu, 2010) in view of the ethnic mix now prevalent in Ireland.(Expert Group on Mental Health Policy, 2006)

Irish Branch of Amnesty International (Amnesty International, 2003) summarised Irish psychiatric services as showing tardy/piecemeal/inadequate/unevenly distributed development with severe under-resourcing in terms of staff, money and available treatments. It urged the Irish government to provide the following:

- Comprehensive, needs-based, service-user led review of services plus full and prompt implementation with due regard to human rights, best practice, and emphasising community care
- Research on needs/services
- Full financial provision
- Necessary resources for MHC
- Effective action on international and Inspector's reports and governmental reviews
- System of personal advocacy and effective complaints procedures (see Health Service Executive, 2005)
- Person-centred service for all in need (emphasis on minorities/children/etc)
- Public education/awareness
- Rights-based legislation

The Irish *Employment Equality Acts* 1998 and 2004 and the *Equal Status Acts* 2000 to 2004 prohibit discrimination on grounds of gender (incl. transsexuality, sexual orientation, pregnancy, maternity leave) or sexual orientation, marital or family status, religion, age, disability, and race.(Equality Authority, 2006)

*Republic of Ireland*³²⁴⁰ *psychiatric in-patient facilities, psychiatric manpower & population*

(a) Irish Psychiatric in-patient facilities:

<i>Year</i>	<i>Total inpatients</i>	<i>Total admissions</i>	<i>Comments</i>
1958	21,000		
1963	19,801		
1876	14,473		
1986	11,559	29,392	
1987	10,681	27,743	Alcohol/depression: commonest diagnoses in males/females respectively
1988	9,500	28,432	12% involuntary and 88% voluntary
1989	8,793		National hospitalisation rate of 2.2/1000 pop.

³²³⁸ Excepting patients resident in excess of 12 months.

³²³⁹ The first general hospital psychiatric unit was opened in Waterford (Ardkeen, now Waterford Regional Hospital) under Tom Lynch during the 1960s. By 2006 there were 22 such units in the Republic. The Inspector of Mental Health services emphasised that psychiatric units in general hospitals had still not replaced some large psychiatric hospitals in 2008. Recommendations for such a move date at least to the *Commission of Enquiry on Mental Illness* in 1966 but the idea is much older having been broached by Conolly Norman (1853-1908) of the Richmond Asylum in Dublin in 1904.

³²⁴⁰ It is interesting to note that Ireland came 16th out of 29 countries in Europe, one place ahead of the UK, on the European Health Consumer Index 2007 of public health care system. The Index is based on 27 indicators, e.g. patient rights/information, generosity of public healthcare, and medication access.(Watson, 2007) Top of the list was Austria, with Latvia at the bottom.

991

1991	7,500		75% voluntary (not quite the same as informal) ; hospitalisation rate of 2/1,000 (or twice the UK rate)
1992		27,148	Hospitalisation rate of 766.8/100,000
1993		27,005	Married > single women admitted (opposite for males)
1994	5,581	26,687	27% first admissions. Rate of all (first) admission = 753.7 (201.4)/100,000
1996	5,212	26,656	Out-patient clinics at 251 locations/233,512 attendances.
1997		26,069	Admission rate = 959.8/100,000 (all) + 256.8 (first). Depression + alcohol + schizophrenia = 67% all (79% first) admissions.
1998	4,820	25,295	
1999	4,469	25,062	11% of admissions were involuntary. All and first admission rates/100,000 population aged 16 and over = 930.0 and 263.3 respectively.
2000	4,230	24,282	Admission rate = 270/100,000 pop. 16 years and over; 70% of all admissions were re-admissions.
2001	4,321	24,446	Admission rate = 5.7/1,000 pop. of all ages. 70% of admissions = readmissions. Highest rate of admissions in 45-54 year old group. 53% of all and 56% of first admissions were male. Longer stays in private facilities but more readmissions in health board hospitals and general hospital psychiatric units (72%) than in private units (59%). It has been suggested that public sector deals with more severe mental illness (SMI). Schizophrenia admissions = 9%, 20% and 23% to private, general hospital, health board respectively. Unskilled over-represented. 11% involuntary (4%, 10%, and 14% respect. for private, general hospital, and health board facilities). 54% of admissions single marital status.
2002	3,891	23,677	Admission rate = 7.817/1,000 pop. aged 16 and over. 48% of discharges within 2 weeks, 69% of discharges within 1 month, 93% within 3 months. 54% of admissions were single.
2003	3,701	23,031	Highest admission rate was for 45-54 year olds. 33% , 18%, and 16% were for depressive, schizophrenic, and alcoholic disorders respectively. 11% were of admissions were non-voluntary.*
2004	3,556	22,279	56% males, 11% of all and 13% of first admissions were involuntary, 2.5% wards of court; 18% of admissions were to private sector; 54% of all admissions and 52% of first admissions were single; unskilled had highest admission rate, 10 times that for employers and managers; 29%, 20%, 14%, and 12% of admissions respectively were for depression, schizophrenia, alcoholic disorders, and mania.
2005	3,475	21,253	
2006	3,389	20,288	Two-thirds single, 18% married, 7% widowed, 1% divorced; single v married men = 6:1; 22% residents involuntary; 29% inpatients for at least 5 years; highest rate of hospitalisation among 75+ years.
2007		20,769	

*In 2003/4, Ireland had an admission rate of 588/100,000, whilst the rates for England Wales were 298 and 521 respectively; the percentage of admissions that were involuntary for these 3 countries were 10.6, 7.7, and 8.9 respectively; and the percentage of inpatients in hospital for 1-5 years was 1.2 for Ireland and 0.1 for England.(HRB, 2005)

<i>Year</i>	<i>First admissions</i>	<i>All admissions</i>	<i>First as % of all</i>
1965	6,210	15,440	40
1970	7,696	20,342	38
1973	9,018	24,036	38
1975	8,873	25,892	34
1980	8,459	27,098	31
1982	8,702	28,778	30

2007 ³²⁴³	5,853	20,769	28

(b) Irish psychiatric manpower³²⁴⁴

Postgraduate Medical and Dental Board (2002):

The number of senior house officers in 2000 = 205.8.

The number of registrars in 2000 = 142.

The number of approved posts at senior/specialist registrar level on 1/2/2002 = total 30 (general adult, 14; child/adolescence, 7; old age, 4; intellectual disability, 2; and 1 each for substance misuse, forensic, & rehabilitation).

The number of consultant psychiatrists on 1/1/2002 = 261.

Comhairle na nOspideal³²⁴⁵ (2003):

15 additional consultant posts approved in 2002. At 1.1.2003, 276 permanent consultant posts, divided up as follows: 49 in child & adolescent, 5 forensic, 171 in general adult, 30 in intellectual disability, 21 in old age psychiatry – this is not synonymous with filled posts. Consultant/population ratio varied from 1/9808 in East Coast Area Health Board (this includes St John of God private sector) to 1/18154 in North-Eastern Health Board. There were 10 permanent part-time consultants and 60 approved non-permanent consultants. 106 permanent consultants were male (50.24%) and 105 were female (49.76%); no other branch of medicine had such parity, the nearest being pathology (61% males v 39% females) and furthest being surgery (95% v 5%). A total of 25 specialists in psychiatry were in private practice, i.e. not contracted to public hospitals.

Comhairle na nOspideal (2004a):

5 additional consultant posts were approved in 2003. There were 281 permanent consultant posts at 1.1.2004, 227 (49% being male) of them being filled: of filled posts there were 44 in child & adolescent, 4 forensic, 124 in general adult, 23 in intellectual disability, 19 in old age psychiatry. Consultant/population ratio varied from 1/10,360 in Northern Area Health Board to 1/18136 in Southern Health Board. There were 14 permanent part-time consultants and 53 approved non-permanent consultants. A total of 27 specialists in psychiatry were in private practice, i.e. not contracted to public hospitals (all but 4 were in the Eastern Regional Health Authority's three area health boards, 14 being in the South West Area Health Board). The percentage net increases per specialty during 1993-2003 were emergency medicine 292, pathology 81, radiology 72, general medicine 70, paediatrics 68, psychiatry 47, surgery 35, and obstetrics/gynaecology 20; the average increase was 56%.

Comhairle na nOspideal (2004b):

The recommended number of posts were: general adult 1/25,000; special interest [s.i.] liaison 1/500 acute beds; s.i. forensic dependent on PICU development; s.i. rehabilitation 1/100,000; s.i. substance misuse 1/300,000; s.i. psychotherapy 1/medical school; s.i. adult learning disability 1/100,000; s.i. child/adolescent learning disability 1/200,000; child/adolescent 1/50,000; substance abuse depending on local needs; forensic based on development of current service; and old age 1/100,000. One general adult psychiatrist/25,000 is recommended.

Irish College of Psychiatrists (2005)

Funding on mental health services accounted for just 6.8% of the health budget in 2003 [7.3% in 2004 – contrast with England & Wales: 12% in 1998 and 13% in 2003; Department of Health, 2004; 6.6% in 2009], of which 5-10% went on child and adolescent psychiatry even though children under 16 years of age accounted for almost 23% of the population. There are 55 whole-time equivalent (WTE) consultant child and adolescent posts (1 per 16,150 of pop. under 15; the Finnish ratio is 1:6,000) and there are 20 beds (156 recommended)! The College estimated that a comprehensive service for people up to 18 would require 150 WTE posts.

Medical Council (2007)

³²⁴¹ All admissions rate = 701/100,000 aged 16 years or over; first admission rate = 195.4; 72% of admissions were re-admissions; male admissions = 55%; divorced persons had highest admission rate; depressive disorders, 30%; schizophrenia, 20%; alcoholic disorders, 14%; 47% of all discharges within 2 weeks of admission; 49, 32, and 19% of admissions were to general hospital units, psychiatric hospitals, and private hospitals respectively; 62 admissions to children's centres; non-voluntary all v first admissions = 11% v 12%.

³²⁴² All and first admissions rates = 478.5 and 132.1/100,000 population respectively; re-admissions = 72% of all admissions; males = 51% and 55% of all and first admissions; 45-54 and 18-19 years of age highest for all and first admissions respectively; divorced and unskilled overrepresented in all and first admissions; depressive disorders = 29% and 32% of all and first admissions respectively; schizophrenia = 20% and 13% of all and first admissions respectively; and alcoholic disorders = 14% and 15% of all and first admissions respectively (highest in East Wicklow, followed by Roscommon); non-voluntary all v first admissions = 11% v 12% (3% of private hospital admissions were involuntary); 47%, 68%, and 93% of discharges were within 2 weeks, 4 weeks, and 3 months respectively; 2% of discharges were in hospital for at least 12 months; average length of stay = 27.5 days. Half, 32%, and 19% of all admissions were to general hospital psychiatric units, psychiatric hospitals (incl. Dundrum), and private hospitals respectively. 398 admissions (271 for first time) were for persons less than 18 years old. (Daly et al, 2007b)

³²⁴³ All and first admission rates = 489.0 and 138/100,000. Readmissions = 72% of all admissions. Admissions M = F, but rate of all admission higher for F and rate of first admission higher for M. Unsurprisingly the least skilled had the highest rate of admission. Cause of all and first admissions by diagnostic group as %: depressive (28, 31), schizophrenia (19, 12), and alcoholism (13, 14). Involuntary admissions = 11% of all and 10% of first admissions; only 2% of all private admissions were involuntary. 49% of discharges occurred in less than 2 weeks from the admission date. (Daly et al, 2008)

³²⁴⁴ To place matters in world perspective, Nigeria has 1 psychiatrist for over 1.5 million inhabitants. (Gureje & Kola, 2007)

³²⁴⁵ *Comhairle na nOspideal* was replaced by the Consultant Applications Advisory Committee (CAAC) which sat for the first time in October 2009.

Total doctors holding internship registration, 652; total holding full registration, 15,512 (1,367 aged 65 years or more; 12, 394 giving Irish address); 3,798 on register of medical specialists (psychiatry, 313; child & adolescent psychiatry, 74; psychiatry of old age, 34; psychiatry of learning disability, 27).³²⁴⁶

(c) Population³²⁴⁷

<i>Year</i>	<i>Total</i>	<i>Males</i>	<i>Females</i>
1901	3,221,823	1,610,085	1,611,738
1961	2,818,341	1,416,549	1,401,792
2002	3,917,203	1,946,164	1,971,039
(2002 65+ yrs	436,001	189,155	246,864)
(2002 25-44 yrs	1,180,259	588,308	591,951)
2006	4,239,848	2,121,171	2,118,677

Discussion

Functions: The emphasis in 'community psychiatry' is on providing a service for a population rather than the traditional focus on patients who come for treatment to a hospital. It is not intended here to describe the basic outline of psychiatric services. Planning of services is required, e.g. resources,(Holloway, 2001; Denihan, 2005) needs,(Slade & Glover, 2001) different requirements of groups of people, liaison with various disciplines, administrators, politicians, clergy, police, and so on. There is a greater emphasis on 'prevention', which often means early recognition of problems. Services should be close to people in need, and must recognise the needs of special groups, e.g. elderly, drug abusers, etc. A multidisciplinary team³²⁴⁸ approach is employed, although considerable gaps remain in filling posts.(Walsh, 2004) What is not needed is the robbing of staff from acute wards to staff the community as happened in the UK.(Samaraskera, 2007) Some services are sectorised³²⁴⁹; some services operate at a district or regional level, e.g. drug abuse or child psychiatry. There is a tension between sectorisation and the need for individual practitioners to gain expertise in defined areas of general adult psychiatry, i.e. sub-specialisation.(Scott, 2002) The hospital may be shared by a number of sectors, collectively a catchment, and used as required. Continuity of care is essential. An exchange of information is needed between different agencies, e.g. GP, general hospital, schools, social services, psychiatrists, psychologists, and community psychiatric nurses (CPNs³²⁵⁰). Privacy of patients must be preserved.(Backlar, 2001) What we write (or store in other ways) has become increasingly important because of freedom of information legislation.

Society requires education about mental health, mental illness, prevention, and services. It is wise to liaise effectively with local and national voluntary groups, e.g. those for schizophrenia, alcoholism, and religious organisations. Too often all that is offered is a 'psychosis only'³²⁵¹ service because of lack of resources and trained personnel in adequate numbers. It is a truism that, despite a widening demand for different services, that even the richest countries are unable to provide for all requests for assistance. A 2002 Irish survey (O'Keane *et al.*, 2004) found that psychiatric clinical resources were not concentrated where they were needed most; rather they were best developed in the wealthiest areas.

Services should ideally be subject to self-audit, research, modification when required, etc. Follow up policies should be crystal clear.

Definitions of resources vary widely. A day centre might provide social activities, company, a cooked meal, possibly a bath and chiropody, but none of the remedial services found in the day hospital. Industrial therapy could be added to this definition.

A day hospital is a building to which patients may come, or be brought, in the morning, where they may spend several hours in therapeutic activity and whence they return subsequently on the same day to their own home or to a hostel. In practice, day hospitals rarely perform as an alternative to acute services, and are more likely to provide rehabilitation for patients discharged from hospital or care and treatment for

³²⁴⁶ For comparison, from specialist register: anaesthesia, 320; clinical genetics, 2; geriatric medicine, 53; neurology, 28; neuropathology, 3; neurosurgery, 16; paediatrics, 182; plastic surgeons, 37; rehabilitation medicine, 9.

³²⁴⁷ Life expectancy in 2001 was 73 yrs for males and 78.5 yrs for females, the lowest in EU; average retirement age from labour force was 63.1 yrs, the highest in EU. Life expectancy in 2009 was 76.8 yrs for males and 81.6 yrs for females, above average in EU.

³²⁴⁸ See *New Ways of Working* in UK: www.newwaysofworking.org.uk.

³²⁴⁹ The best available public system until someone comes up with a better one.

³²⁵⁰ Known under a variety of names, e.g. community mental health nurse (CMHN) or 'psychiatric nurse in the community'.

³²⁵¹ Although psychotic patients **should** be prioritised.(Reed, 1991; Dillner, 1994) The fact that schizophrenic patients are at increased risk of dying alone is troubling.(Nilsson & Lögdberg B, 2008)

those cases not viewed as requiring admission. (Burns, 2001) According to Marshall, (2003) day hospitals have been eclipsed to some degree by a vogue for home care, but day hospitals save travelling time and may not carry the same staff safety problems inherent in home visits.

Some barriers to discharge from hospital (e.g. Ishikawa & Okamura, 2008)

Advanced age

Violence (suicide, homicide, and damage to property)

Severe symptoms

Unrealistic understanding of life outside an institution

Financial (inadequate funds or housing)

Wishes of families and community

Note: the MHC (2009a, c) expect that discharge planning start soon after admission³²⁵²

There will always be a small core of patients who need longstay care in hospital. Longstay beds in Irish psychiatric hospitals fell from 11,355 in 1984 to 5,368 in January 1994. Longstay patient accumulation in general hospital psychiatric units became a major problem from the early 1990s with calls for 'hospital hostels' to be built for decanting purposes. The rate of new longstay patient accumulation in 1992 in Ireland was 4 times the UK rate. It has become routine practice now to telephone around asking for the loan of an acute bed.

Stigma has already been discussed. Suffice it to say here that, despite the common belief that tolerance comes with age, it is more often older people who show less tolerance for the mentally ill.

There is increasing pressure from various groups (e.g. MIND) to give patients say in how the mental health services are run. In the USA, community mental health centres, which do not necessarily see the worst cases, have been required by law since 1975 to evaluate the patient's satisfaction with the services.

However, the methodology underlying such reports may be open to debate.

Some recommendations for those involved in community psychiatry (Rowland ea, 1989)

Comprehensive services (adequate range of resources: Trieman ea, 1999)

Continuity of care

Allow wide range of individuals to survive optimally in as normal a situation as possible

Government should have a definite policy and employ a minister (nowadays a 'Tsar') to carry it out

Establish minimum standards

Services from health and social agencies must be integrated

Emphasis must not be on 'discontinuities of location and the run down of hospital beds'

Health services must take continuing responsibility for what happens after discharge

Services for re-admission must be in place

High levels of care and supervision when necessary

Services must be individualised

Consumer, where realistic, should be involved in planning

Assessment and planning should be multi-disciplinary

Avoid creating jobs with conflict of interest (e.g. save money v create resources)

³²⁵² The MHC (2009c) has published guidelines concerning admission, transfer, and discharge to/from approved centres of both voluntary and involuntary patients. Some parts of this document are highlighted hereafter. Proper information exchange between service providers is important in ensuring care both during and after admission. Normally, the patient's consent should be sought. The care/treatment plan should include a risk assessment and a preliminary discharge plan that includes obstacles to discharge, such as homelessness. Approved centres should provide key workers. Admission consent forms conform with good administrative practice but do not obviate the requirement of consent for specific interventions. Entries in case files should be signed with full names, not just initials. Signature banks for everyone (including students) should be maintained and updated. Discharge plans (and summaries) should be comprehensive and include, e.g., follow-up plan and early warning signs of relapse. A comprehensive pre-discharge assessment is advised and those who should know (e.g. the GP) should know as soon as possible that a discharge has occurred. Patients should have somewhere to live before being discharged. They should know what to do if significant problems arise and early appointments should be given to those most at risk. Also, patients should have ample forewarning of discharge. The guidelines suggest that the inspection reports for nursing homes for the last 3 years should be examined before an elder is discharged to such a facility (presumably a role for the social worker). Guidelines (guidance)/codes of practice, whilst not legally binding, can be referred to by Courts or disciplinary hearings.

Do not lose the skills of former hospital staff and develop a skilled community workforce (Sims, 1991)
 Make sure that ex-patients have enough money and have the skills to spend it sensibly

Models: There are a number of models for a community psychiatric service of which only three will be mentioned.

Hive System (Peter Tyrer) - hospital is centre of activities

Facilities such as day hospitals and hostels - often containing very ill people (Marshall & Gath, 1992) - and clinics are essential components

Network System (Malcolm Peet) - starts in community and emphasises development of network of community resources involving people with helping skills, both professional and non-professional
 Hospitals are a resource but not a dominant one

Matrix Model (Thorncroft & Tansella, 1999) - *geographical* (at country/national, local/catchment, and patient levels – called, 1, 2, 3) and *temporal* (with input, process, and outcome phases – called A, B, C) dimensions

Use these two dimensions to create a 3x3 matrix with 9 cells made of three ‘ACEs’: firstly autonomy, continuity, and effectiveness (principles at national level); secondly accessibility, comprehensiveness, and equity (at local level); and thirdly accountability, co-ordination, and efficiency (at individual patient level)

Ian Falloon in Buckinghamshire hired the few beds that he claimed to need in an affluent community. Supervision registers in Britain must list patients who are at risk for violence, suicide or significant self-neglect. A key worker (usually a CPN) is assigned to every discharged patient. Care Programming infers adequate multidisciplinary assessment of patients and co-ordination of plans by the key worker/care coordinator. The *care programme approach* (CPA) was introduced in Britain³²⁵³ ‘to provide a framework for the care of mentally ill people outside hospital, requiring health and social care authorities to work together’. (Agnew, 2004) It rose over concerns following closure of large psychiatric hospitals. Such concerns included inaccessible, confusing or duplicated services, public safety, and the (overlapping) boundaries between health and social services.

Chief elements of CPA

Systematic assessment of health and social care needs

Agreed care plan

Assignment of named care co-ordinator

Regular reviews where needs are reconsidered and plans are altered as required

CPA has been accused of bringing with it much time-wasting bureaucracy. (Freeman, 1999) Interestingly, a positive association with a case manager in Manchester was associated with a relatively poor outcome (Tattan & Tarrier, 2000) and case-load reduction did not lead to a reduced need for inpatient care in psychosis in another study. (Burns et al., 2002: the age of the patient, prior length of inpatient stay, and recruitment from hospitals did correlate with outcome) As Kingdon and Amanullah (2005) point out, CPA should be monitored to ensure that it delivers what it was intended to deliver³²⁵⁴ rather than act as a ‘Trojan Horse’ to integrate ‘ill-thought through management initiatives and bureaucratisation’.

The centres of major cities, with their high levels of socioeconomic deprivation, represent severe challenges to any model. Rural services, on the other hand, have to contend with greater distances. The major preoccupations of most psychiatrists, often shared by their general medical colleagues, are bed occupancy and shortages³²⁵⁵. Back-up beds for patients who remain too ill or damaged to survive in the

³²⁵³ CPA was introduced in the UK in 1990 and was shown during the mid-1990s to reduce drop-out from care but to dramatically increase time in hospital, probably because admission decisions fell on junior staff more than on multidisciplinary committees. This led to great pressure on beds, particularly in London. (Tyrer & Milner, 2008, p. 165)

³²⁵⁴ Those who need the services most get them.

³²⁵⁵ A retrospective English study of voluntary and involuntary psychiatric admissions between 1996 and 2006 found more involuntary admissions into less public beds; a case mix shift towards psychosis and substance misuse (drastically changing ward milieu), and more involuntary admissions to private facilities. (Keown et al., 2008)

community are fast disappearing.(Dillner, 1994; O'Shea, 1998) Back-up beds are essential to the success of community psychiatry.(Williams ea, 1992) Also, community residential places (of all levels of supervision) have not always kept pace with demand.(Expert Group on Mental Health Policy, 2006, p. 97) It was decided to phase out mixed sex wards (as distinct from units) in Britain in 1997 for reasons of 'safety, privacy, and dignity'. Asylums of the early twentieth century often had separate buildings for both sexes, and the present author witnessed separate hospitals for both sexes in Western Europe during the 1980s.

There often exists an uneasy relationship between psychiatry and justice departments, each redefining the other's territory. Similar tension exists over definitions of who is the responsibility of which sector. Most of this unhappy state of affairs is born of resource considerations rather than from any inherent ill will or any verifiable scientific bank of facts. Illicit drug users present particular problems for security in treatment facilities, as they do in prisons.(Gunn ea, 1991)

GP practice-based psychiatry in Britain has developed unevenly and tends to cluster in those practices with a greater number of partners, training practices, and those running stress, bereavement, or other mental health clinics. While it may reduce clinic referrals there is no evidence that it reduces in-patient numbers. Research in Britain suggests that GPs often want the psychiatric services to continue to look after the psychiatric needs of patients in the longterm, which creates problems for discharge from bulging clinics.(Bamrah ea, 1991; Watters ea, 1994)

Comprehensive home-based care of the seriously mentally ill can be relatively satisfying for both patient and relatives (Wood & Carr, 1998; McLoughlin ea, 2005; Gibbons & Cocoman, 2006) but requires heavy staffing input and there have been occasional tragedies. Withdrawal of such care may lead to loss of gains in the patient and decreased morale in the care team. Catty ea, (2002) in their systematic review, point out that the evidence for home-based treatment of patients is inconclusive because of inadequate descriptions of experimental and control services, the brevity of some studies, and the fact that the nature of others did not allow one to generalise. Johnson ea (2005) have produced somewhat similar conclusions.

Burnout is more common in community-based psychiatrists, particularly within cities, than among those working solely within hospitals.(O'Shea, 1998) The same staff should look after patients whether they be inside or outside hospital. Neglect of this rule may lead to long crisis admissions.(Marks, 1998) Burnout may be quite common in mental health social workers.(Evans ea, 2006)

Recovery model: 'Medicine has come to mean to mend somebody mechanically, rather than to journey with them towards meaning, solace, and harmony'.(Yawar, 2008b) This idea is reminiscent of nineteenth century 'moral therapy'. Alcoholics are said to be 'in recovery' as distinct from 'cured'.(Jacobson & Greenley, 2001) The recovery movement stems from civil rights and disabilities movements³²⁵⁶ and stresses individual experiences (of self and the environment) of the person with a mental disorder, how he/she negotiates a passage through the illness, and the inclusion of attitudes, fears, hopes, and the unique social situation into a comprehensive treatment package. People are inspired by the personal narratives of others who survive significant difficulties. Recovery is never-ending, it is a journey that emphasises the recovery of meaning and value rather than elimination of problems *per se*.(Irish College of Psychiatrists, 2007; MHC, 2008a) The patient wants help to live as full a life as possible. A collaborative rather than prescriptive approach is expected from therapists.(Khan & Murray, 2008; Sugarman ea, 2010) Professionals may worry that adoption of the model may be inappropriate in the face of chronic disorders, amounting in effect to denial, or that it might be employed as an excuse to reduce services. Whilst some suggest that a firm evidence base is required in order to successfully use the model (Schrack & Slade, 2007; Holloway, 2008), there is every justification for tempered optimism applied in an individualised manner.(Roberts & Hollins, 2007) Also, the good doctor will relate to both person and disorder and employ techniques which have the best evidence base.(Mountain & Shah, 2008)

Recovery (MHC, 2005; Irish College of Psychiatrists, 2007)

Individual should not be forgotten in favour of a diagnosis

Treatment and self-management are developed in a collaborative way³²⁵⁷

Optimistic stance is taken

³²⁵⁶ In the US it was promoted by consumer advocacy organisations such as NAMI (National Association of the Mentally Ill).

³²⁵⁷ Psychiatrists may not be very practiced at involving patients in decisions.(Goss ea, 2008)

Support of peers and community resources are identified and used
 Human relationship is fostered between therapist and client
 Service users are involved in service planning³²⁵⁸
 Equality of access to mainstream housing/education/health/social services is ensured
 Wide range of values are addressed in research projects³²⁵⁹ as a balance to 'reductionist' research

Rehabilitation³²⁶⁰ (see also chapter 31)

³²⁵⁸ In a non-scientific (e.g. percentage response not stated) but useful postal questionnaire study carried out by the National Service Users Executive (NSUE, 2009 – info@nsue.ie and www.nsue.ie) 52%, 39% and 9% of respondents respectively were happy, unhappy, and 'maybe' (uncommitted or unsure?) with the mental help service being provided. Patients sometimes feel that they are humoured rather than involved in decisions about their care. The NSUE feel that users may need to represent their own wishes more forcefully or to be accompanied by someone who will advocate for them. Only 59% felt that they were treated with dignity, 34% having the opposite view. Listed 'priorities' for change was headed by 'less medication' but this may have been a self-fulfilling prophesy since it appeared first in a list of possibilities and could be ticked or not (i.e. the answer may have been 'forced'). Interestingly the 'large majority' of members do not have access to the internet, a point that service organisers/providers should keep in mind.

³²⁵⁹ Action research models, psychosocial research, qualitative studies.

³²⁶⁰ The following notes on **rehabilitation** are of a general nature and should be read in conjunction with chapter 31. Early attempts at rehabilitation, as in the York Retreat in England, were nullified by the overcrowding of asylums that followed and the negative institutional values that ensued. (Goffman, 1961) Discharges were much more frequent during the early years of the asylum era than was the case later on. The English charity *The Mental After Care Association (Working for Wellbeing since 2005)* was founded by the chaplain of Colney Hatch Asylum in 1879 to develop ways of supporting discharged patients. Industrial therapy developed after the Second World War. The move to deinstitutionalise the residents of stand-alone psychiatric hospitals has magnified the need to prepare patients, many of whom have no skills or have lost skills, to survive in the wider world with its multiplicity of challenges. In the past there was relatively little attention given to supporting and facilitating daily functioning and social interaction. Treatments often had little impact on daily living, socialization and work opportunities. Patients were marginalised in the same sense that convicts were ostracized. They were often abandoned by their families and were relatively unlikely to be married or cohabitating. There were strong barriers to social exclusion in the shape of stigma and prejudice. Psychiatric rehabilitation work emerged with the aim of helping the community integration and independence of individuals with mental health problems. Quality of life is often poor for people with severe and enduring psychiatric disorders. Their ability to lead meaningful lives is often significantly compromised. Psychiatric rehabilitation (Pratt ea, 2002) is the process of restoration of community functioning and wellbeing of an individual who has a mental disability. Rehabilitation work is undertaken by multi-disciplinary teams and should be evidence-based. Such teams may generalist or specialist or indeed subspecialist (e.g. forensic [Forensic rehabilitation services in particular are underdeveloped in Ireland.] or intellectual disability or head injury: Roberts ea, 2006). Psychiatric rehabilitation seeks to effect environmental change and/or to modify a patient's capacity to cope with the environment. Psychiatric rehabilitation may combine medication, independent living and social skills training (such skills training has not been particularly effective, partly due to poor generalisation: Bebbington ea, 2002), psychological support to patients and their families, housing, vocational rehabilitation, social support and network enhancement, and access to leisure activities. The team should focus on helping patients acquire skills and access necessary resources. Stigma and prejudice are confronted in order to allow social inclusion. The team works collaboratively with patients so that the latter is empowered. The process is person-directed and the plan individualized to the client's unique circumstances. The ultimate aim is full biopsychosocial recovery. Services may include help dealing with government agencies (e.g. benefits), liaising with probation officers and courts, accommodation, supported employment, education, assertive outreach, medication management, family therapy/psychoeducation, coping skills, activities of daily living (ADLs) and help with socialising. Hygiene, which is often poor, requires ongoing intervention. Other issues include sexual health, interpersonal boundary management, budgeting, and advocacy. Physical health is often poor (whether primary or secondary to treatment) and liaison with medical services, especially the GP, must not be neglected. Engagement in more active lifestyles (including sports) should be encouraged. Many clients have disorders that have been unresponsive or poorly responsive to treatment in the past and such interventions must be thoroughly reviewed with the aim of optimising medication (e.g. clozapine) or other (e.g. CBT, cognitive remediation) therapies. Patients may experience problems with understanding or dealing with interpersonal situations (e.g. misreading social cues and not knowing how to respond), prejudicial attitudes or bullying from those who view mental patients as 'different', problems coping with stress (e.g. travel, shopping, using the telephone, or seeking assistance), and poor attention and concentration. Avolition, anergia, and unusual behaviour (responding to hallucinations, mannerisms, and stereotypes) add to the list of energy and motivation. The 'recovery model' (O'Shea, 2009) has assumed central importance in contemporary psychiatric practice. Core components of the model include instilling hope, empowering clients, user-defined goals, a search for meaning, and a clear focus on quality of life. Permeating practice is a willingness to listen to the patient's life story and a reduced emphasis on the psychiatric anamnesis. Longstay patients may have become disillusioned by the low expectations of others, repeated failure, loss of friends and roles, loss of independence and prospects, lack of useful and fulfilling activities, and the passivity of intramural life. 'Recovery' aims to put illness in perspective: this is not a 'schizophrenic' but rather a fellow human who happens to suffer from schizophrenia.

Wing's (1993) social consequences of mental illness

Impairment – direct effect of being ill, e.g. avolition

Disability – problems carrying out ordinary chores

Social handicap – difficulties in performance of social roles and living as one would like to

Personal reaction to having an illness – responses to being ill of self and others

Much of what can be written generally about rehabilitation applies equally to other endeavours in psychiatry. People with mental health difficulties, who should have the same rights and entitlements as are enjoyed by the general population, are more likely to be unemployed, to lose their jobs, and to be in debt than are people with other disabilities. Following a thorough assessment of needs, rehabilitation aims to alter a wide range of personal attributes in order to improve quality of life within the limitations imposed by illness. (Killaspy *et al.*, 2005) Rehabilitation efforts in Ireland have tended to respond to downsizing or closure of large psychiatric stand-alone facilities with 'resettlement' of long stay patients into a variety of community facilities³²⁶¹ with minimal regard to rehabilitation needs. (Irish College of Psychiatrists, 2007) People with severe and enduring mental disorder who were already in the community were little better served. The emphasis was on care rather than self-actualisation (independent living, open employment, own home, education, etc). Whilst antipsychotic drugs improved symptoms much less progress was made in terms of personal, self-care, social, or occupational³²⁶² aspects of their lives. The Irish College of Psychiatrists (2007) adopted the recovery model in order to emphasise a *person-centred approach* (PCA).³²⁶³ Relatives should be included, informed, and supported. Specialised multidisciplinary teams devoted to rehabilitation are essential to effective evaluation and prosecution of rehabilitative efforts.

Stigma/discrimination – how other people view the mentally ill and how they act based on these views

Rehabilitation psychiatry focuses on function rather than symptoms and on assets rather than deficiencies. The patient's understanding of their illness should be elicited. Risk factors for disease (e.g. obesity or smoking), substance misuse, and health screening (blood pressure, serum cholesterol, QTc, cervical smears, mammography, etc) are addressed. A longterm view replaces the shorter vista entertained in acute settings. A continuous process of assessment is necessary. Any positive existing relationships need support and reasonable attempts should be considered to reignite potentially helpful family contacts.

Some useful assessment instruments

Camberwell Assessment of Need (CAN: Slade *et al.*, 1999)

Social Functioning Questionnaire (SFQ: Clifford & Morris, 1983)

Manchester Short Assessment of Quality of Life (MANSA: Priebe *et al.*, 1999)

What the patient can do acts as a starting point in planning activities. The team must acquaint itself with the accommodation history of their client and strive for an understanding of how things might have gone awry. Is the client literate and numerate and does he/she need assistance in handling money? Is basic education or training in novel skills (e.g. computers) required? Does the team need to put in place arrangements that ensure bills are paid in a timely fashion.

The best occupational outcome is the quick return to employment after an episode of illness. Those patients who have been ill or institutionalised over long periods require skilling, re-skilling, training in time-keeping and help with using transport. Volunteer and part-time work may pave the way for full-time work. Many agencies are involved in a tiered approach to training for work and the rehabilitation team should become involved with these organisations (including sitting on management meetings). Some user-led organisations (e.g. the *Clubhouse Model*) have offered supportive employment for people with severe and enduring mental illness. Traditional 'train and place' approaches may not be as effective as 'place and train' methods, i.e. get the job and support the patient in the workplace rather than spending years training for a job that may not even arise.

It is illegal in Ireland (*Employment Equality Act 1998* amended by the *Equality Act 2004*) to discriminate against an employee because of mental health problems.

Risk assessment (and a plan to deal with crises) is a part of rehabilitation just as it is a component of all psychiatric practice. For example, substance misuse or significant sexual vulnerability may influence placement. The 'relapse signature' (early manifestations of relapse) of individual patients should be known to those entrusted with caring or supervisory roles. What medication worked best in the past, how can this be optimised, are side-effects being reported or ignored, and does the patient need prompts to aid compliance? Lauriello and Keith (1997) stress the risk of carers simply being asked to take over from the staff of back-wards of institutions. This negative outcome must be avoided. Adequate support for carers may prevent burnout and disengagement.

A Vision for Change (Expert Group on Mental Health Policy, 2006) recommendations included those for 'recovery and rehabilitation' services for severe and enduring illness. There was to be one Community Mental Health Team/100,000 population. There were to be three community residences (10 places/100,000), 1-2 day centres (30 places)/300,000, and one service user-provided support centre/social club/100,000 population. Rehabilitation psychiatrists are not universal at the time of writing; even less common are full teams.

Rehabilitation psychiatry is a relatively new subspecialty (Irish College of Psychiatrists, 2007) and it behoves psychiatrists practicing in this area to fight their corner for the development and maintenance of services. Practitioners are obliged to audit their work, perform research into process and outcomes, to compare various interventions with one another, to monitor standards, and to be aware of international progress. (Tyrer, 2006)

³²⁶¹ Often they were simply transferred to other similar institutions.

³²⁶² Traditionally, Irish vocational rehabilitation has been divorced from mental health services and has often been too time-pressured for patients.

³²⁶³ PCA involves focusing on the hopes and aims of recovering patients and seeing these as vital aspects of our interventions. Goals defined by the patient define the starting point of the recovery process and should not be overshadowed by the goals of service providers. (Kartalova-O'Doherty & Tedstone Doherty, 2010, p. 46)

Flexible borders are required between general adult psychiatry and the rehabilitation team. The full range of in-patient and community-based residential facilities are required for an effective rehabilitation service. (Kavanagh *et al*, 2009) It is essential to forge links with employment and housing authorities and voluntary agencies. Funding for the training of professionals should be ring-fenced. Research is required for epidemiology, planning, ensuring service quality and development, pushing staff development, outcome assessment, and economic aspects of rehabilitation.

Innovative rehabilitation in poorer countries is illustrated by Chatterjee *et al* (2009) who reported a longitudinal study of patients (N = 256, mean follow up = 46 months) who had been ill for an average of eight years with various psychoses (schizophrenia, bipolar disorder, and others) in a rural Indian community. A community-based package was delivered and consisted of medication, psychoeducation, adherence management, psychosocial rehabilitation, and livelihood support. Over 80% engaged with the programme and there were significant reductions in disability. Good outcome was associated with lower baseline disability, family involvement with the programme, medication compliance, and membership in a self-help group. Poor outcome was associated with schizophrenia and not sticking with the programme. The *Camberwell Assessment of Need* (CAN: Slade *et al*, 1999) consists of a number of questionnaires that assess a wide range of problems³²⁶⁴ experienced by people with severe mental illness. It looks at the perceptions of the patient (service user), his/her carer, and his/her professional worker.

Economics: What is a cost effective strategy in one country and at a particular point in time may not translate to a cost effective strategy in another country or at a different point in time. (Burns, 1999) A 1991 estimate of the annual cost of mental disorder in Britain came to £5 bn, less than a third of which was for direct services. Many homeless psychiatric patients do not apply for benefits. About €1.6 bn per year is spent on disability benefits in Ireland: €640 million (40%) goes on claims for mental illness with the next highest category, musculoskeletal injuries, accounting for 27%. (Baxter, 2004) The relative cost of community versus hospital care has attracted a large but impotent literature. (see Scull, 1977) The provision of hostel and other accommodation rarely seems adequate for the number and variety of those that might benefit from them. Day centres often have to stagger attendances to cope. Homelessness is a major problem among former inmates of psychiatric hospitals, be they patients who stayed for long periods of time in hospital or who are frequently in and out of hospital. Los Angeles has been dubbed America's 'homeless capital'. Rents for private accommodation has tended to spiral beyond the reach of those discharged from hospital. (O'Shea, 1998) There is much bad will between those who want these people treated in hospital under compulsory order and those who see this as a breach of human rights, and this division may be reflected among patients themselves. (Crawford *et al*, 2004)

Methods of evaluating cost of psychiatric services

Macroanalytic – total system

Microanalytic – part of system, divisible into:

Cost-effectiveness – compare 2 therapies of equal cost for effectiveness

Cost-offset – cost of therapy minus cost saved

Cost-minimisation – compare costs of 2 interventions of equal outcome

Cost-benefit – measuring monetary value of more one outcome

Cost-utility – measuring quality-adjusted life years³²⁶⁵ instead of money

Absconding: Tomison (1989) defined the characteristics of patients who left a psychiatric hospital without announcing, the fact (patients leaving against medical advice or failing to return off leave were not included) as being male, young, involuntary, a discharge diagnosis of schizophrenia, single, many past admissions, longer total length of stay, and police involvement in the admission. Walsh *et al* (1998) defined absconders as single, involuntary, schizophrenic or personality disordered.

Non-attendance: Why do patients not keep appointments? Factors predictive of this phenomenon are summarised in the table (Mitchell & Selmes, 2007).

³²⁶⁴ It looks at 22 different life areas. There are 3 versions of the CAN: CAN-C or clinical, CAN-R for research, and CANSAS which is a short version.

³²⁶⁵ QUALYS – length + quality of life.

Failure to keep appointments

Youth, poor, non-adherence, uninsured, no address, lack of transport
 Forgot, mistake, ill, lower social desirability, non-secure attachment style
 Demented

Personality disorder, drug abuse, neuroses, unclear diagnosis, lack of insight
 Communication problem between GP and patient, doesn't want to see a psychiatrist or sceptical about psychiatry, poor quality referral letter, long delay before appointment, early treatment stage, poor therapeutic alliance, does not feel involved in making decisions

Carers (Lefley, 2001): Relatives may score higher on scales of anxiety, depression, etc. (Livingston, 1987) than the patients themselves. The reasons for forming relatives' (self-help) groups include information, support, pressure groups for improved facilities (including respite care), therapy for the patients to be given by relatives, therapy for the relative (e.g. stress management), and fund raising for research and resources. Relief admission refers to admission to relief carers during a crisis, whereas respite admission refers to regular, pre-planned breaks from caring. Patient self-advocacy groups are a relatively new phenomenon. The (Irish) Mental Health Act 2001 provides for patients/consumers sitting on the Mental Health Act Commission.

Community treatment orders³²⁶⁶ (CTOs): Bursten (1986) discussed the creation of CTOs whereby treatment at an outpatient department (or back in hospital) after discharge from hospital becomes mandatory. The evidence that CTOs reduce admissions or days in hospital is very limited³²⁶⁷ (Kisely, 2009; Kisely et al., 2007; Kisely & Campbell, 2007; Jethwa & Galappathie, 2008; Hall & Ali, 2009) and Ireland would be wise to wait and see how CTOs perform in Britain before introducing them here. (Walsh, 2010) Tennessee instituted such a policy by statute in 1981 with a subsequent fall in re-admission rates. However, comparison with control groups failed to support the conclusion that these results are due to constraints on outpatients. CTOs are today legally authorised in many American jurisdictions as well as in Australia³²⁶⁸ and New Zealand, (McCall Smith, 2000; Preston et al., 2002; Dawson, 2009) and in England and Wales under the 2007 Act³²⁶⁹. The English *Mental Health (Patients in the Community) Act 1995* allowed the right to remove a patient to a place of treatment wherein the patient could not be given treatment unless he/she so wished! (O'Shea, 1998) Because of this, it was little used in practice. (Taylor & Estroff, 2003, p. 607) Numbers of CTOs under the English *Mental Health Act 2007* exceeded expectations but the infrastructure needed to support compulsory extramural treatment may be less than adequate. (Skuse, 2009) The question of the validity of 'informed consent' from patently disturbed clients is subject to continued debate. Unfortunately, the media is inclined to give rare murders committed by discharged patients (or those lost to

³²⁶⁶ See Dyer (2007) for discussion of the heat surrounding CTOs in the British Parliament and Lawton-Smith et al. (2008) for debate.

³²⁶⁷ The question of the optimal length of hospital stay for patients with psychosis is often driven by economics rather than by clinical considerations. (Capdevielle & Ritchie, 2008) Catts and McGorry (2007, p. 353) are very clear that, at least in Australia, patients on CTOs spend less time in hospital and have less severe symptoms and disability. They also suggest that effective CTOs are those lasting at least 6 months. According to Kisely (2009) of Australia, in terms of numbers needed to treat (NTT) it takes 85 CTOs to prevent one readmission, 27 to prevent an episode of hopelessness, and 238 to prevent an arrest!

³²⁶⁸ Prof Terry Carney of Sydney (2009), a professor of law, stated that Australia uses five times more CTOs per head of population than is used in the US and that these patients are not provided with a second opinion and 'there is no inspectorate'.

³²⁶⁹ *Mental Health Act for England and Wales 2007*, in force from November 2008. This applies only to patients detained in hospital for treatment. If treatment is to be given forcibly the patient must receive such treatment in hospital. Only the Responsible Clinician (RC) (i.e. the Approved Clinician [AC] in charge of that CTO patient) can recall a CTO patient. Recall must be in writing and handed directly to the patient, put through their letter box or posted (first class) to their last known address. Recall does not have to be to the same hospital, or group of hospitals, as manage the CTO. There must be cover arrangements for when the RC is not available. Once a RC has recalled a patient, the patient is AWOL - immediately if the recall note is handed to the patient, at 00.01 the next day if put through the letter box and the next but one working day if posted - and must return to hospital. If anyone interferes with this, s. 128(3) MHA 1983 may come into play: 'Where any person knowingly harbours a patient who is absent without leave or is otherwise at large and liable to be retaken under this Act or gives him any assistance with intent to prevent, hinder or interfere with his being taken into custody or returned to the hospital or other place where he ought to be he shall be guilty of an offence. The penalty is up to two years in prison and/or an unlimited fine.' Once recalled the patient should be assessed and, if appropriate and authorised, treated. This can be undertaken by the RC or by others on his or her behalf. Whether this is the same RC or another one, and, if another one, whether it is an AC from the ward, CRHT or somewhere else is for the protocol to decide. The RC may revoke the CTO such that the patient is again detained (under their previous section unless the patient was transferred to a CTO directly from supervised discharge under the transitional arrangements). This may lead to yet another RC being allocated.

follow up) enormous coverage. Whilst stranger homicides increased in England and Wales between 1967 and 1997, this was not attributable to homicides by mentally ill people. Although there are infamous exceptions, stranger homicides are more likely to be related to alcohol and drug abuse by young males.(Shaw ea, 2004)

Kisely (2009) suggests that a superior approach to orders made in the community is to place a patient on an intervention on leaving hospital, although he admits that research is needed into the long-term effects of such approaches.

Supervision orders have been described (Holloway, 1994) as a bureaucratic solution to inadequate resources and (McCreadie, 2000) as a rod with which to beat psychiatrists should things go wrong. The names of particular patients requiring supervision (violent, suicidal, or self-neglecting) are placed on a special register and close follow up is mandated. Inclusion criteria tend to be vague and such registers present litigation dilemmas for workers – who to include, who to exclude? Despite exhortations, there is little evidence that supervision registers are effective in practice.(Hindler, 1999; Kisely & Campbell, 2007) Neither is there evidence that community care leads to an increase in homicides.(Taylor & Gunn, 1999; Leff, 2001; Simpson ea, 2004) Rose(2001) talks of ‘scare in the community’ (a play on ‘care in the community’)!

Prisons: Concern has been raised over the number of psychiatrically ill and intellectually disabled people in prison. For example, 2% of male and female English prisoners were reported to be psychotic.(Maden ea, 1994)

Seclusion: A small number of patients require therapeutic seclusion.(Gutheil & Shader, 2003) The Irish MHC (2006, 2009e) rules governing seclusion state that it should only be used in the best interests of the patient (not to ameliorate staff shortages) and only if the patient represents an immediate danger to self/others (that cannot be contained by other means). Seclusion must only be initiated by a registered nurse or doctor.(MHC, 2009a) The patient must be told what circumstances will dictate an end to seclusion and he/she must be informed of the termination of a period of seclusion and given the opportunity to discuss the episode with members of the multidisciplinary team. If a patient with capacity refuses to allow staff to inform relatives of the occurrence of seclusion this must be honoured (and documented) unless there are overriding legal or professional considerations. If a patient is subject to 7 or more seclusion orders over 7 consecutive days the Inspector of Mental Health Services must be told of this in writing with reasons given for the practice and details of alternative therapeutic options that were considered. Each approved centre’s policy must state what attempts are to be made to minimise use of seclusion.

If CCTV or other monitoring device is used to monitor patients in seclusion then only designated personnel should be able to view what is shown; it should not be capable of recording or transmitting images (other than the monitoring station); it should not be used if the patient starts to act in a manner which compromises dignity; and it does not replace more direct monitoring of the patient.

Mechanical restraint: Once popular in these islands³²⁷⁰, physical restraint, except in the immediate acute situation whilst something else is being done (talking down, medicating or secluding), is no longer popular. It has been used rather more freely in America. In this author’s view, there is still a need for gentle restraint (‘soft supports’, Posey restraints³²⁷¹) in confused, demented elderly patients who might otherwise need extra medication or suffer fall or other injuries. It also stops injury to others. Common sense, knowledge of local laws and protocols, supervision by senior personnel and inspectorates, and a humanitarian outlook should avoid abuses. The Irish Mental Health Commission (MHC, 2006, 2009d) rules governing mechanical restraint state that it should only be used in the best interests of the patient (not to ameliorate staff shortages) and only if the patient represents an immediate danger to self/others (that cannot be contained by other means).

³²⁷⁰ E.g. during the 1840s, Samuel Hadwin of Lincoln Lunatic Asylum viewed restraint as the very basis of good treatment.

³²⁷¹ Posey Criss-Cross Vests have a circumscribed place in the care of the elderly where a fall could lead to injury. Their use should be strictly supervised and documented and subject to regular review. The ‘V’ neck should face forward. A flat hand should fit between the device and the patient to ensure that it does not interfere with breathing. Pelvic pieces may be required to reduce sliding down. Straps must be secured out of the patient’s reach.

Cot sides are used to prevent patients falling from their beds. Injuries may result from hitting the head of the sides, climbing over the sides, unlatching the device, or catching the head or neck between the bars. Gaps should not occur between the mattress and the cot side (entrapment hazard), and the mattress (e.g. ripple) should not be high enough to compromise the safety of the cot sides. A risk-benefit assessment should be performed before use and periodically thereafter³²⁷². Use of cot sides and bed rails to prevent injury to the patient does not constitute mechanical restraint within the MHC (2009a) updated rules.

Disaster and military psychiatry

A disaster is severe ecological/psychosocial disruption that overwhelms the coping powers of a population.(WHO, 1992) Modern attempts to understand the psychiatry of disasters date to 1942 and Erich Lindemann's³²⁷³ study of the Coconut Grove fire survivors in Boston. In war zones, debriefing was employed in order to return soldiers to frontline service.

Combat effects may be persistent (Prigerson et al, 2002), e.g. PTSD, depression, occupational difficulties/unemployment, abuse of loved ones/divorce/separation, and substance abuse. Health worries that fail to reach syndromal level are common following combat and other catastrophic events. For example, people may worry excessively about exposure to toxic chemicals. People exposed to warfare or catastrophes may develop psychiatric problems for many reasons: prior coping and functional capacities, previous exposure, sex (e.g. females are more prone to PTSD whilst males are more likely to abuse drugs or act out), leadership offered, unit cohesion and support of buddies, severity and duration of exposure, injury/sexual assault, witnessing death/mutilation/massacres/atrocities, and brain-related factors (CRF, ACTH, catecholamines, and activation of amygdala³²⁷⁴).

The soldier who is subjected to combat-related psychic trauma is helped if he feels safe and properly cared for after removal from the frontline and if he knows that the folks back home care about him. Onerous rotations to frontline service may be damaging. Re-traumatising should be avoided where possible. Society can help to minimise traumatisation by recognising the sacrifices of its soldiers and by not confusing their political beliefs and the efforts of its combatants³²⁷⁵.

Recent large scale catastrophes have included famines, bombings, school campus mass shootings, civil wars, aviation and other-travel related events, flooding, and earthquakes.

Disasters

Natural – hurricanes, conflagrations, flooding, high winds, icebergs, heat waves, etc

Manmade – (a) accidental (e.g. nuclear plant leakage, locomotive derailment)

(b) intentional (e.g. strategic bombing, terrorist attacks)

Planning for disasters must prioritise the meeting of basic needs (e.g. transport, water, food, clothing, shelter, communication with loved ones, acute medical and surgical interventions, monitoring for ongoing threat, provision of accurate information, etc). Communications and delegation aspects require considerable forethought. Services should be so designed as to be capable of expansion as needed. Collaboration and familiarisation with other agencies are prerequisites.(Grant et al, 2008) It should be assumed that existing services may break down. Medico-surgical preparation for such events must include psychiatrists because of (a) the psychological effects of disaster and (b) the experiences of psychiatrists in dealing with strong emotions in victims and tolerating strong personal affect. Psychiatrists should have input into organising appropriate responses to catastrophe. They should employ a wide range of interventions - psychotherapeutic, pharmacological, and group work. Psychiatrists should be prepared to enter affected areas (outreach). Interventions will encompass immediate and longer term involvement of mental health professionals. Friends and relations, witnesses, helpers (including professionals), and direct victims may be traumatised.(Fullerton et al, 2003) Debriefing has not been convincingly demonstrated to prevent PTSD and

³²⁷² The reality is that research data on risk assessment and fall prevention does not necessarily support the efficacy of well intentioned measures.(Cumming et al, 2008)

³²⁷³ Lindemann (1900-1974) was born in Germany and immigrated to the US in 1927. He worked in Boston with Stanley Cobb and Walter Cannon. The Coconut Grove had 1,000 occupants instead of the official limit of 460. The fire, which killed 492 people, seems to have been caused by a flammable methyl chloride leak from a faulty refrigerator. The best known victim was Charles 'Buck' Jones (1891-1942: born Charles Gebhart) a cowboy film star.

³²⁷⁴ Encoding of memories with strong affective loading and instigation of conditioned responses.

³²⁷⁵ E.g. the derision experienced by US soldiers on return from Vietnam.

it may in fact be harmful.(Lilienfeld, 2007) After Action Reports may sustain combatants in the warrior mode and further group identification. They are also an opportunity to identify those who need psychiatric help. CBT and other psychotherapeutic (including group) approaches may be beneficial. Psychiatric patients may miss or stop medication. Some people may experience abstinence syndromes. In such chaotic situations it should be recalled that most people cope³²⁷⁶ with supportive measures (listening, advice, information, normalising experiences, etc) and that what differentiates the normal from the abnormal is the level of incapacity caused as well as the degree of interference with functioning, relating, and employment of coping powers. Services offered should be culture-friendly and the practitioner should not ignore traditional approaches to diversity, e.g. ritual and local healers. Medical services may be over-stretched during warfare or other calamities and trained non-medical personnel may need to be called on.

Conclusions

Community-based services, just like intramural services, vary enormously in quality³²⁷⁷ and resources. Even politicians have occasionally expressed fears that ‘the pendulum has swung too far’ on occasion.(Groves, 1993) There was concern over a British White Paper proposing a broadened definition of mental disorder and the extension of compulsion into the community.(Grounds, 2001 – a Bill before the Westminster Parliament advocating compulsory treatment outside hospital) Priebe and Turner (2003) suggested that there may be a ‘largely unnoticed process’ of re-institutionalisation afoot in the form of an increase in forensic bed numbers in the UK (including in the private sector), increased numbers of compulsory admissions in Europe (inter-country variation is large), a large increase in supportive housing of varying levels of dependence, assertive outreach teams throughout Europe, and early intervention³²⁷⁸ teams. Under the Irish *Housing (Miscellaneous Provisions) Act 2002* local authorities must provide housing to people in their area who require it.

The best asylums provided a wide range of services for the chronic mental patient that are difficult to reproduce extramurally.(Murphy, 1991) The move from vast asylums (Coxe, 1872; Thornicroft, 1992) into the community has brought many challenges with it such as a vastly increased and increasing demand for psychiatric problems from a much wider array of clients than heretofore.(Charlton, 1991; IMJ Editor, 1998; Freeman, 1999; Rose, 2001) Research is constantly reminding us of a vast untouched psychopathology ‘out there’.(Anonymous, 1993) Increasing responsibility (for their own and for others’ work) has been twinned, unfairly, by suspicion of psychiatrists’ motives as mirrored in terms like transparency, accountability and litigation.(Coid, 1994; Turner ea, 1999; Rose, 2001; Tyrer ea, 2001)

St John-Smith ea (2009) stated that novel centralised approaches to public services administration in England diminished the central role of clinicians and the latter have been superseded by audits, targets, and a single remedy for everyone (‘New Ways of Working’). People who know little about psychiatry make the decisions and ‘generic mental health workers’ are tasked with work that they are not qualified to undertake. Instead of a diagnosis, tailored treatment and a therapeutic relationship we now have risk- and needs-assessments, ‘generic psychosocial support’, and isolated groups providing impersonal ‘person-centred services’! Of course, as in other countries, politicians can still send their ill loved ones to the private sector to be seen by a doctor.

A patient sought High Court leave to challenge his committal after such leave had been refused under Section 260 of the 1945 Mental Treatment Act in 2004. The court finding was that Section 260 (granted leave only if the doctor could be shown to have acted in bad faith or without reasonable care) was unconstitutional having regard to Articles 6 and 34 of the Irish Constitution. In Britain the number of unfilled psychiatric posts was a worry,(Storer, 2002; Brockington & Mumford, 2002) as are the posts filled in a temporary capacity in Ireland. Here, as in our neighbouring country, foreign ‘drives’ were undertaken to procure junior doctors and nurses, both of which are in short supply.(Dunne, 1991) Predicting staffing requirements is not a very accurate science. In America there has long been a flight from public psychiatry into the better-paid private sector.

³²⁷⁶ **Resilience** is the capacity to adapt and function despite adversity.

³²⁷⁷ The quality of a service can be viewed in terms of 6 dimensions: safety (no unavoidable morbidity/mortality), equity (equal service for all), effectiveness (no unnecessary suffering), efficiency (no waste), patient centred (clients do not feel helpless), and timeliness (no unavoidable delays).(Bell ea, 2006)

³²⁷⁸ English early intervention teams are often underdeveloped/funded.(Pinfold ea, 2007)

10 guiding rules for re-designing health care in USA (Pincus ea, 2007)

24-hour responsive providing care through a variety of media and in many forms

Meet needs, choices, and preferences

Encourage shared and informed decision-making with patient

Share records and knowledge with patient

Evidence-based approach

Patient safety³²⁷⁹

Transparency

Anticipate need rather than react to events

Use resources in a non-wasteful manner

Co-operate with other clinicians for patient's good

One reason for the use of high doses of neuroleptics may be an attempt to control cases quickly with a view to quicker discharge from a dwindling bed pool.(Dunne, 1991) Tyrer ea (1998) have warned that the development of community psychiatry is useless if one has to look for beds outside the catchment area and that such practice causes disintegration of service delivery. Keogh ea (1999) suggested that there would be no bed problem if there were somewhere to transfer non-acute patients. There is no evidence to suggest that the CPN is any better than the GP at managing non-psychotic disorders and there is much to recommend that the CPN stick to looking after psychotic patients.

Planning using national norms may be inappropriate to local needs. Services need to be designed with the local environment in mind,(Bebbington ea, 2002) e.g. assertive treatment may be more appropriate for areas where services are underdeveloped but less useful in the midst of well-established services.(Tyrer & Milner, 2008, p. 162)

Staff turnover and burnout has correlated with intensity of community work.(e.g. Webb, 1993; Tyrer ea, 2001) High staff to patient ratios (as in the British PRiSM Psychosis Study) and medium-term high-intensity 24-hour input (e.g. in Australia) can produce excellent results in the community that are almost impossible to replicate under cash straitened circumstances.(see Killaspy, 2007) The opposite has also been found, when standard services reduced disability where intensive service failed to do so!(Wykes ea, 1998) Burns (2009) suggests that methodological issues (using treatment as usual instead of head-to-head comparisons) obscure research results in this area and he believes that community mental health teams are a more cost-effective and evidence-based approach than assertive outreach. It is far from clear that intense community-focused care reduces cost or improves clinical status.(Harrison-Read ea, 2002; Tyrer & Milner, 2008, p. 163) Also, standard care may appear inefficient only because of under resourcing.(Bebbington ea, 2002) Priebe ea (2004) looked at assertive outreach and found that weekend working, staff burnout and lack of contact of the patient with other services were independently related to the likelihood of admission, voluntary or involuntary! Craig ea (2004) found a non-significant effect on relapse of assertive outreach over standard care, with only reductions in total number of re-admissions and dropout rates being attributable to the former approach. No firm conclusions could be drawn from this research because of the 'modest sample size'. Johnson ea (2005) used a 24-hour crisis resolution team to augment existing acute services and found that hospital admission was rendered less likely over the ensuing eight weeks; however, compulsory admission rates were not significantly altered. Assertive outreach teams in North East England appear to be reaching the most severe cases (Schneider ea, 2006) but community mental health teams in North London are as effective with such cases as are assertive outreach teams, although the latter may be better at engaging clients and may be better appreciated.(Killaspy, 2006; Killaspy ea, 2009; see Glover ea, 2006) Also, Glover ea (2006) did not find that assertive outreach reduced overall admissions. Whilst Dibben ea (2008) found that a crisis resolution and home treatment team reduced hospital admissions for elderly people but there was no important change in length of stay once in hospital and carers may have been happier with the service than were patients. A Welsh study (Tyrer ea, 2010) found that crisis resolution and home treatment teams reduced voluntary admissions at first but that involuntary admissions increased later on. Bertelsen ea (2008), in Denmark, found that whereas the positive effects of assertive community treatment versus standard care for first episode psychosis waned between two and five years

³²⁷⁹ Most inpatient units in the USA are locked because third-party payers will only release money if the unit reaches standards for the most at-risk cases.(Beck, 2008, p. 923)

(the assertive approach lasted for the initial 2 years) there may still have been a reduction in hospital bed usage. McCrone *et al.* (2009) reported that a South London crisis resolution team saved money when compared to existing services.

Defining features of assertive community treatment³²⁸⁰ (ACT: Mueser *et al.*, 1998)

- 24/7 coverage
- Direct delivery by a 'multi-disciplinary' team (usually a psychiatrist, a nurse, and at least two case managers)
- Low staff to client ratio of 1:10
- Provision of services at home or at least not in the office
- Caseloads shared across clinicians rather than individual caseloads

Integrated (ACT, programmes for family involvement, and social skills training) treatment was better over two years in reducing psychotic and negative symptoms, substance misuse, non-adherence, and dissatisfaction with treatment than was standard (offer of contact with community mental health centre) in patients with a first episode of schizophrenia spectrum disorder in Denmark. (Petersen *et al.*, 2005) Intensive case-management is best at decreasing hospital use by patients who already use hospitals a lot! (Burns *et al.*, 2007)

In the late 1990s there was talk in Britain of building small hospitals 'in the community' to replace asylums (In Italy, 'residential facilities', catering for very ill people who are rarely moved to independent accommodation, have replaced mental hospitals: De Girolamo *et al.*, 2005). There was also talk of locking up all 'personality disorders'. Hospitals are still collecting 'new long stay' patients such as the young, single male schizophrenic with a history of violence or the middle-aged female with affective disorder or dementia³²⁸¹. New long stay patients, defined as those cases needing longterm inpatient care and refractory to extensive rehabilitative efforts, were accumulating at a rate of 0.4/100,000/years in England circa 1991. Cognitively damaged patients are particularly difficult to rehabilitate and require high levels of support. In fact, cognitively impaired schizophrenics may deteriorate extramurally. (Wykes, 1994)

There is also a residuum of ageing patients, mostly with organic disorders, who are difficult to place in the community. This was made clear from the TAPS (team for the assessment of psychiatric services – the results of which studies have been generally positive for community living) project in Britain. The cases that were decanted first from institutions tended to do relatively well if their discharge was planned, but the remnant population was much more damaged, i.e. the best cases were picked first. That is why it may be unfair to compare the leavers and the left! The population is getting older and this brings with it increasing levels of chronic morbidity and demands for total care. The mushrooming of nursing homes is paralleled by the increasing use of psychotropic drugs to contain behaviour because of the lack of other feasible alternatives. Psychiatrists are increasingly being asked to do something about elderly patients whose 'depression' or 'paranoia' or disinhibited behaviour is only one aspect of a multiplicity of organic disorders.

Percentage of Irish public health budget spent on psychiatry (e.g. Anonymous, 2004)

Fell by 27.4% between 1971 and 1993 (13.5 to 9.8)

Fell from 8.96% to 7.34% between 1997 and 2004

The MHC (2003):

7% of national health budget went to mental health services

20-30% of health disability is caused by mental ill-health

³²⁸⁰ ACT began in the early 1970s in Dane County (Madison is the county seat), Wisconsin, when Len Stein and Mary Test decided to treat people with serious mental illness in the community. It should be recalled that resources were scarce because monies had been diverted into President Kennedy's community mental health centres which catered for the less seriously ill. (Tyrer & Milner, 2008, p. 159) Whilst progress has been made with crisis resolution/home treatment (CRHT) teams in England only 40% of 243 teams were fully established in a survey covering 2005-6. (Onyett *et al.*, 2008)

³²⁸¹ General hospitals will need to increase their resources in order to cope with the rising prevalence of dementia. (Sampson *et al.*, 2009)

Special care must be taken, and seen to be taken, to make sure that the bulk of mental health funding goes to direct, frontline services. (Thornicroft & Strathdee, 1991; Zinn, 1993) There is great variation in funding in different parts of Ireland (Sheppard & Browne, 2005) and monies awarded should take account of factors such as socio-economic deprivation. Per capita funding in 2005 in the Republic of Ireland ranged from highs of 495.47 for St Brendan's Hospital in Dublin and 323.47 for East Galway through 85 for Wicklow to lows of South Lee in Cork of 53.74 and Kildare of 37.97. Rather than simply taking from better-funded areas, the lesser-funded areas require greater funding.

Survey of Irish psychiatric services (O'Keane *et al.*, 2003)

(1 consultant/each of 32 catchment areas completed questionnaire)

Over-stretched and developed on *ad hoc* basis

Best developed in most affluent areas (negatively correlated with an index of relative deprivation, i.e. medical cardholders)

Limited availability of (sub-) speciality services (e.g. 82% of areas had child psychiatry, 12% had eating disorder services, and 6% had neuropsychiatry)

Quality Framework (MHC, 2007)

Provide holistic, seamless service with full continuum of care provided by multidisciplinary team

Respect and empathy³²⁸²

Empowerment³²⁸³

Good physical environment

Access to services from the community

Families, parents and carers act as part of the team

High quality staff

Systematic evaluation/review of services using best practice

The Lie of the Land (Barry *et al.*, 2008)

Hard-hitting analysis of situation in January 2008: 'asset stripping process'

Attempts to cherry pick parts of Experts' Report for implementation

Asylum lands being given away/sold with no/little financial benefit for psychiatry

Many dilapidated asylum buildings still in use – half of services supplied from such

Some general hospital units outmoded/unsafe

Long-stay patients in dilapidated/deeply impoverished/stigmatising environments

Dwindling relative funding

Fair Deal for Mental Health (RCPsych, 2008)

Funding should meet needs and research

Access to services, especially for most overlooked groups, e.g. adolescence-adult watershed

In-patient services to be improved and locally accessible

Recovery (model) and rehabilitation – especially for chronic illness

Discrimination and stigma – to be tackle everywhere

Engagement with service users and carers – not just at token level

Availability of psychological therapies for all who need them

Linking mental and physical health in practice

The MHC (Finnerty, 2008; MHC, 2008b, 2009b) has expressed concern that staffing of mental health teams has been tardy. The MHC (2009b)³²⁸⁴ reported cuts in already limited community resources and a lack of progress implementing *A Vision for Change*, the need for greater monetary investment by the State (e.g. monies derived from selling of buildings to be spent on community services), a lack of multidisciplinary teams, a need to change clinical work practices (move from institution to community and out-of-hours service provision), best management of resources, and the need to set up a specific Directorate with the HSE to oversee mental health services. The College of Psychiatry of Ireland (Barry & Murphy,

³²⁸² Poor outcomes are associated with patients' perceptions of being ignored or disrespected. (Gordon & Beresin, 2008, p. 3)

³²⁸³ 'Not allowing people to use the abilities that they do have is disempowering in the extreme'. (Brooker, 2008, p. 239)

³²⁸⁴ Within the same report the Inspector of Mental Health Services pointed out that many children are still being admitted to adult settings.

2009) has been critical of the lack of implementation of the recommendations of *A Vision for Change*, e.g. low levels of recruitment of multidisciplinary team members.

Even the best-resourced nations do not reach everyone with a mental illness. Whereas 74% of mentally ill Europeans receive no treatment, the comparable figure for diabetes is only 8%. (Thornicroft, 2007) In fact, unmet need is pervasive and particularly bad in poorer countries. (Wang et al., 2007) Simply providing resources will not ensure that the clinical, as distinct from social, needs of community-based patients are met. (Keogh et al., 2003) Individualised treatment is still essential.

24

Psychotherapy³²⁸⁵

Brian O'Shea

'Now it is true that what doctors accept into a treatment trial is invariably more exclusive than that which they accept for treatment on a daily basis'. (Clare, 1993)

'...the availability of specialist psychological treatments is not what it should be'. (Nutt *et al.*, 2002)

'The unconscious conflicts of the analysts are now described as hippocampally-based implicit memories and contextual fears by neuroscientists'. (Gorman, 2004)

'One in six people in the UK suffer from depression or anxiety, yet psychological services are almost non-existent'. (Wilkinson, 2007)

'If feelings can be objectified, their power to distress or overwhelm is mitigated'. (Holmes, 2008)

Psychotherapy, in the sense that it is used here, occurs when a person becomes involved in structured interaction with a trained, ethical, licensed individual who endeavours to influence the former's mental state in order to reduce suffering and/or to improve that person's options in terms of psychological function, interpersonal activity, and behavioural repertoire. The aim of all psychotherapy (Ursano *et al.*, 2008, p. 1173) is to help a patient expand his/her range of behaviours and thereby ameliorate symptoms and change patterns that have caused morbidity and that potentially shorten life. Every treatment approach has its devotees and it is important to keep this in mind when evaluating evidence, e.g. Turner (2010, p. 15) was spurred to remark that 'CBY has become almost a panacea'. Historically other treatment approaches have occupied this lofty position, such as psychoanalysis in post-1945 USA.

Psychotherapy can change brain structure and function. The mind and brain are interdependent and neuroimaging shows brain changes after either psychotherapy or physical treatments. However, there may be differences in the direction of change on PET scanning in patients receiving either cognitive behaviour therapy (increased activity in hippocampus and dorsal cingulate gyrus and decreases in cortical activity) or paroxetine (decreased activity in hippocampus and dorsal cingulate gyrus and increases in prefrontal cortical activity) for depression. (Goldapple *et al.*, 2004) Major depressives who responded to cognitive-behaviour therapy (CBT) or venlafaxine showed reduced metabolism in several prefrontal regions on 18F-fluorodeoxyglucose PET scans, although there were additional differences attributable to either modality. (Kennedy *et al.*, 2007) Hippocampal volume was not affected by effective psychotherapy in outpatients with PTSD in a Dutch study. (Lindauer *et al.*, 2005) Functional imaging in patients with social anxiety disorder (Furmark *et al.*, 2002) showed overlap in functional brain changes (blood flow) in patients improving due to CBT or citalopram. Behaviour therapy for anxiety disorders leads to attenuation of abnormalities on brain images in expected areas and activation of regions connected to positive interpretation of stimuli that otherwise lead to anxiety. (Roffman *et al.*, 2005) PET scans with 18F-fluorodeoxyglucose in OCD patients revealed that responders to both medication or behaviour therapy had reduced activity in the right caudate head compared with non-responders. (Baxter *et al.*, 1992) Successful cognitive remediation in schizophrenia may increase activation in fronto-cortical areas on fMRI (Wykes *et al.*, 2002) and *Aplysia*, a simple mollusc, shows neuronal chemical changes when it learns avoidant behaviour and such changes reverse following repeated exposure to the avoided stimulus. (Kandel, 1989)

Despite advances in the neural sciences, people will always need to talk about/out their problems. Some patients simply want to gain greater control over their feelings, even if their symptoms survive, whilst others seek symptom removal. Psychotherapy is not learned from a book (Markowitz, 2003, p. 1219)

³²⁸⁵ The literature contains many studies of psychotherapy on its own or in comparison with other interventions (waiting list, drugs, etc). This chapter will confine itself to general principles.

although knowledge of theoretical frameworks is helpful. Supervision by an experienced and interested therapist offers the best teaching milieu. Greben (1981) defined psychotherapy as any form of treatment strategy wherein a trained individual associates with a person who is looking for help and who, by listening and talking to him, the therapist helps him. He also wrote that 'those who claim special knowledge, who have elaborate rites of passage, who indulge in mystifying private congresses have left the field of psychotherapy and wandered into the field of religion'. Fisk (1993) bemoaned the tendency of psychotherapists to identify with specific schools rather than with the whole field of psychotherapy.

Undoubtedly, no matter what the technique employed, the personal skill of the therapist is highly relevant to outcome. The biggest problems with psychotherapy are poor availability (Guthrie & Sensky, 2007, p. 809), a lack of skilled practitioners (Wykes ea, 2005), and the variability of results with therapies like CBT in clinical trials which are probably reflected in clinical practice. (Jacobson & Hollon, 1996)

The trainee³²⁸⁶ must follow up individual cases for long periods and not get entrenched in the conveyor-belt approach to psychiatry. He/she must experience pain born out of the individual interactions with patients, reminders of our own unresolved problems. His/her elders must not take flight into administration or academia, or give the example of defensive hostility towards patients. Personal and clinical maturity comes with time and interaction with real patients, who can be very demanding, as can their relatives. It is advisable to start reading psychotherapy with a broad-based text³²⁸⁷ and to maintain a broad-based interest in the subject until the basic principles are well entrenched. Bloch (1979) suggested that there are 7 factors which indicate a good prognosis in psychotherapy: personality integrated and functioning reasonably, patient motivated to change, expectations are realistic, at least average IQ, non-psychotic, but can suffer from mild personality disorder or a neurosis, strong affect, and life problems not immutable.³²⁸⁸

All of the 'psychotherapies' share three general, if not particular, characteristics. Each has some goal (insight, behaviour change, symptom control, social competence, etc), a technique, (free association, sculpting, video feedback, etc), and a target of intervention (a symptom, family dynamics, interpersonal problems, etc).

Shared functions of different psychotherapies – reestablishment of morale (Frank, 2006)

Combat sense of isolation³²⁸⁹

Reawaken hopes

Supply with novel information as basis for cognitive and experiential learning

Stir emotionally

Provide experiences of mastery and success

Encourage application of learned material

³²⁸⁶ O'Shea ea (1983) and Cahill ea (1983) investigated the attitudes of trainee psychiatrists to psychotherapy and the perceived quantity and quality of their training in the art. Their findings were very similar in both the eastern and northern regions of Ireland. They concluded that trainees expressed the wish for supervised exposure to psychotherapy and that their training to date was inadequate. What use they would make of greater exposure and training is debatable. In fact, there is little provision for psychotherapy within various public mental health and managed care services. (Amies, 1996; Power & Gilbody, 2005) Psychotherapy training opportunities seem to have improved in Northern Ireland relative to the Irish Republic and the strongest perceived need appears to be for cognitive-behavioural psychotherapy training. (Rooney & Kelly, 1999) However, uptake of training in Northern Ireland is reported as poor. (McNeill & Ingram, 2009) In 2001 the RCPsych mandated 5 basic psychotherapy requirements for trainees: interview skills, psychotherapeutic formulation, one 12-18 month case using any model, at least 3 cases lasting 12-16 sessions using different models, and some experience of group, couple, family, or systemic therapy. However, Agarwal ea (2007) found that only 9% of SHOs eligible for MRCPsych part II met these requirements and less than one-third of all trainees were aware of the requirements! Provision of psychotherapy by American psychiatrists has declined in favour of drug treatment. (Mojtabai & Olfson, 2008) The best way to ensure trainee training is to make training mandatory. (Denman, 2010)

³²⁸⁷ E.g. Bloch, 2006. Bloch (1986, 2006) supplies a comprehensive reading list and no attempt to will be made to imitate him. A more comprehensive text is Gabbard ea. (2005)

³²⁸⁸ 'Yavis' (young attractive, verbal, intelligent, successful) indicates the desired attributes in a client for psychotherapy in psychoanalysis!

³²⁸⁹ Ward ea (2007) conducted a nationally representative study of 2,711 people aged at least 18 years who lived in private Irish households and found those most willing to disclose distressing information to others were female, younger, and in better mental health.

Assessing a patient for psychotherapy (Roth & Fonagy, 2005; Margison & Brown, 2007; Fonagy, 2010)

Use evidence from literature and from experience

Formulation containing what is unique to this patient (idiographic)

Try to find a 'fit' from good studies, i.e. match patient with a relevant therapy (nomothetic)

Integrative/eclectic psychotherapy (Garfield, 1995)

Very common in practice

Willingness to use approaches that are not viewed as part of the primary treatment, e.g. support during psychoanalysis or cognitive work during supportive psychotherapy

Ventilation infers that the patient confides in others and confesses information about his past and present. Clarification arises from discussion of problems - their nature and relations become clear. Abreaction³²⁹⁰ is the rapid release of emotionally charged material and may be aided by music, deep breathing, and by drugs such as sodium amytal. The repeated ventilation of emotion may desensitise the patient; this is classically seen in mourning (the social expression of grief). 'A problem shared is a problem halved'.

The *therapeutic alliance* is the working relationship that develops between therapist and client when trust has developed between them. It has its origins during infancy and is based on the bond of real trust between the child and his mother. A positive transference³²⁹¹ reaction might take the form of a requirement for the doctor to be omnipotent. This is clearly inappropriate. A negative transference stems from the child's negative emotions, such as fear or mistrust, of his parents. What is required for effective progress is that the patient's 'mature, rational observing ego' combines with the psychiatrist's 'analytic abilities'. (Scheiber, 2003)

Manualised therapies should involve serialised explicit strategies. They are useful for reaching many people who require training in novel treatments. (Mansfield & Addis, 2001)

The functions of the ego include relationships with reality³²⁹², regulation and control of drives, relationships between the self³²⁹³ and others, defence of the self, synthesis³²⁹⁴, cognition, and autonomy.

The chief types of client who are suitable to psychotherapy are 'neurotics'³²⁹⁵ and some patients with personality disorders or psychosomatic conditions. Guided mourning in cases of abnormal grief reactions is a good example of how the act of focusing attention on a problem may facilitate natural healing processes.

The traumatic experience of being psychotic or being related to someone with psychosis requires psychotherapeutic intervention to assist in coping and adaptation. (Holmes, 1991) Psychotherapy, at the very least, improves compliance with medication. (Pampallona ea, 2004; Miklowitz, 2008) although this is by no means a universal explanation of how it works. (Tarrier ea, 2004) and, at least in regard to treating depression, client preference for psychotherapy or medication may, at least partly, determine choice of intervention. (De Jonghe ea, 2004; Olofinjana & Taylor, 2005) The main predictors of compliance with psychotherapy for depression in a study conducted by Ayuso-Mateos ea (2007) were social support and previous use of social or health services.

The *Balint technique* (Balint, 1964) is based on psychoanalysis but has been adapted for general practitioners. A more eclectic technique is favoured today. The *systems approach* was discussed earlier in the book.

Psychotherapy on the internet/computer-assisted therapy. There is increasing use of psychotherapy by computer (or books - bibliotherapy) rather than by live therapist. (Christensen, 2007; Spek ea, 2008) Marks ea (2007) list reduced waiting lists,

³²⁹⁰ There are attempts being made to use LSD again in therapy, albeit under stronger controls. (Morris, 2008)

³²⁹¹ I agree with Browne (2008, p. 268) that much of what psychoanalysts would say arises from the subconscious past during transference is in fact derived from here and now, real evoked feelings. True transference and countertransference are *unreasonable*. (Nurcombe & Ebert, 2008, p. 53)

³²⁹² Adaptive, reality testing, and maintenance of a sense of reality.

³²⁹³ The modern name for ego is self.

³²⁹⁴ Able to hold together as an individual.

³²⁹⁵ Although obsessionals may incorporate intellectual insights into their obsessional thinking, rather than benefiting from them.

increased convenience and confidentiality, and lessened stigma, as advantages of this technique. Christensen ea (2004) recruited people with depressive symptoms by survey and assigned them to a cognitive behavioural therapy website or an information website or to an attention placebo condition: only both of the former approaches reduced symptom levels; the authors point out that sustainability of results require testing and that drop out rates can be a problem (do completers differ from non-completers?). Nevertheless, computer-assisted cognitive therapy reduces the need for therapist contact,(Wright ea, 2005) although some contact with a live therapist seems to be important.(Baer & Geist, 1997; Spek ea, 2007; Schmidt ea, 2008; de Graaf ea, 2009) According to Christensen ea (2006), brief online CBT for depression is inferior to extended interventions (but see Mackinnon ea,2008, for an opposite opinion), but longer programs lead to more dropouts. Systematic reviews (Kaltenthaler ea, 2008a,b) found some evidence for the effectiveness of computerised CBT for depression but noted high drop-out rates in one review and rates comparable to other forms of treatment in another review and little consideration of patient preference or treatment acceptability as well as a lack of information on how cases were recruited. Another systematic review (Waller & Gilbody, 2009) noted the high drop-out rates and the need for considerable support of clients from staff as well as the interesting finding that clients looked more favourably on computerised CBT than did therapists! Carlbring ea (2007) found internet-delivered CBT for social phobia better than being on a waiting list. Computer-assisted cognitive remediation exercises show promise in the amelioration of the cognitive effects of depression (Elgamal ea, 2007) although the benefits in schizophrenia may be less certain.(Dickinson, 2010) Computer-assisted CBT may broaden its availability for the adjunctive treatment of substance dependence.(Carroll ea, 2008) Brief computer-based interventions have not been shown to be effective for alcohol-use disorders.(Maio ea, 2005)

Virtual reality exposure. Computer-generated video simulation offers a practical approach to real world fears , e.g. fear of heights, spiders, or flying.(Maltby ea, 2002)

Telephone-administered psychotherapy. Mohr ea (2005) found that depressed patients improved significantly during 16 weeks of telephone-administered CBT. Lovell ea (2006) reported equal effectiveness for exposure and response prevention for OCD given telephonically or face to face.

Counselling³²⁹⁶ is a relatively superficial intervention. It may be non-directive³²⁹⁷ or directive.³²⁹⁸ Specific advice or assistance may be offered and self-help materials may be recommended. Few GPs have the time to do much in the way of formal counselling so they may wish to employ a counsellor. Practice nurses could be trained to counsel patients with mild mood disorders. Indeed, primary care-based counselling was as effective as cognitive therapy for depression.(Ward ea, 2000)

Crisis intervention is associated with Lindemann and Caplan. It aims at limited but definite changes in the way one deals with distressing situations. It is short in duration and is based on the assumption that out of the flexibility that is created by chaos may come improved functioning if guidance is given at the right time.

³²⁹⁶ A rash of 'counselling' in recent years has led to a strong call for qualifications and a system of accreditation.(Okasha, 2002)

³²⁹⁷ Client controls session content; counsellor listens and responds in a warm and supportive fashion, and tries to understand problems and ask appropriate questions.

³²⁹⁸ In directive counselling, specific sources of distress in the patient's circumstances are identified and encouragement is given to directly tackle problems or to make lifestyle changes.

Existential psychotherapy looks at the ways we deal with fundamental issues of living, e.g. the concept of freedom. An increased self-awareness is seen as being of greater importance than any delving into the unconscious mind.

Group therapies (O'Shea, ea, 1984) had their beginnings in tuberculosis sanatoria (Pratt, 1907). Joseph Henry Pratt³²⁹⁹ found that if patients confessed to others in a group and received inspiration from the other group members that their health improved. The group becomes the external world in microcosm, albeit a world in which evoked thoughts and feelings can be safely explored. The aim is to nurture insight and strength that are then used in the real world. Many varieties of group therapy have evolved since then. Groups may be 'open' or 'closed' depending on whether new members are allowed in or not after the sessions have started. The average group has about eight members, meets weekly for sessions lasting about an hour, and continues for one to two years.

Small group³³⁰⁰ psychotherapy

Cohesiveness - members feel that they belong to the group

Interpersonal learning - learn from others' experiences

Altruism - hope is won back by being valued and helped by others

Modelling - learn from others' reactions to oneself, and copying of others' behaviour

Universality - others have similar problems

Catharsis - opportunity to express strong emotions³³⁰¹

Characteristics found in a group

Common experience (or disability) of members

Mutual help and support

Reinforcement of self-concepts of normality

Collective willpower and belief - looking to other members for validation of their feelings and attitudes

Promotion of factual over intrapsychic understanding of personal problems

Action-orientated - members learn by doing and are changed by doing

Confidentiality is essential if members of a group are to feel confident about opening up and confessing to others.

Group therapy has expanded into the wider areas of self-help groups such as weight-watchers, groups for relatives of patients with psychoses, and skill-learning groups.

It is difficult to design a randomised control trial of therapy in mixed groups.

Encounter groups³³⁰²: 8-16 participants take part, making it bigger than small group therapy groups.

Personal growth is the aim. Emphasis is placed on frank expression and honesty. The group leader promotes closeness, interaction, cohesion, a sense of belonging, and mutual concern. Group meetings may be once off (e.g. marathon group) or held more frequently.

Psychodrama (Jacob Moreno) attempts to help participants through role-play. Conflicts are re-enacted in a group format. The patient/protagonist selects other group members/auxiliaries to adopt roles (parent, sibling, etc) to allow him to relive relevant past/current conflict-laden situations. A fellow group member may act as alter ego (i.e. act the part of the patient) in order to explore communication and divine better coping mechanisms. There is emotion release and learning

Supportive³³⁰³ psychotherapy, an often-undervalued intervention (Ursano & Silberman, 2003, p. 1197; Grant, 2007, p. 114) and rarely taught skill, remains the most commonly practiced form of psychotherapy in psychiatric practice. (Tanielian ea, 2001; Winston, 2008, p. 1257) Support is an integral part of all psychotherapies and most schools practice supportive strategies at various points in the course of therapy. It may be specific for certain disorders, e.g. psychoses or borderline personality disorder. From an analytical

³²⁹⁹ Pratt, an Internist at Massachusetts General Hospital, gathered TB patients at the Boston Dispensary for weekly discussion groups and found that such groups offered mutual support and diminished levels of depression and isolation.

³³⁰⁰ As distinct from therapeutic communities.

³³⁰¹ Excessive intellectualising can be confronted by the group to the benefit of members who have 'insight' without feelings, i.e. those using *isolation of affect*. This may be easier to achieve in a group than in individual therapy.

³³⁰² These were started by Carl Rogers (Lieberman ea, 1973) who also invented client-centred/Rogsonian therapy.

³³⁰³ L. *supportare*, to carry.

perspective, suitability includes poor reality testing, poor impulse control, poor interpersonal relations, inability to sublimate, poor balance of affects, and poor verbal facility. These are seen as symptoms of ego deficits. Supportive therapy is not as glamorous as the so-called 'brief therapies' (in fact, most therapies are brief because of dropouts and clinical improvement – Levenson et al, 2000), offspring of psychoanalysis. Defences are shored up rather than broken down. The therapist adopts the role of auxiliary ego for the patient. Techniques include suggestion, reassurance, reinforcement, advice, reality testing, cognitive restructuring, clarification, limit setting, environmental interventions, and current use of medications. 'Lending ego' refers to the modelling of mature behaviour by the therapist. Interventions are tailored to suit the patient (flexibility). The material dealt with resides close to the patient's awareness.

Nidotherapy³³⁰⁴ is a systematic attempt to change the environment (which may precipitate relapses) rather than the patient in cases where the latter is unable to change (older readers will remember the term 'environmental manipulation'). It tries to develop an 'adaptive fit' between person, who if well informed should decide their needs, and environment. Motivation to change is unnecessary. (Tyrer et al, 2007) Evidence of efficacy is limited to case reports. (Tyrer, 2002)

The psychoanalytic family of psychotherapies: Therapy duration has become progressively shorter over the years and more focused on current problems, and has shown a trend away from the old *tabula rasa* (blank screen³³⁰⁵) approach that invited transference to a greater and more open involvement by the therapist. Transference is perhaps the same as (or similar to) the behaviourist's notion of generalisation.

Selected prominent figures from history of psychoanalysis

Sigmund Schlomo Freud (1856-1939), founder of psychoanalysis, neurologist, born in Freiburg (now Příbor) in Moravia, parents Jacob Freud and Amalia Natanson. His half-brother Philip made Amalia pregnant, which possibly influenced Oedipus complex³³⁰⁶ idea. A refugee of the Third Reich himself, four of Freud's five sisters died in Nazi camps. Early on, Freud published neurological and neuroanatomical works, including a monograph on aphasia that Erwin Stengel (1902-1973) translated into English in 1953. Married Martha Bernays, studied under Charcot and published, with Josef Breuer (1842-1925: of reflex fame) *Studies on Hysteria* in 1895. Possibly addicted to cocaine; his colleague, Carl Koller (1857-1944), discovered its local anaesthetic properties. In 1894 and 1899, he had nervous breakdowns. During this period, immortalised in *Traumdeutung* (1900), Freud corresponded with Wilhelm Fliess, inventor of the concept of a nasal reflex neurosis. Freud analysed himself, so starting a family of analysts, and each member thereafter being analysed by someone who was analysed by someone else. Claims for cures criticised in recent years, with talk of former patients dying in mental hospitals. He provided a framework allowing the conceptualisation of mental processes where there had previously been only demonology and degeneracy. Mapother believed that Freud was more of an artist than scientist. Freud may have got major ideas from the German philosopher Friedrich Nietzsche (1844-1900). Merskey attacked Freud's idea of 'repression', believing that it has been used unethically to produce false memories of sexual abuse in infancy. Suffered from carcinoma of maxilla and palate from 1923 and received repeated surgery and radiotherapy. On September 23, 1939 in London, his physician and friend Max Schur administered an overdose of morphine at Freud's request.

Bertha or Elsa Pappenheim (Anna O) (1859-1936) is the best known patient of Freud and Breuer. Lessons learned during her treatment were used in the writing of *Studies on Hysteria*. She would later become interested in separation anxiety. Merskey argues she had a depressive disorder, morphine and chloral hydrate dependence, hysterical conversion, and cyclothymia! Other patients of Freud included Ida Bauer (*Dora*) and Sergej Pankejeff (*Wolf Man*).

Anna Freud CBE, (1891-1982), a school teacher and child analyst, was Freud's youngest child and closest disciple. She observed children at play, was analysed by her father, had no medical qualification, and remained a spinster. Her main contribution was *The Ego and the Mechanisms of Defence*, developed from her father's work.

Carl Gustav Jung, (1875-1961) leader of the school of 'analytical psychology', student of Janet, and a pastor's son, was born in Switzerland and worked with Bleuler at Zurich. Jung corresponded with Freud from 1906 and met him in Vienna a year later. From 1908 to 1914 he was Freud's closest disciple. Jung was concerned with the inner world of fantasy and with interpreting unconscious material in dreams and artistic production. He propounded three levels of psyche: conscious (including persona – outer crust of personality), a 'personal unconscious', containing unique drives and memories, and 'collective unconscious', an inherited, deeper level composed of collected ancestral memories: we are programmed to act in archetypal ways (e.g. the 'hero'). Well-known archetypes (ancient stereotypes) include the 'persona', our social mask, the 'anima', the inner soul-self that is in touch with the unconscious, and the male counterpart of the anima, the 'animus', and the 'shadow', the latter containing unconscious tendencies that must be 'revealed' in therapy. A 'complex' consists of a group of interconnected ideas that arouse feeling and influence action. Jung wrote about 'introversion' and 'extraversion', whereby libido is directed inward or outward. The 'Self's' objective is to maintain an integrated, stable personality. 'Individuation' is the struggle for self-realisation, this process being disturbed in neurosis.

³³⁰⁴ L. nidus, nest.

³³⁰⁵ The 'therapeutic frame' refers to the relative anonymity of the therapist, the fact that sessions are held for a specified time in a specified place, and the fact that meetings outside session time are the subject of exploration within sessions.

³³⁰⁶ A 'triangular' complex, which includes the preoccupations of boys and girls with both parents, has been suggested to replace the Oedipus complex. In reality, many people do not remember much about this phase in their life because it did not cause much upset at the time.

Karen Horney (1855-1952), a native of Hamburg, rejected Freud's 'penis envy' and blamed woman's inhibition on the strictness of her upbringing, i.e. women have sexual problems because of social circumstances not because of biology; she believed that aggression is learned, not inborn.

Melanie Klein (1882-1960) worked with pre-oedipal children using play analysis and she placed the Oedipus complex in infancy! Objects, for the infant, are good or bad; part is confused with whole: breast is equated with mother. At about six months the baby is biting objects (oral sadistic stage) and fears mother will punish him for this hostility. Through denial and projection (attributes of self are imagined to belong to others) the infant assumes a 'paranoid position'³³⁰⁷. Ambivalence towards objects may lead to guilt and a 'depressed position'³³⁰⁸. Klein's 'projective identification' (subject projects part of self onto object, then identifies with object or elicits response in object corresponding to qualities of the projection) was further developed by Wilfred Bion (1897-1979). Klein's first 'patient' was her own daughter, Melitta Schmideberg, who later became an analyst working with delinquent adolescents and who resented her own mother's intrusions so early in life!

Alfred Adler (1870-1937) was born in Vienna, had rickets as a child, trained as an eye specialist, converted to Christianity from Judaism, and died at Aberdeen. He met Freud eight years before Jung. He later broke with Freud, rejected libido theory, founded 'individual psychology', and taught that contemporary environmental factors were more important than sex in determining human behaviour. Adler tried to understand how an individual arrived at his present life-style. Current problems were given due attention in therapy. According to Adler, we all have an 'inferiority complex' and compensate for this via the 'masculine protest'.

Harry Stack Sullivan, (1892-1949) stressed interpersonal dynamics and defined personality in terms of relative and enduring patterns of recurring interpersonal behaviour. Sexual problems are but one aspect of a person's difficulties. Treatment should be centred on the patient-therapist relationship. Sullivan discussed everyday events with his clients and used pointed questions and provocative statements in preference to theory-based interpretations. A homosexual himself, Sullivan believed that patients need a same-sexed therapist.

Helene Deutsch (1884-1982) wrote *The Psychology of Women* and challenged Freud's dictum that the 'enigma of the female' could not be understood by either sex.

Psychoanalysis was the child of S B Freud (see boxes). Freud identified dreams³³⁰⁹, slips of the tongue, and free associations as important windows on the influence of childhood and the present conflicts of the patient. The goal was to elucidate the 'childhood neurosis' as presented in the transference neurosis. Therapy focuses on the recovery of early experiences as they appear in the patient-therapist relationship. The transference neurosis, as distinct from transference phenomena, is the sustained appearance of the transference over time. The patient experiences the analyst as he/she once did an earlier significant figure. The analyst avoids gratifying wishes (abstinence – avoids becoming a figure from the past in reality) and does not take sides in the patient's conflicts (neutrality). Such stances assist in the emergence of the transference³³¹⁰. Classically, countertransference is the analyst's response to the client (modern analysts admit that some responses are 'normal' or non-neurotic). Resistance (experienced by the analyst) derives from the client's defences and may lead to the break down of free association³³¹¹. Interpretations, often given piecemeal, involve the linking together of the patient's experience of an event with the transference experience of the analyst and the significant figures from childhood. Many analysts wait until material is very close to consciousness (or is a symptom of resistance) before offering interpretations (unless it is 'trial interpretation' during an assessment for analysis). Too early interpretation may make the patient feel that the analyst is lost in his own theoretical world and hadn't been concentrating on his client. Shorter (focused) psychodynamic treatments necessitate earlier interpretation than is the case for open-ended analysis. Unless resistance is addressed early time-limited therapy will founder. (Gabbard & Nittler, 2008, p. 672)

Some psychoanalytic ideas

Instincts (drives): The frontier between the mind and body; the physical representative of stimuli coming from within the organism and reaching the mind; and a measure of the demand made upon the mind for work because of its connection with the body. (Freud, 1915) Inner pressure builds up within the person from a source in a bodily stimulus (e.g. mouth, anus, phallus) and the instinct is used to eliminate this pressure through another person (e.g. sexual activity). Freud's first instinctual theory opposed sexual and self-

³³⁰⁷ Good and bad aspects of the mother are split. The internalised good aspect is threatened by the externalised bad aspect. The results are fear, rage, and hatred.

³³⁰⁸ The child realises that mother has both good and bad aspects and so comes to fear that she, the loved one, will be destroyed by the child's hatred.

³³⁰⁹ Freud described dreams as the 'royal road to the unconscious' whereas Beck described emotion as the 'royal road to cognition'.

³³¹⁰ According to Melanie Klein, transference is not just a re-run of past relationships, but also derives from current intrapsychic relational patterns.

³³¹¹ Counter-resistance refers to the impedance of therapy by psychological processes in the analyst.

preservative instincts. His final instinctual theory opposed the controversial death instincts (Thanatos) which he saw as tending towards destruction of the life instincts (Eros: sexual and self-preservative instincts).

Personality development: Freud described child development as passing through psychosexual stages. During the oral stage the erotogenic zones (skin or mucous membranes possess the capacity to sexually arouse³³¹²) are mouth, lips and tongue. This stage lasts until about 18 months when the major source of conflict revolves around feeding, the latter providing a major focus for the relationship between mother and child. It is very important for a mother to tune into her child. Erickson defined a developmental crisis at this stage of basic trust versus mistrust. The anal stage lasts from approximately 1 to 3 years, conflict being focussed on toilet training with major issues over power and control between parent and child (Erickson's autonomy versus shame and doubt). The phallic stage centres on penis and clitoris (about 3–5 years of age) with the main issue being the Oedipus complex. The boy wishes to possess his mother physically in a manner derived from his observations/intuitions about sexual life and he tries to seduce her by proudly showing her his penis. (Freud, 1940) He wants to supplant father in mother life. He is scared that his longings will lead to loss of paternal love and protection. He imagines that girls once had a penis and lost it as a punishment and worries lest the same will become him as punishment for his desires. As a consequence, castration anxiety³³¹³ and abandonment of oedipal wishes follow and he identifies with his father and wants to be like his father rather than to usurp him. (Erickson's stage: initiative versus guilt). A latency period follows (about 5-12 years) when sexual impulses tend to become repressed (controversial). (Erickson: industry versus inferiority). The child applies himself to his education. The final stage is the genital one wherein penis and vagina constitute erotogenic zones (achieved at adulthood). Heterosexual relationships, love, affection, the development of a secure identity and a capacity for intimacy are of major import as is adapting to the values and expectations of society. Fixation develops when excess libido (psychic energy) remains at one of the earlier stages: this may arise from deprivation or over-indulgence, e.g. anal fixation (obsessional personality with excess orderliness, retentiveness and obstinacy). Regression occurs when there is a return of libido to an earlier stage.

Model of mind: Freud divided the mind into conscious, preconscious and unconscious parts. Consciousness is a highly transient state. (Freud, 1940) and the preconscious can become conscious relatively easily. Strong censorship resides between unconscious and preconscious. The contents of the unconscious are instinctual. (La Planche & Pontalis, 1973) The form of thinking in the unconscious is known as primary process thinking: opposites occupy the same time space, related concepts are condensed into unity, fractions of ideas represent whole ideas., sense of time is absent, the pleasure principle predominates, and there is indifference to reality. Rendering the unconscious conscious is the goal of treatment.

Structural model

The primary process, the pleasure principle and wish fulfilment are aspects of the **Id**.

The **Ego** has conscious, preconscious and unconscious components. It can adapt to reality (*reality principle* allows for a delay of discharge of impulses until a suitable object can be found). Secondary process thinking (rational, capable of solving problems and self-protective) replaces primary process thinking. The Ego reconciles demands of the Super Ego and Id. The Ego has a variety of defence mechanisms that come into play in response to anxiety.

The **Super-Ego's** role is judicial in nature. Freud attributed three functions, to the Super Ego: conscience, self-observation, and the formation of ideals. The Super Ego is heir to the Oedipus complex and is set up by internalising parental prohibitions, ideas and values. Classically it develops about 3 – 5 years of age, whilst Melanie Klein described its development at an earlier stage (supported by observation). Through the Super Ego, the child internalises social (parental) standards.

Concepts

Treatment Alliance is the non-neurotic, rational, reasonable rapport that the client has with the analyst. It allows him to work purposefully in analysis. The patient has to want treatment and has to harbour basic trust and a capacity to deal with the frustration and the rigours of treatment.

In the **transference** the client unconsciously displaces behaviours/feelings from childhood figures onto the analyst. He re-lives childhood conflicts (relating to important figures in the past) with the analyst in the here and now. This can be negative (when feelings for a punitive parent are transferred onto the analyst) or positive. Transference interpretations are at the core of psychoanalytic treatment. The erotic transference is based on severe childhood dependence and hostility.

Counter-transference involves the patient coming to represent a figure of the analyst's past since the analyst cannot deal appropriately with what the patient relates because these are jar with the analyst's own unresolved issues. Such unresolved conflicts and problems in the analyst interfere with his ability to work satisfactorily with the client and it because of this that training analysts are required to deal with trainee analyst's blind spots and bring them to conscious awareness.

Resistance is the client's attempts to block the process of developing *insight* to his unconscious. Clues to resistance include long silences, acting out behaviour, demeaning the treatment, inappropriate challenging of the therapist, lateness, and not paying for sessions. Resistance interferes with treatment. This can include *secondary gain* (privileges from being ill), fear of reaching painful feelings/memories, and resistance to change. Symptoms may also be wrestling guilt or need for punishment and the client may cling on to these feelings in order to deal with some of his guilt. He dreads cure because this would end the analysis and would cause the loss of the relationship formed with the analyst.

Patients demonstrate a **negative therapeutic reaction** by not improving during treatment or even disimproving because of an unconscious sense of guilt. Freud (1923) indicated that such cases cannot endure any praise or appreciation, their symptoms representing a need for punishment or suffering and their way of dealing with a harsh super ego.

As Freud (1914) pointed out that the patient does not remember anything of what he has forgotten and repressed but instead may **act it out**: instead of talking about conflicts the patient enacts them (**acting in therapy**).

Triangle of conflict includes hidden feelings, defences against them, and anxiety lest defences do not work. (Grant, 2007, p. 110)

Working Through is required if lasting changes are to happen. Conflicts need to be worked through many times. Patients resist change and are compelled to repeat the past. Attempts to avoid change despite understanding must be dealt with repeatedly.

³³¹² Infants were born 'polymorphously perverse', i.e. a child may derive libidinal pleasure from various body parts.

³³¹³ 'Body damage anxiety' in boys and girls may be a more accurate reflection of what actually occurs. Freud was wrong when he believed that girls and boys focus only on the penis. In reality, girls focus on the genitalia as much as boys do on theirs.

*Psychoanalytic psychotherapy*³³¹⁴ recognises the development of transference and resistance and, depending on the number of foci, can be long-term or brief. Psychoanalytic psychotherapy is normally more focused, based more on the here-and-now, less determined to reconstruct developmental conflict origins, and more likely to use clarification, suggestion and learning through experience than psychoanalysis. There are three phases. The opening phase involves dealing with magical expectations and the desire for rapid symptom relief. Current problems, defences, coping styles and the developmental roots of the central issue are the subjects of examination. The middle phase is preoccupied by resistance and negative transference. The patient feels frustrated. Defences are analysed. Working with the transference is crucial. Termination and resistance to the ending of therapy occupy the end phase.

*Psychoanalytic group therapy*³³¹⁵: An individual member of the group may be treated whilst in the group (analysis within the group, associated with Wolf and Schwartz), the group transference may be the focus of interpretation (analysis of the group, associated with Bion and Ezriel), or there may be analysis through and of the group, the latter technique being associated with Foulkes.

*Brief*³³¹⁶ *dynamic psychotherapies*: Practitioners of brief dynamic therapy utilise 'selective attention' and 'benign neglect' in order to prevent being swamped by the client's complex emotional experiences.

Treatment is supposed to initiate a process of change that continues long after termination of sessions.

Treatment may be needed on a number of occasions over the life span. The therapist is more verbal than in psychoanalysis. (Fleggenheimer, 1982) Clients are usually highly selected and highly functioning. Good ego strengths, rapid involvement in and contribution to therapy, a history of meaningful relationships, an adequate IQ and psychological sophistication indicate suitability for this type of intervention. Psychosis, major affective disorder, drug abuse, suicidal risk, impulsivity, organic brain disorder, and borderline or schizoid personality disorder indicate non-suitability. (Malan, 1963)

Gabbard et al. (2002) in their review of psychoanalysis and related therapies, reported that there was 'preliminary evidence' suggesting that 'psychoanalysis' is consistently helps people with mild disorders and is 'somewhat helpful' for those with severe conditions.

Bioenergetics: Wilhelm Reich formulated the view that body posture and movement can reveal attitudes and defences, so-called 'character armour'. This idea led on to bioenergetics (Lowen, 1958) that aims to interpret these messages or meanings for the patient. Exercises (relaxation, breathing, massage, etc) are used to alter posture and behaviour and release muscular tension. The hope is that such changes will alter psychological function and self-expression.

Rogsonian client-centred therapy consists of open and frank discussion of concerns. The Rogerian therapist shows 'accurate empathy', 'non-possessive warmth', and 'genuineness'. The emphasis is on the positive qualities of clients. Negative feelings and deeper problems are ignored.

Transactional analysis (TA) is fairly superficial. It is usually conducted in a group format, but can be individual. It attempts to look at what part of the self – parent, adult or child – is used in communicating or 'playing games'. Such communication may be inappropriate and maladaptive. The aim is to relate in a more appropriate and direct fashion (adult to adult) and learn mature problem-solving techniques.

Gestalt therapy³³¹⁷ holds that abnormal behaviour derives from aspects and feelings being split off, denied or repressed. The aim is to reconstitute wholeness or *Gestalt*. Gestalt therapy is usually conducted in a group. Direct communication is stressed, yet one can become angry at objects instead of people, e.g. break a chair or bash a pillow in order to get in touch with feelings.

Family therapy (Barker, 1986) involves all the members of a family. The family may act as a source of stress for the identified patient, it may be a resource for the patient, or it may serve to maintain the patient's difficulties. (Harari & Bloch, 2008, p. 684) In the therapeutic community setting of Maxwell Jones the patients and staff meet regularly to govern their own affairs along democratic lines. The family is the most continuous source of care for and interest in the patient in the community. Crisis in the family should be dealt with by anticipatory action, the professional must be seen by the family as being of positive

³³¹⁴ Psychoanalytic-oriented therapy, psychodynamic psychotherapy, or explorative psychotherapy.

³³¹⁵ Initiated by Wolf and Schwartz.

³³¹⁶ Freud often practiced quite brief therapy, duration of treatment tending to lengthen after Freud. (Levenson et al., 2003) Ferenczi and Rank advocated time-limited therapy during the 1920s, and idea later taken up, among others, by Alexander, Malan, Sifneos and Davanloo. Catalysts for brevity include fiscal constraint (managed care in US), a need for more rapid relief than can be found in full analysis, and a need to reach a greater number of patients.

³³¹⁷ Introduced by Fritz Perls of the Esalen Institute in California.

assistance, and some member of the clinical team should be available to help the family for as long as is required.

Symptoms or disturbed behaviour of one family member is viewed as an expression of total family functioning. The cause is not to be found in the individual but must instead be understood in terms of the interaction and feedback between family members. Much of family therapy derives from systems theory, itself a daughter of *cybernetics* or the study of control, regulation and communication. Families communicate via instrumental (practical doing) and affective (feeling) channels. A child may get caught up in inter-parental problems (*triangulation*). Alliances within the family, such as mother-son v stepfather, may be abnormal and dysfunctional.

Family therapy terms

Collateral therapy – one therapist sees spouse/family subsystem and other therapist sees other spouse/family subsystem

Co-therapy – pair of therapists attend together at sessions

Conjoint therapy – therapist(s) meet spouses or parents and children together in same session

Family time line – chronology of events graphically displayed

Genogram – systematic family tree with life cycle and family history issues graphically displayed

Cultural genogram – a genogram that captures cultural; issues e.g. migration, immigration, and acculturation

Group therapy – therapist(s) meet with a number of couples/families in same session

Team participation – colleagues observe (as through a one-way screen) and give feedback, support, etc

Double bind – conflicting messages cause confusion, anxiety, and loss of sense of identity

Enmeshed family – non-permeable boundary with outside world; no interaction with extramural happenings; problems hidden within nuclear group, e.g. anorexia nervosa

Disengaged family – opposite to enmeshed; overt problems; ill-defined boundary with external world, e.g. delinquency

Semi-permeable boundary – this characterises most families; members feel like they belong to a family but are able to interact with the outside world

Boundaries – these are important between the outside world and the family but also between family subsystems, e.g. child v parents (too close or too distant, etc)

Hierarchy – a consistent healthy hierarchy is required within the family; this will be challenged by, e.g., adolescent rebelliousness

Family therapy approaches³³¹⁸ can be either problem-solving (brief, focused and pragmatic) or intergenerational (exploratory and growth oriented). Problem-solving approaches can be structural (associated with Minuchin), strategic/systemic (Palo Alto Group, Haley and Madanes, Milan [Palazolli, Boscolo, Prata, Cecchin] approach, etc), behavioural (Patterson, Alexander, etc) or psycho-educational (Anderson, Falloon, etc) whereas intergenerational approaches may be psychodynamic (Ackerman, Boszormenyi-Nagy, etc), Bowen-inspired (Bowen, Georgetown Group, etc), or experiential (Satir, Whitaker, etc).(see table) Narrative family therapy (White of Australia, Epston of New Zealand, and Tom Andersen of Tromsø) is another approach. An integrationist approach (using interventions derived from different approaches) is gradually replacing strict adherence to individual 'schools'.(Ritvo ea, 2008, p. 1317) Indications and contraindications for family therapy are summarised in the table.(Glick ea, 2000, p. 593-651)

Approaches to, indications for, and contraindications for family therapy

Approaches to family therapy summarised

Structural

- The problem indicates imbalance in family organisation, especially a malfunctioning hierarchical arrangement with unclear parent-child subsystem boundaries
- Symptoms often reflect maladaptive reaction to change/developmental requirements (e.g. life-cycle transition)

³³¹⁸ Classification systems vary.

1022

- Child-focused problems are symptoms of system in trouble and are used to detour inter-adult conflict
- Strategic/systemic*

- Focus on immediate social situation of identified patient
- Assumes all problems have multiple origins
- Presenting problem is a symptom plus a reaction to family dysfunction
- Learn family language and conceptualisations in order to see problem from family viewpoint
- Initiate change to help un-stick family from unworkable patterns that maintain symptoms

Behavioural

- Family rules/communication processes important
- Focus on interactional behaviours and conditions under which social behaviour is learned, influenced and changed
- Often used for marital conflict and with families containing behaviour disordered offspring
- Relationship failure results from deficient reward exchanges, as in coercive control
- Symptoms/maladaptive behaviour is reinforced/rewarded by family

Psycho-educational

- For families containing patient with serious mental illness, chronic physical disorders, or undergoing stressful lifecycle changes
- Provides education/concrete guidelines/support
- Views family as collaborator (not as a cause, as in schizophrenia)

Psychodynamic - Conceptualises family interactions in terms of

- Object relations - relation between subject and object as unconsciously perceived by the subject; internal representations of people that are not necessarily realistic
- Internalisations
- Introjects/projection – do the adult partners act in non-neurotic way – symptoms reflect attempt to work through conflictual material – may scapegoat member – look at behaviour of various generations for clues to current functioning – members must directly confront one another to resolve conflicts

Bowen approach

- Highly anxious and emotionally reactive relationships
- Stress can make matters worse
- Aim to resolve conflicts with families of origin

Experiential

- Life experiences cause the present problem
- Old pains propagated by current stress
- Resolve problems via open, intensive, affective, spontaneous interaction
- Employs sculpting and role play

Narrative

- Change occurs through new language
- Families are 'stuck' by 'stories' (possibility-limiting narratives) and constricted dialogue
- Need to uncover main stories (beliefs, culture) and bring more optimistic stories to the forefront
- Deconstruction (problems are not synonymous with people) and reconstruction (new ways of seeing stories) – the family joins together against identified (named) stories rather than against the member who has the problem
- Focus on times when person acted as if problem did not exist
- Reflecting team – clinicians watch via one-way mirror and then share observations
- Ideas are not right or wrong but are helpful or unhelpful
- Letters to patients after sessions constitute the clinical record

Brief solution focused

- How do family members relate to each other?
- Use findings to create novel strategies, e.g. people who do not express strongly felt feeling may be told to practice arguing

Indications and contraindications for family therapy summarised

Indications

- Family requests it
- Symptoms precipitated by relationship problems
- Child/adolescent is presenting case
- Changes in one member significantly affect another member
- A member reinforces symptoms in a co-member
- Sexual problem/dissatisfaction present
- Family disrupted by crisis/transition
- To investigate/influence severe mental disorder in one member

Contraindications

- Needs to be delayed until some other procedure is undertaken, e.g. detoxification from alcohol
- Family seems at ease with problem (ego syntonic)
- Family do not want external intervention (e.g. for religious/cultural reasons)
- Family are using the therapy to evade individual responsibility for personal problems
- Patient demands individual therapy only or patient needs help to individuate
- Failed family treatment where a member still needs help
- Family denial of problem or absence of crucial family members
- Aspects of one member (paranoid, manic, agitated, violent)
- Sufficiently significant parental pathology that indicates seeing child alone is the correct course to take

Marital therapy: It has been said that marriage is a great place for kids to grow up in but a poor place for the married couple to grow up in! A person's strongest interpersonal relationship, if positive and stable, acts as a buffer against any genetic tendencies to illness. (Ritvo et al, 2008, p. 1316) Marriage is about giving and receiving and about compromise. Many influences come to bear on a relationship, such as occupational stresses, sharing child-rearing decisions, growing old, and past and present issues relating to families of origin (breaking the umbilical cord, expectations derived from parents, looking after grandparents, etc). Whatever technique is employed³³¹⁹ (psychodynamic, behavioural or systems), the therapist avoids becoming over-identified with one partner (taking sides and keeping secrets are taboo). The focus is on the interaction between the two partners, i.e. the relationship rather than the individuals involved in it. Structural and strategic marital (or family) therapies are derived from systems theory. The term 'couple therapy' accommodates an 'unmarried but committed couple' (Fields et al, 2003, p. 1373) e.g. homosexuals.

Some approaches to marital therapy

Psychoanalytic/psychodynamic – unconscious processes originating in childhood but operating currently in the dyad and as transference reactions to the therapist; the therapist aims to reveal these to the conscious minds of the couple

Systemic – behaviour has a role, a meaning and a purpose in the system; areas of interest include use of language to manipulate the emotional space between couples and the use of power in the relationship; the therapist may seek parallels between what is happening now and how the couples' parents acted; problems may be reframed/redefined, e.g. a depressed husband may have assumed this emotional position to prevent his anger being directly expressed

Emotionally-focused – based on attachment theory; the therapist tries to more secure ways of experiencing emotion and to decrease the maladaptive responses (e.g. tension and avoidance) to perceived insecurity

CBT – up to 25 sessions; unwanted thoughts and behaviours are targeted; techniques include communication skills training and homework

Contraindications to marital/couple therapy

On-going violent/dangerous relationship

Violent partner does not/cannot commit to non-violent contract

Only one member wants to change or work on improving relationship

³³¹⁹ Modern approaches tend to be more integrative, here-and-now-based, and more likely to consider how the current problems arose over time. (Ritvo et al, 2008, p. 1322)

Active (extra-marital/couple) sexual liaison told to therapist 'in secret'
 Many attempts at therapy end in failure and current relationship is cold and untrusting

Interpersonal psychotherapy³³²⁰ (IPT): Interpersonal psychotherapy aims to reduce some of the social problems that may provoke or prolong an episode of depression, e.g. loss of a close relationship or interpersonal conflict. Such events need not have directly caused the depression but should have occurred around the same time as the lowering of mood. Specific targets (selected interpersonal focus areas) include abnormal grief, role transitions, role disputes, and interpersonal deficits. The therapist is active and supportive. Areas of enquiry include options and expectations in relationships. Role-playing is used in order to perfect tactical approaches to problems. There is no analysis of transference and no emphasis on homework. Toward the end of therapy, the therapist reinforces client competencies and the patient learns how to recognise triggers for depression. There is evidence that IPT improves social functioning but (unlike with CBT) personality disorder may adversely affect outcome in treating depression.(Joyce ea, 2007) It can be used as alternative or adjunctive treatment for depression. It has also been used in the treatment of bulimia nervosa. IPT performed better than CBT in a meta-analysis of studies of psychological interventions aimed at preventing onset of depressive disorders.(Cuijpers ea, 2008) Availability and training are problematic.(Markowitz, 2003, p. 1219) A maintenance form of IPT has also been developed in which long-standing patterns of maladaptive interpersonal behaviour become the focus of treatment.(Frank, 1991) Also, 'interpersonal counselling', an adaptation of IPT with a maximum of 6 sessions and often delivered by nurses, is designed for sub-syndromal patients in primary care settings.(Klerman ea, 1987)

Psychodynamic-interpersonal therapy³³²¹ (PIT): The main components are a rationale for exploratory treatment, development of a shared understanding, focus on the present, 'staying with feelings', understanding interpersonal issues, a sequence of interventions, testing solutions, and examining barriers to change. The one-sided relationship of traditional psychoanalysis is jettisoned for a negotiating style. Metaphors used by the client are used to help in understanding. PIT has been used to treat depression, anxiety, deliberate self-harm, and somatisation.(e.g. Guthrie ea, 2001)

Cognitive therapy/cognitive-behavioural therapy or CBT (see tables; Sudak, 2006; Gaudiano, 2008; Friedman ea, 2008): Beck ea (1979) hold that depression is maintained by misinterpretation and distortion in the evaluation of events³³²². This, they hold, is achieved through selective attention (remembering unpleasant events more than pleasant ones), arbitrary inference (attaching undue importance to minor events), and magnification (construing events in ways detrimental to the self when there is no basis for doing so). The notion of the 'cognitive triad' includes devaluation of self, a negative view of life experiences, and a pessimistic view of the future. The dysfunctional assumptions that need to be identified and challenged are not based on current reality, are rigid, over-generalised ('Absolutely everything I do goes wrong') and extreme, they block rather than further achievement of goals, they are associated with excessive emotion when thwarted, and are difficult to alter in the face of daily experience. Patients with such assumptions set excessively high standards for themselves, crave acceptance, and want to be strong. CBT has been applied to various problems, including depression, anxiety, personality disorders, eating disorders, and, with somatic therapies, psychoses. It is held that different psychiatric disorders are associated with distinct cognitive profiles (the *cognitive content specificity hypothesis*³³²³). The requirement of 'cognitive flexibility concerning delusions' may rule out many psychotic patients.(see Turkington ea, 2006) There is no evidence that negative cognitions are a cause rather than a consequence of depression and the presence of the expected cognitive set is not predictive of response to CBT.³³²⁴ Also, successful drug treatment in the absence of CBT provides remission of negative cognitions.

³³²⁰ This non-interpretative, non-cognitive, non-behavioural, here-and-now-focused therapy was developed by Gerald Klerman ea (1984) and is based on the work of Adolf Meyer, H S Sullivan, Frieda Fromm-Reichman and John Bowlby. Klerman, a psychiatrist, and Myrna Weissman, a psychologist, adapted the approach of social workers who focused on current interpersonal relationships.

³³²¹ This hybrid psychotherapy was developed by Hobson.(1985)

³³²² Beck's cognitive (or cognitive processing) model holds that affective response to an event depends on the meaning ascribed to the event.

³³²³ Anxious people feel threatened and vulnerable whereas depressive themes involve low self-esteem and loss.

³³²⁴ Burns and Spangler (2001) found no relationship between dysfunctional attitudes and treatment outcome in CBT-treated patients. Also, *acceptance and commitment therapy* (ACT) tries to reduce avoidance patterns without directly dealing with distorted cognitions.(Hayes ea, 2006)

CBT may be relatively ineffective in depressed adolescents.(March ea, 2004) Parker ea, (2003) who suggest that the efficacy of CBT in depression has been overstated, suggest seven possible ways in which it might work: modification of ongoing cognitive vulnerabilities (but they feel that it is the least cognitively impaired people who do best with CBT and that symptomatic improvement may predate cognitive restructuring), behavioural therapy component, non-specific therapy and therapist effects, a credibility effect, increased mastery over ones life, extended contact with a therapist, and acting on anxiety (or some other problem) for which depression is a downstream effect. The efficacy of CBT has been shown to differ between centres (Tarrier ea, 2004) and, based on a meta-analysis of 'well-controlled trials', Lynch ea (2010) found CBT to be no better than control interventions for schizophrenic symptoms or relapse rates, of small but positive effect for major depression, and not effective for preventing relapse of bipolar disorder. Among the various behavioural procedures employed in CBT are Socratic questioning (guided discovery), activity scheduling, graded task assignment, behavioural rehearsal, response prevention, distraction, relaxation exercises, breathing control, assertiveness training, modelling, and social skills training. Activity scheduling involves the use of a daily or weekly activity log wherein the patient records what was being done every hour of the day and rates each activity for mastery and pleasure. In graded task assignment a behavioural goal is broken down into smaller steps that can be taken one at a time. A typical course of CBT takes about 15 hours. CBT is not readily available in many areas (Department of Health, 1995; Taylor & Estroff, 2003, p. 606; Nutt ea, 2002, p. 88; Ballenger, 2004; Pollack ea 2004, p. 197; Stein, 2004, p. 7; Wilson & Shafran, 2005; Schatzberg ea, 2005, p. 341; Clark ea, 2009) and brief training courses may be ineffective.(King ea, 2002) CBT consists of many manualised interventions for numerous disorders, a fact that undermines training and application.(Olatunji ea, 2008, p. 199) Some patients require pharmacotherapy prior to CBT in order to make use of psychological interventions. Criticisms of CBT research include the use of comparator antidepressants in too low a dose for too short a period of time and the use of drugs in mild cases that might not be expected to respond.(Jarrett & Rush, 1994) CBT may be particularly useful for personality-disordered depressives³³²⁵. A perceived gulf between efficacy (in research) and effectiveness (in practice) of CBT among many experienced clinicians may be due to many factors, e.g. differences in clientele, training, workload, availability of CBT, or working outside specialist units (e.g. for eating disorders).(APA, 2002, p. 741) Luty ea (2007) found CBT superior to IPT for severe depression in outpatients. Publication bias (Cuijpers ea, 2010a) may have given an exaggerated view of the benefit of CBT for depression. We should make selective rather than blanket referrals for CBT.(Scott, 2008)

Cognitive therapy

Automatic thoughts³³²⁶ occupy a relatively superficial mental position. At a deeper level are schemas (less open to conscious awareness, deeper, reinforced by experience, core beliefs). Schemas are more difficult to identify and modify than automatic thoughts. Experience in recognising automatic thoughts should reveal underlying patterns/schemas. The patient should keep a list of uncovered schemas.

Techniques used for modifying automatic thoughts

- examination of evidence for and against
- decatastrophising – try to conceptualise feared outcomes in a way that promotes coping and problem solving
- daily record of dysfunctional thoughts – use columns – stressful events, automatic thoughts – score degree of own belief in such thoughts – emotional response – record more rational or realistic set of cognitions

³³²⁵ See Fournier.(2008)

³³²⁶ **Negative automatic thoughts** may refer to the self ('I'm no good'), now ('I can't do anything correctly'), or the future ('I will never improve'). These are due to processing errors leading to distortions, e.g. *overgeneralization* (sweeping judgements based on a single example, e.g. 'Nothing I undertake succeeds'), *selective abstraction* (paying attention only to the negative, e.g. 'It was doom and gloom all week'), *dichotomous reasoning* (extreme thinking, e.g. 'If I don't get every question right I'll be a failure'), *personalisation* (accepting responsibility for things one has minimal/no control over, e.g. 'I'm responsible for my boss's mistakes'), and *arbitrary inference* (jumping to conclusions based on flimsy evidence, e.g. 'I couldn't handle the first assignment and therefore I'll not be able to handle any other work I'm asked to do').

- cognitive rehearsal – patient uses imagery or role play to identify possible distorted cognitions that could occur in a stressful situation and then work to modify them – the use imagery or role play again to practice the more adaptive pattern of thinking – then homework assignment wherein new cognitive patterns are tried out in vivo

Procedures used to uncover schemas

- Socratic questioning – guided discovery – help patient to move from a ‘closed mind’ to a state of inquiry and curiosity
- imagery
- role play
- thought recording

Interventions used to modify schemas

- examining the evidence
- listing advantages and disadvantages
- generating alternatives
- cognitive rehearsal

Options when treatment fails

- Continue treatment for longer
- For interpersonal issues consider a different approach, e.g. marital or family therapy
- Psychodynamic therapy or related approaches
- Somatic therapy +/- cognitive therapy

Selected research findings in CBT

1992. Relapse after CBT associated with slower response to therapy, single marital status, and high residual scores on Dysfunctional Attitudes Scale.

1999. In RCTs cognitive therapy (CT) more effective than drugs in 2/7 studies and equally effective in 5 others.

Specificity of CT/CBT questioned – when its components are removed it remains effective!

2002. Mild to moderate depressed outpatients given (a) TCA or phenelzine, (b) psychotherapy, or (c) ‘control conditions’: dropouts were 37.1%, 22.2%, and 54.4% respectively; ‘remissions’ were 46.4%, 46.3%, and 24.4% respectively.

2004. Four sessions of CBT given early to mildly/moderately injured A&E attenders modestly reduced symptoms of PTSD, but not depression or anxiety.

CBT is no better in schizophrenia than non-specific interventions.

2005. Combined CBT and mood stabilisers superior to mood stabilisers alone in terms of clinical outcome and cost-effectiveness for patients with frequently relapsing bipolar disorder.

2007. Cognitive self-therapy for depression or GAD decreases need for therapist input but was not proven superior to treatment as usual.

2008. Generic CBT for routine relapse prevention in patients recovering from a recent relapse of non-affective psychosis was unsuccessful.

RCT with children 7-17 years old with various anxiety disorders compared placebo drug, CBT, sertraline, and CBT plus sertraline: CBT and active drug reduced anxiety symptoms, combined treatment being superior to either treatment used alone; no child attempted suicide; and patients given CBT had less insomnia, fatigue, sedation, and restlessness than had children given sertraline.

Cognitive analytic therapy (CAT: Ryle³³²⁷ ea, 1992; Treasure & Ward, 1997): Heinz Hartmann (1894-1970) developed an ego psychology with the aim of replacing self-deception and misjudgements with new connections. As such his work exemplifies a partial bridge between psychoanalytic psychotherapy and CBT/CAT³³²⁸. CAT is time-limited (usually 16 sessions, sometimes more). The patient’s past and present is reformulated, the patient is assisted to recognise recurrent ways of formulating problems, and is help to revise such formulations. Negative assumptions act as ‘traps’ by causing a person to act in ways that cause consequences that reinforce those assumptions, e.g. excessive attempts at pleasing others³³²⁹. ‘Dilemmas’

³³²⁷ Dr Anthony Ryle was a GP who ended up as a consultant psychotherapist with the NHS in Britain. He was influenced by George Kelly’s (1905-1967) repertory grids (1950s) that present relationships in visual and mathematical formats.

³³²⁸ CAT focuses on relationship patterns whereas CBT focuses on symptoms, beliefs, and behaviour.

³³²⁹ The patient tries too hard to please in order to elicit care, is taken advantage off and feels angry, and then tries even harder to please.

are represented by false dichotomies: the often unconscious viewing of possible actions as black or white, with no shades of gray, e.g. the person who learned to hide their feelings from parents who ridiculed him now is caught between the loneliness of lack of emotional openness with others and the possibility of humiliation. More appropriate strategies are dismissed for consideration because of perceived 'snags': 'they wouldn't work because they are dangerous/forbidden/likely to meet opposition.' 'Sequential diagrammatic sequencing' is basically a diagram that helps the patient to remind him/herself of how he/she has used maladaptive coping strategies over time. The patient is helped to recognise automatic reactions in a timely matter, thus allowing time for consideration of alternative strategies. Other components of CAT include work done outside of therapy sessions (homework) and the exchange of (goodbye) letters that focus on what has been and what remains to be achieved.

CAT (Kerr & Ryle, 2006)

All mental activity is influenced by internalised experiences

This results in formation of 'a repertoire of *reciprocal roles*' (RRs: 'complexes of implicit relational memory, including perception and affect'³³³⁰

Most psychopathology stems from unhealthy RRs that manifest as 'self-perpetuating procedural enactments'

Latter may show as damaging relationships or poor self-care

Some enactments are feared or forbidden, as when self-assertion is disallowed by internalised 'voices' from parents or culture

Interpretations are not used in CAT because they are viewed as arising from theory and as attempts at convincing patients to accept what cannot be known to them. Patients who need further work may receive further sessions or psychoanalytic therapy.

Applications for CAT are developing, e.g. borderline personality disorder.

Cognitive behavioural analysis system of psychotherapy (CBASP: McCullough, 2006; Swan & Hull, 2007): This is a treatment for chronic depression developed by James McCullough of Virginia. Symptoms are believed to arise from arrested pre-operational³³³¹ (2-7 years) Piagetian development in early-onset cases. Late-onset cases are due to increased emotionality and regression. Interpersonal problems develop (and are perpetuated) from cognitive and behavioural patterns. Having learned this, the patient must now change maladaptive interpersonal behaviours. The therapist represents a stable interpersonal style. Kocsis et al (2009) found no significant benefit from CBASP as an augmentation strategy over flexible, individualised pharmacotherapy for chronic depression.

Dialectical behaviour therapy³³³²: This special form of CBT (Linehan, 1987, 1993) has been used in the treatment of borderline personality disorder. It consists of manualised weekly individual psychotherapy, group psychoeducation to improve skills, and, when indicated, telephone consultations. The aims are to teach problem solving (to help regulate emotions and tolerate distress), validation of perceptions, and meditation skills. Reflection prior to action is encouraged. Impulsive and self-destructive behaviour are not rewarded. It is hoped to include social effectiveness. A non-judgemental approach to events is encouraged. Linehan felt that conventional CBT mandated change and thereby reproduced the invalidating early experiences of the borderline patient. The DBT therapist shows that she understands why the patient acts as she does (i.e. their function) whilst acting as an advocate/guide for change. Missing a stated number of sessions leads to the patient not receiving DBT for a fixed period of time. (Sudak, 2006, p. 133) Dialectical behaviour therapy is probably more effective in reducing certain behaviours, such as self-harm, than in

³³³⁰ Early relationships with parental figures result in roles being gradually built into the mind (Cf. psychoanalytical *internalisation* and *schemas* in cognitive therapy).

³³³¹ Pre-operational functioning is represented by use of symbols, words and pictures to represent absent things; attending to part rather than the whole (centration); ability to accept what cannot be understood (intuitive thought); can only see things from own viewpoint (egocentrism); and inability to perceive conservation following change, e.g. in volume.

³³³² Developed by Marsha Linehan (University of Washington, Seattle), 'dialectical' refers to an attempt to help a person view **both sides** of an argument rather than focusing on one side only. According to Melanie Klein (1882-1960), objects, for the infant, are either good or bad, not both; part is confused with whole: breast is equated with mother and is either a good or bad breast depending on the service the infant receives. An ability to see that everyone has positive and negative attributes is a normal developmental acquisition

changing personality as such. (Linehan et al., 1993; Verheul et al., 2003) It has been described as 'an elaborate and expensive treatment' that is 'demanding on those who would practice it'³³³³. (Palmer, 2002) Chiles and Strosahl (2005, p. 164) emphasise what clinicians have always known: 'the repetitiously suicidal patient needs maintenance treatment that may span years if not decades'. The treatment team should have regular consultation meetings.

Rational emotive behaviour therapy (REBT): Developed by Albert Ellis, REBT assumes that thinking, emotions, and behaviour are interrelated. People may have poor tolerance for frustration and harbour illogical ideas ('shoulds'). The aims of therapy are to alter beliefs and to allow behaviour to become more rational.

Coping skills training therapies: Coping strategies may be emotion- (anything that contains stress) and/or problem-focused (ways of managing events/difficulties) Therapeutic interventions include 'stress inoculation therapy' and 'systematic rational restructuring'. The patient learns to use skills designed to help him cope with stressful situations.

Problem-solving therapies: The therapist teaches strategies that help others cope with problematic situations. Problems are identified, broken down into manageable components and skills (prioritising, brainstorming solutions, and making lists of advantages and disadvantages) to solve these are developed. These approaches have been shown to be effective in anxiety and depression in primary care and in helping people who self-harm. (Guthrie & Sensky, 2007, p. 801) Duration is 4-6 sessions, each of 20-30 minutes length. Only a short period of therapist training is required.

Mindfulness³³³⁴-based cognitive therapy: This approach (Segal et al., 2002), based on American work with patients experiencing chronic pain and somatic illness, is used to reduce the chances of relapse in recurrent depression. (Ma & Teasdale, 2004; Kingston et al., 2007) Patients are thought to disengage from their episodes of self-perpetuating ruminative, automatic thoughts so as to reduce reactions to them. Minds have a will of their own and what we do or feel may be determined by streams of thoughts about what belongs to the past or future. We should focus instead on the here-and-now. Unlike traditional CBT, the patient is asked not to engage with negative thoughts. The aim is to prevent minor drops in mood leading to depression via rumination. Usually conducted over eight sessions, the patient learns meditation (practiced regularly), breathing exercises, and yoga.

Behaviour therapy: This approach is based on learning theory: psychiatric disorders are seen as learned and therefore as being capable of unlearning. (see individual syndromes throughout text) There are 2 basic behavioural theories, Pavlovian (classical conditioning - the association of conditioned stimulus [CS] with unconditional stimulus [UCS] to produce the desired response – desensitisation³³³⁵ and implosion are probably best when there is a narrow range of anxiety manifestation with predominance of autonomic imbalance) and Skinnerian (operant conditioning - alternation of the frequency of a piece of spontaneous behaviour by means of reward, withholding reward or punishment). Punishment only produces short-term reductions in target behaviours when used alone and is more effective if combined with simultaneous reinforcement of desired behaviour.

Ivan Petrovich Pavlov (1849-1936) Nobel Prize 1904

Behavioural therapies useful for

Single phobias - desensitisation and flooding

Obsessional problems - response prevention, audiotaped habituation³³³⁶

Sexual dysfunction - Masters and Johnson techniques

³³³³ See also Hawton. (2005, pp. 205-6)

³³³⁴ The Buddhist notion (*Vipassana*) of *mindfulness* refers to non-judgemental awareness of personal experiences as they occur.

³³³⁵ *Self-control desensitisation* resembles ordinary desensitisation because it employs a hierarchical presentation of fear-relevant cues but differs from it by using various strategies to reduce anxiety during exposure, e.g. coping self-statements and cognitive challenges.

³³³⁶ Audiotaped habituation: used for obsessive ruminations – anxiety-producing thoughts are taped and played over and over again until there is significant reduction in anxiety.

Paraphilias - aversion, covert sensitisation – in the latter, the patient imagines target behaviour couples with something disgusting or painful
 Marital problems - contract therapy
 Enuresis - bell and pad
 Intellectual disability - behaviour modification
 Chronic schizophrenia

A phobia, for example, can be learned by classical conditioning, and because avoidance reduces the fear (hence rewards avoidance), it can be maintained by operant conditioning. This bringing together of both theories is known as the double learning theory. The more circumscribed the phobia the better the therapeutic results.

Behaviourists use directive treatment methods, with clear goals, and an objective measurement of outcome. Pavlov's experiments with dogs are well known. He paired food with a bell and the dog salivated.

Eventually the dog learned to salivate with the sound of the bell only. Operant conditioning employs immediate rewards following the appearance of the desired behaviour. The patient's speech or actions are shaped by the use of token economy³³³⁷. Token economy has become less popular because of fears that its effects might not last, that it deprived people of their rights, and that changes, if any, might be due to staff attention rather than the token. Operant techniques are probably best for behavioural problems in which there is some proportion of voluntary control.

The *Premack*³³³⁸ principle states that any frequently performed piece of behaviour can be used as a positive reinforcer of the desired behaviour. Intermittent reinforcement is more resistant to extinction than continuous reinforcement. *Shaping* involves providing successive approximations to the required behaviour, with contingent positive reinforcement. Behaviourists observe and concentrate on the symptoms or behaviour rather than, as in analytical approaches, looking for hidden psychic problems.

Desensitisation in imagination is not as effective as *in vivo*³³³⁹ desensitisation as the patient may fail when he faces a real feared situation. Safety seeking behaviours³³⁴⁰ that are practiced or even thought to be available diminish the outcome of exposure to the feared stimuli and patients must agree not to employ such behaviours; it is best to concentrate on the 'core threat' during exposure³³⁴¹. *Flooding* (implosion) is rarely used today compared with the past because of the extreme stress involved and the relatively equivocal results.

Behaviourist terminology

Avoidance training: one learns to remove oneself from the source of a noxious stimulus before it can happen, e.g. a bell forewarns a rodent of a forthcoming shock.

Chaining: piecemeal addition to a behavioural chain that eventually produces a full action. The first bit of behaviour is reinforced, the two bits, etc. For example, holding a spoon, then holding the spoon and putting it in the mouth, and so on, in an attempt to teach a child how to eat. 'Forward chaining' and 'backward chaining' are terms used when the first and last steps in a desired sequence are reinforced first respectively.

Classical: used to account for development of emotional responses – automatic, involuntary behaviour, such as reflex response to physical stimulus.

Classical conditioning (respondent learning): leads to unconditional reflex arising from a stimulus that does not normally produce it – this new stimulus is called a conditional stimulus, i.e. its ability to so is dependent upon/conditional on its having being associated with the unconditional stimulus.

Conditional reflex: reflex produced/elicited by the conditional stimulus.

Conditioning: a very simple form of learning.

³³³⁷ *Token economy* was employed extensively in rehabilitating chronic inpatients. A token (e.g. a coloured ticket, or, in practice, a cigarette) was given for desired behaviour (e.g. using an ashtray instead of the flowerpot to douse a cigarette). This token was added to those already collected. Tokens were used in exchange for privileges, such as a visit to the cinema or extra time in the TV room.

³³³⁸ David Premack (b. 1925, South Dakota) professor of psychology, University of Pennsylvania, did groundbreaking work on language and symbols in chimpanzees.

³³³⁹ The best results from exposure occur with real life exposure, longer exposure, and regularly practiced exposure with homework tasks. (Drummond & Warwick, 2007)

³³⁴⁰ E.g. the patient who fears elevators goes on one but brings a friend or a mobile 'phone with him.

³³⁴¹ E.g. the patient who fears heights leans against a balcony with hands clasped behind his back, i.e. he employs an 'opposite action' to that which he might ordinarily use (e.g. hugging a wall).

Continuous reinforcement: every occurrence of a particular behaviour is followed by reinforcement.

Discrimination of stimulus: learns to respond to one stimulus but not another.

Escape training: one learns to do something because it removes a noxious experience.

Extinction: loss of learned response due to absence of reinforcement

Generalisation of stimulus: after learning to smile at a parent the child proceeds to smile at others.

Incubation: reinforcement of avoidance due to brief exposure to feared object or situation.

Intermittent reinforcement:: behaviour reinforced only some of the time – in general, intermittent reinforcement renders learned behaviour more resistant to extinction.

Modelling: a form of observational learning wherein one learns by watching someone carrying out an act. It is employed to treat phobias and as part of social skills training.

Negative reinforcement: behaviour occurs because of removal of a 'reinforcer'.

Observational learning: process whereby one learns a response vicariously by observing an event and its consequences.

Operant: a desired piece of behaviour; used to account for development of voluntary behaviour, such as social, language and motor skills.

Operant conditioning (instrumental learning): concerned with behaviour that is under control of the individual, i.e. he 'operates' on the environment using it; how frequently he performs an operation depends on the consequences.

Positive reinforcement: behaviour increases because of addition of a 'reinforcer'.

Paradoxical intention: reduce anxiety by encouraging subject to carry out feared action.

Prompting: learner is guided by verbal or physical prompts to make the required response.

Reinforcers: a stimulus or event that reinforces a given behaviour, e.g. escape for noxious stimulus, receipt of food, etc. Can be 'primary' (satisfies a basic drive, as food does for hunger) or 'secondary' (not occurring naturally –acquires this property by regular association with primary reinforcer, e.g. bell associated with food causes lever to be pressed in attempt to get food even when food is not forthcoming).

Reward training: one does something more frequently because of rewarding consequences.

Shaping: method of successive approximations - shaping reinforces behaviour that gradually becomes more similar to the final, required behaviour.

Spontaneous recovery: reappearance of apparently extinct behaviour.

Unconditional (unconditioned) reflex: natural, innate, occurring without previous learning.

Unconditional stimulus: stimulus that brings about an unconditional (unconditioned) reflex.

Simply removing a fear may not suffice, e.g. attention may need to be given to changed interpersonal relationships as a result of the behavioural intervention, e.g. a spouse may be left without the praise given for accompanying a husband/wife on the elevator – it might have been wiser to have involved her somehow in the treatment process.

Behavioural activation (BA): Developed by Neil Jacobson and others in the University of Washington, BA grew from an attempt to remove the 'cognitive' from CBT. The withdrawn, avoidant depressive is trying to avoid feared consequences of becoming involved. Depressive thinking *per se* is more important than what one is thinking. The patient is coaxed to become involved in pleasant, meaningful, and necessary activities. There is evidence of equivalence between BA and medication in preventing relapse of severe depression, and statistically significant superiority of both to cognitive therapy. (Temple & Geddes, 2008, p. 511)

Relaxation: Decreased oxygen consumption and a fall in blood pressure/heart rate/respiration rate accompany the 'relaxation response'. Of importance for the relaxation response are quiet, decreased muscle tone, repetition of a sound, word or phrase (e.g. 'relax') silently or audibly, and a passive attitude. The response is mediated by the parasympathetic nervous system. The instructions given to the patient might include that he sit quietly in a comfortable position, close his eyes, deeply relax all his muscles (start at feet and progress to face, and then keep them relaxed), and breath through his nose (become aware of your breathing - during each expiration say 'relax', or whatever helps, silently to yourself). This should continue for 20 minutes. The patient may open his eyes to check the time but should not use an alarm. At the end, he should sit quietly for several minutes, at first with the eyes closed, then with opened eyes. He should not worry about how well he is doing and he must ignore distracting thoughts. The client should practice twice

daily (not within two hours of meals - digestion possibly interferes). The doctor/therapist should practice relaxing and exude confidence in the procedure.

Social skills training: This type of therapy/training has traditionally been carried out by occupational therapists. The aim is to assist individuals to relate to others with confidence and without undue anxiety and to cope with demands of daily living. The approach is primarily behavioural: role play, modelling, positive reinforcement and practical assignments. With the intellectually disabled or the chronic psychotic patient it is often necessary to commence with 'living skills' training, e.g. shopping, value of money, cooking, etc. One can then proceed to coping and interactional skills, e.g. how to conduct a conversation or to make a job application. A review of nine randomised controlled trials in schizophrenia found no significant reduction in relapse rates from social skills training regardless of length of follow-up, and a tendency for more dropouts than with the comparison treatment. (Pilling *et al.*, 2002a) These results are described as 'disappointing'. (Bebbington *et al.*, 2002)

Assertiveness training: Patients are trained to assert themselves, to say what they mean to say, to self-express in body language, to manage anger, to give compliments, and so on. Features include instruction, modelling and role-play.

Reminiscence therapy is an attempt to assist elderly and confused patients with memory problems to improve their social interaction. It is often conducted in weekly group format. Personal and historical past events are discussed. Audio-visual presentations, music, photographs, newspapers and other media may be usefully employed.

Art therapy can involve various media, varying from water colours to pottery. At its most basic level the emphasis is producing art without attempting to interpret it. The therapist may look for aspects of the therapeutic relationship or a reflection of the person's past in the artwork and tell the patient about this (art psychotherapy) or a deeper transference-related interpretation may be proffered (analytical art psychotherapy: Schaverien, 1991). Serial artwork may reflect changes in mental state, e.g. reality-orientation or affect. The hopes are that art will enable clients to express what they find difficult to verbalise and to facilitate psychological change. There are important concerns around inter-rater assessment reliability and the ability of raters to be able to tell which works were done at the various stages of art therapy! (Eitel *et al.*, 2008)

Music therapy involves making or listening to music with a trained music therapist. There is evidence that patients with a wide spectrum of serious mental disorders benefit from this modality, especially when the treatment is prolonged. (Gold *et al.*, 2009)

Reality orientation is an attempt to maintain orientation in cognitively disturbed people. Large clocks and visual display boards (giving day, date, time, place, weather, next meal, etc) are employed. Staff must reinforce the information regularly. However, this approach needs to take account of the needs of each individual and practitioners should not confront their charges (Simard & Sampson, 2008, p. 237) if they are to avoid causing frustration, anger, and depression.

Cognitive remediation

Patients with schizophrenia have problems with attention, processing speed, memory, planning, and abstraction. Patients practice on laboratory-derived tests of cognitive function or on procedures designed to address cognitive deficits. Pilling *et al.* (2002b) examined four randomised controlled trials and found very little support for cognitive remediation. Dickinson *et al.* (2010) found that measured improvements failed to generalise, e.g. there was no improvement in function.

Hypnosis: Relaxation/altering state of awareness is probably the basic therapeutic ingredient in hypnosis (Heap, 1988; Mathew, 1993; Kay & Tasman, 2006, p. 903 *ff.*). Alpha rhythm increases on the EEG during hypnosis. Studies involving attempts to block or reverse states of hypnotic analgesia with naloxone do not favour a role for endogenous opiates. (Maldonado & Spiegel, 2000) An alternative theory of hypnotic pain relief involves activation of descending antinociceptive mechanisms that exert control at the spinal level. Any condition or procedure, in which the patient is in pain, discomfort, or a state of tension, may be an appropriate indication. The patient may be hypnotised by a hypnotist and/or by self-hypnosis.

Autohypnosis may help the patient feel in control of the process. Perhaps 10% (20-30% according to Maldonado & Spiegel, 2003, p. 1299) of adults are highly hypnotisable, 25% not being hypnotisable at all. There is no gender difference in hypnotisability. Hypnotisability is high for patients with PTSD, patients with pseudoseizures, and in those with severe dissociative disorders. It is said that patients with

schizophrenia, GAD, and, to a lesser degree, major affective disorder are difficult to hypnotise. The fact that a person is hypnotisable does not mean that hypnosis will be effective in that case.(Shader ea, 2003, p. 369) The *eye-roll sign for hypnotisability* (Spiegel & Spiegel, 1987) is a measurement of the distance between the lower border of the iris and the upper border of the lower eyelid (O, no change – 4, iris gone up behind upper lid and only sclera visible) when patient is instructed to gaze upward and lower eyelids. Hypnosis has had various applications, such as headaches (including migraine), bleeding (haemophilia), hypertension, asthma, the irritable bowel syndrome, stress-induced vomiting, drug-induced vomiting, duodenal ulcer (to reduce relapse rates), acute and chronic pain, dentistry, relaxation and anxiety control. Hypnosis aids recall of true and confabulated memories, and there may be a tendency to hold inaccurate memories with confidence following hypnosis.(Maldonado & Spiegel, 2003, p. 1319) Heap(1988) sees it as ‘an adjunct to therapy rather than a therapy in itself’. A number of authors deny that a state of hypnosis exists,(Wagstaff, 1981) whilst others worry about the potential for harm.(Hoencamp, 1990) Many authors are sceptical about patients’ ability to alter their immune system with hypnosis.(Covino & Frankel, 1999) The public often have exorbitant beliefs about the ability of hypnosis to ‘recover’ memories from the time of birth or even from past lives.(Maldonado & Spiegel, 2003, p. 1290) Patients should not be advised to start on a path of litigation or to confront others simply on the basis of ‘recovered’ memories.(Maldonado & Spiegel, 2003, p. 1321)

Motivational interviewing/motivational enhancement therapy has been mentioned in this text in relation to eating disorders, and alcohol and nicotine dependence. This empathic, non-judgmental approach attempts to win the patient’s active collaboration, to build a therapeutic alliance, to explore ambivalence (wavering), and examine the readiness of the client for change³³⁴². A cost-benefit analysis of change/no change is undertaken. Rather than dictating to the patient, he/she helps the patient to decide about change based on understanding/information. Common concerns, such as health status, are exploited. The *pre-contemplative* stage, where the patient has not yet considered change and may be under pressure from third parties (e.g. the boss or a spouse), is a time for empathic listening, information giving, and discussing the pros and cons for change. The *contemplative* stage is present when a client has done some thinking about the benefits and drawbacks associated with changing behaviour. Careful discussion aims at reappraisal of ambivalent thinking and bolstering of self-efficacy. The *determinative* stage simply infers that a decision to change has arrived. A course of action is discussed, as are ways of coping with the effects of change. During the *action* phase the patient must build up social skills, gather support, avoid precipitants (pubs, certain foods, etc), and continue to examine the negative consequences of reverting to former habits. Lastly, in the maintenance stage, relapse prevention strategies are employed (e.g. view transient drinking as a lapse rather a relapse to avoid catastrophising and giving up), to widen the repertoire of activities and skills, and to explore areas that might increase vulnerability to reversion to earlier maladaptive coping mechanisms.

Outcome research: Prioleau ea (1982) could find no convincing benefit over placebo for a ‘real patient’ of receiving psychotherapy and Storr (1979) and Wampold (1999) held that outcome is independent of underlying school of psychotherapy! Svartberg and Stiles (1991), in a meta-analysis of short-term psychodynamic psychotherapy, found greater changes in treated than in comparable untreated patients, but no difference in outcome for different forms of therapy. Outcome research has become more rigorous over the intervening years,(Roth & Fonagy, 1996) although Clare’s statement quoted at the start of this chapter is still held to be true by many clinicians. Knekt ea³³⁴³ (2008) compared short- and long-term psychodynamic therapies for mood and anxiety disorders and found that the former gave the quickest and the latter the best results, although they could not answer who would benefit from receiving either approach. Research should include an intention to treat analysis and also report on adverse effects such as excessive introversion, exacerbation of symptoms and acting-out behaviour. Dropouts from therapy should be followed up and reported. Compliance with somatic therapies has not been routinely monitored in comparative studies. Back in the 1950s, when psychoanalysis held sway, the typical characteristics of dropouts from therapy were described as poor, uneducated, non-integrated socially, less persevering with other treatments, and dissatisfied with treatment. Also, the stated form of psychotherapy in a published paper may not match what was given in reality.(Ablon & Jones, 2002) Controls are difficult to find for very long term therapies.(Levenson ea, 2003, p. 1171) Cuijpers ea (2010b) examined 115 RCTs of

³³⁴² The therapist points out discrepancies, ‘rolls with’ resistance, and contrasts the patient’s aims and behaviour.

³³⁴³ Helsinki Psychotherapy Study.

psychotherapy for adult depression and only 8 met the quality criteria³³⁴⁴ they had set; the resultant meta-analysis suggested that psychotherapy has significant effects but that the magnitude of such effects are much smaller than has been assumed.

Problems with randomised controlled trials and psychotherapy (Margison & Bateman, 2006)

Danger of randomising people to unsuitable treatment

Expectation of therapy influences outcome³³⁴⁵

Starts as random with small numbers and attrition thereafter (i.e. not random)

Different therapists employed who may differ in approach and adherence to protocols

Therapists rarely matched to patients³³⁴⁶

Non-specific factors influence outcome³³⁴⁷

Hard to achieve blind evaluations

Investigator allegiance influences results³³⁴⁸

Evidence-based research and psychotherapy (Bateman, 2007, p. 262)

Process-outcome research – informs on what works and how it works, maximising efficacy, improving treatment delivery

Measuring outcome – scale-derived scores (symptoms) are insufficient and batteries of measures inform more broadly on effects of therapy, e.g. change in social or interpersonal domains; must also look at avoided negative outcomes, e.g. suicide

Deciding on who measures outcome, e.g. patient satisfaction as part of the study

A *dismantling study* divides a psychotherapeutic package into component parts in order to test if the whole or part of that package is necessary to achieve the same outcome. For example, in a component analysis of cognitive-behavioural therapy, Borkovec *et al.* (2002) compared applied relaxation plus self-control desensitisation, cognitive therapy, and their combination in patients with generalised anxiety disorder and found no significant differences between them.

A potential fallacy is that treatments, including psychotherapy, administered over long periods of time may coincide with a remission or resolution rather than directly result in cure.

25

Psychotherapy with Children

26

Physical therapies

Brian O'Shea

*Electroconvulsive therapy (ECT)*³³⁴⁹

'It should not be relegated to a treatment of last resort'. (Lamprecht ea, 2005)

There is no doubt that ECT was overused in the years immediately after it was discovered, so creating an unfortunate legacy that militates against its proper use today.

Outdated ECT machine

Availability, acceptability and standards

Strenuous efforts have been made to maintain standards in the practice of ECT. (Pippard & Ellam, 1981; Latey & Fahy, 1986; Andrade ea, 1993; RCPsych' Special Committee on ECT, 1994; Fergusson ea, 2003; Fergusson ea, 2004)

1992: European Court of Human Rights ruled in *Herczegflavy v Austria* that ECT did not amount to torture (Lepping, 2003)

Main goal for the future is to discover what central effect(s) of ECT are fundamental for efficacy (Fink, 2002)

³³⁴⁹ See also O'Shea, (2007a,b) In 1937 Cerletti and Bini (published 1938) induced fits by passing an electric current (ECT) between two electrodes placed on the front of the head. Ugo Cerletti was professor psychiatry in Rome from 1935 and Bini was his assistant. After preliminary work in Rome's slaughterhouses, where electricity was already in use to stun or kill animals, their first human subject was a schizophrenic patient who appears to have benefited. Bini realised that the high mortality among dogs given electrical treatment was the fact that placement of electrodes at head and rectum led to passage of current through the heart. (Abrams, 1988) No aspect of electricity is essential to the benefit of ECT. (Fink, 2002) Indoklon (ether flurothyl) inhalation, reported first in 1958, is just as effective as ECT but is not as 'clean' a procedure (could not be combined with a muscle relaxant and often caused a second fit). Photically induced convulsions (given without anaesthetic) are possible but are not employed in practice. The psychiatrist Abram E Bennett (1898-1985) of Omaha, Nebraska was the first to use a muscle relaxant with ECT, a curare preparation, in 1940. Holmberg and Thesleff of Karolinska Institute, Stockholm, suggested using succinylcholine in 1952. Unilateral ECT was introduced by E Friedman and P H Wilcox in 1942 and was first used to minimise memory problems by J Thenon in 1956. About 20,000 people receive ECT annually in Britain. (Wise, 1997) In fact the numbers of individual ECT administrations fell in the UK NHS from 137,940 in 1985 to an estimated 65,930 in 1999. (Eranti & McLoughlin, 2003) It continued to fall in England to 2006 but the detained patients were more likely to receive it than in the past. (Bickerton, ea, 2009) The annual rate of ECT for Scotland was reported by Fergusson ea (2003) to be 142 individual treatments/100,000 of the total population. Use of ECT in the Republic of Ireland was officially reported for the first time in 2003: 859 people received this mode of treatment, although use varied by region from 38.7/100,000 in the South Eastern Health Board to 8.4/100,000 in the Southern Health Board. (Daly ea, 2004) In 24 approved centres in the Republic of Ireland in 2008 there were 407 'programmes' of ECT (9.6 programmes/100,000 population) with a national average of 6.7 treatments/programme.

Need for improvement in some procedural aspects, e.g.

Must have a designated ECT consultant in centre carrying out ECT or an ECT team (with designated members) serving a number of centres

Use of recommended machines, regular servicing of machines (Andrade *et al.*, 1993)

Better supervision of junior medical personnel³³⁵⁰

Training in explaining ECT to patients (Wise, 1997; Duffett & Lelliott, 1998; Trezise, 1998; Blaj *et al.*, 2007)

Unmodified ECT is still used in Malawi, apparently without serious complications³³⁵¹ (Selis *et al.*, 2008)

2008: *Mental Health Act 2007* (England & Wales): ECT cannot be given to a person who has capacity unless in an emergency, i.e. to save the person's life or to prevent serious deterioration in his/her condition; a 'Second Opinion Doctor' has to examine the patient; parental permission does not override the decision of patients aged 16-17 who have capacity

2010: ECT practice in Asia is suboptimal: schizophrenia is the main indication; sine wave is used; unmodified ECT is common; always bilateral; EEG use is uncommon; continuation ECT is rare; and there is no formal training (Chanpattana *et al.*, 2010), although (recent) progress is being made in Japan (Takebayashi, 2010)

ECT is still used in the USA³³⁵², especially in private facilities.(see Hermann *et al.*, 1995; Kramer, 1999), despite restrictive regulations and limited availability.(Weiner *et al.*, 2001, p. 98) Prudic *et al.* (2001) were not impressed with ECT standards³³⁵³ in a minority of New York facilities. Benbow (1991) found that most old age psychiatrists would consider using ECT in appropriate circumstances, especially for psychotic depression; most used bilateral ECT; and psychiatrists did not consider age to be a contraindication to giving ECT. Bhat (2003) predicted an increased use for ECT in elderly depressives. Although the literature consists mainly of single case reports (Rey & Walter, 1997), ECT in people under 18 years old has similar effectiveness and side effects as in adults.(Duffett *et al.*, 1999a) ECT may be under used in the intellectually disabled.(Waarde *et al.*, 2001)

Attitudes

Medical students

Have poor knowledge of ECT (Abbas *et al.*, 2007)

Often very negative about ECT (Gazdag *et al.*, 2005)

Knowledge and attitudes intermediate between MRCPsych trainees and lay public (McFarquhar & Thompson, 2008)

More positive after seeing patients receive it (Ryley & Friedman, 1991)

More positive after seeing patients receive it than simply receiving didactic instruction (Shah & Averill, 2009)

More positive after seeing patients receive it (Kinnair *et al.*, 2010)

Australian mental health nurses

Rated ECT as a treatment for depression between that of psychiatrists and lay people – they preferred medication, counselling and physical activity.(Caldwell & Jorm, 2000)

Dublin nurses, including psychiatric nurses

Poor knowledge of ECT and negative attitudes to the procedure

Exposure to ECT did not change attitudes among nursing students (Byrne *et al.*, 2006)

London mental health nurses

Exposure to ECT led to positive attitudes (Wood *et al.*, 2007)

Turkish psychiatric nurses

Education about ECT improved nursing practice and increased patient satisfaction (Arkan & Üstün, 2008)

³³⁵⁰ An 'ECT training head' (Dantec Electronics in UK, distributors for Thymatron machine) is a dummy that offers experience in giving ECT and interpreting the EEG. According to Halliday and Johnson (1995) one in five doctors were not supervised when administering ECT for the first time in New South Wales.

³³⁵¹ No oxygen, anaesthetic or muscle relaxant is used. An English ECT device manufactured during the 1960s is in use (constant current, brief pulse waveform) although 2 newer machines have been donated from Scotland.

³³⁵² ECT was originally in favour in state institutions as a treatment of chronic illnesses such as schizophrenia.(Marangell *et al.*, 2003, p. 1123) Less than 8% of all US psychiatrists provided ECT in 1998.(Hermann *et al.*, 1998) Worries have been expressed that use of ECT in the US may be in decline despite its strong evidence base.(Levy, 2007) Hungarian psychiatrists, especially those dealing with outpatients, may have negative attitudes toward ECT, although their knowledge of the treatment was found wanting by Gazdag *et al.*(2004) ECT rates have increased in Australia where it is more likely, as in many countries to be given to older people.(O'Connor, 2008, p. 201) New Zealand psychiatrists are generally well disposed to ECT although they may resort to it somewhat less regularly than do British psychiatrists.(Strachan, 2001) Public use of ECT in Hong Kong is much less frequent than in the UK and a few private practitioners were noted to be using outdated technology.(Chung *et al.*, 2003)

³³⁵³ Same electrical charge given to everyone, use of old sine wave stimulation, no monitoring of seizure duration, and failure to examine cognitive state.

Non-psychiatrist Indian doctors

More positive attitudes towards ECT if they had experienced practical work in psychiatry (Chakrabarti *et al.*, 2003) although Chanpattana *et al.* (2005) reported that about 50% of ECT was unmodified

Media

Unhelpful (O'Shea & McGennis, 1983; Andrade & Rao, 1996; McDonald & Walter, 2001; O'Shea, 2002; Dowman *et al.*, 2005; McFarquhar & Thompson, 2008; Euba & Crugel, 2009)

Patients

Most patients reported that ECT helped them; that ECT had been adequately explained; and side effects were mild or moderate (Benbow & Crensil, 2004)

69% of Australians who had ECT as adolescents would have it again if needed and 77% would recommend it to others; 92% rated depression and medication as worse than ECT (Walter *et al.*, 1999)

'A Practicing Psychiatrist' (1965) was positive about the effectiveness of ECT and philosophical about side-effects.

Donahue (2000) received unilateral ECT (changed to bilateral), believed it saved her from suicide, could not remember parts of her life, and would have it again if needed.

*Relatives*³³⁵⁴

Turkish relatives of bipolar patients had positive attitudes toward ECT (Viritt *et al.*, 2007)

'Guidance' from the UK National Institute for Clinical Excellence (NICE)³³⁵⁵ published in 2003 attempts to restrict the use of ECT to the level of a brief intervention³³⁵⁶ in severe depression, mania or catatonia.³³⁵⁷

Irish MHC (2008) definition of ECT**Medical procedure**

Current passed briefly through brain via scalp electrodes to induce generalised seizure

A programme (course) of ECT consists of no more than 12 treatments (applications)

Irish MHC (2006) rules governing use of ECT, e.g.

Written consent required for ECT session including anaesthesia

Second consultant authorisation is needed for patients unable/unwilling to consent

Alternative therapies must be discussed with the client

The initial electrical dose must be determined in advance

Cognitive function must be regularly assessed

Anaesthetist must conduct pre-anaesthetic assessment

Designated ECT nurse carries out various duties e.g. checking that assessments are completed

Irish MHC (2009a, c) rules governing use of ECT, e.g.

Capacity to consent includes understands and believes broad consequences of not receiving ECT

Patient must be told about likely adverse effects, including cognitive impairment/amnesia

Initial stimulus dose must be discussed and agreed between treating and ECT-administering consultants

Perform cognitive assessment before and after each course ('programme') of ECT – keep copies in patient's file

Unless it cannot be so, use same ECT machine for each application

Monitor EEG with 2 channels

At least 2 registered nurses must be present in ECT suite

Irish MHC (2008, 2009b) code of practice for ECT prescribed for voluntary patients³³⁵⁸

³³⁵⁴ For a positive, personal view see Webber.(2009)

³³⁵⁵ NICE: www.nice.org.uk.

³³⁵⁶ Maintenance treatment excluded.

³³⁵⁷ This was welcomed by the mental health charity MIND and by Carney and Geddes,(2003) the latter having been involved in Department of Health systematic review work on ECT, but is seen as too restrictive by most British psychiatrists. Interestingly, NICE was advised by the WHO to 'break its close links with the drug industry and to make its processes more transparent'.(Kmietowicz, 2003)

³³⁵⁸ A private proposal by Irish senators that the *MENTAL HEALTH (INVOLUNTARY PROCEDURES) (AMENDMENT) BILL 2008* amend Sections 58 and 59 of the Mental Health Act 2001 as follows has been suggested by some:

1.—That Section 58 (psychosurgery) of the Mental Health Act 2001 be deleted.

2.—That Section 59 (ECT) of the Mental Health Act 2001 be deleted and replaced as follows—

(1) A programme of electro-convulsive therapy (ECT) shall not be administered to a patient unless the patient gives his or her informed

consent in writing to the administration of the programme of therapy;

(2) The Commission shall make rules providing for the use of ECT and a programme of ECT shall not be administered to a patient except in accordance with such rules.

A named consultant psychiatrist³³⁵⁹ should have overall responsibility for ECT
 Must have patient's³³⁶⁰ written consent to ECT/anaesthesia
 Consultant psychiatrist should be satisfied patient has capacity to consent³³⁶¹
 Patient must know that consent can be withdrawn at any time
 Coercion and threats should not be used
 ECT consent form must contain at minimum the particulars included in form suggested by MHC
 A registered medical practitioner working under responsible consultant's supervision must obtain written consent prior to each application of ECT
 Information must be oral and written, clear and simple, and interpretation/sign language made available as needed
 Unless an emergency is at hand, at least 24 hours to allowed for consideration of response by the patient
 If he/she so wishes; advocacy should be granted; and questions should be answers
 Only the responsible consultant prescribes ECT and he/she records reasons for prescribing, alternatives considered, initial stimulus dose, details of discussion, and current mental status of patient
 Clinical status is assessed before and after each application of ECT
 Reason for terminating a course of ECT is to be documented
 A consultant/supervised anaesthetist should give the anaesthetic and formally have the (correct) patient identified (see original document for details of other requirements)
 Designated ECT nurse checks equipment
 Constant current, brief pulse ECT machine delivering 25 to 1,000 milli-coulombs or more
 For details of ECT suite see original document

ECT is rarely used before 16 years of age.(Parmar, 1993) It can, however, be effective in prepubertal children, e.g. for mania.(Hill ea, 1997; Willoughby ea, 1997)

Patient preparation

Patients generally forget explanations about ECT and many fear it.(O'Shea & McGennis, 1983)
 Explanations need to be repeated as required throughout a course of ECT. Some degree of apprehension is normal and does not contraindicate ECT. The patient should be told that it is usual to have a memory blank for the time surrounding a course of ECT. A printed pamphlet or booklet can be of great help to patients and relatives. A signed consent form is essential,³³⁶² perhaps repeated every 6 months for maintenance ECT. People will differ later on how valid the consent given at the time was. This has been interpreted as either placing trust in the doctor or as reflecting inadequate attempts to get true consent.(Rose ea, 2005)
 Psychiatrists may be less likely to agree among themselves when it comes to giving ECT to seemingly incapacitated (lacking capacity) but compliant patients than when giving the same treatment to capacitated and non-compliant cases.(Law-Min & Stephens, 2006) The patient should receive an adequate explanation of the procedure and the reasons why it is being prescribed, the likely consequences of the treatment, and the consequences of not receiving ECT. He may need time to think about it or to discuss it with relatives or GP. In the case of patients who are unable to sign, because of their mental (including cognitive) status or legal status the local legal requirements should be followed. The (Irish) Mental Health Act 2001 requires

A major omission in the Mental Health Act 2001 is the lack of provision for treating voluntary patients who suffer deterioration of mental status but do not seek to leave hospital.(Dunne ea, 2009) The Wards of Court system is, in the author's experience, likely to take too long to take effect and may only become involved where there is a substantial estate.

3.—This Act may be cited as the *Mental Health (Involuntary Procedures) (Amendment) Act 2008*.

³³⁵⁹ Not necessarily the patient's responsible consultant.

³³⁶⁰ Consent must be given for each ECT programme (including anaesthesia) and for each individual ECT (including anaesthesia). Specific consent must be given for *maintenance/continuation ECT* and renewed after 6 months. The patient must be made aware that if ECT is refused alternative treatment will be offered. **No one can give proxy consent for ECT.**

³³⁶¹ I.e. can understand what ECT is, why it is proposed, understand risks/benefits/alternatives and broad consequences of not receiving ECT, retain the information for long enough to make decision, and be able to communicate decision. Likely effects of ECT including 'risk of short-term cognitive impairment' must be explained. Also, it must be confirmed that alternatives treatments will be given if consent to ECT is not given. Written record of capacity assessment kept in clinical file.

³³⁶² Or a witnessed mark, or documented and witnessed statement that a patient indicates non-verbally his/her consent non-verbally. Consent is sought for a course of ECT, not just for one application. Consent can be withdrawn at any time. Rush ea (2008) reported on 89 consecutive patient who received ECT in a private Dublin hospital: an average of 17 weeks post-ECT there were low rates of perceived coercion, high rates of satisfaction with consent procedures and information and staff support.

written consent from the patient and the agreement of two consultant psychiatrists, one being the treating consultant.

Normal precautions for a general anaesthetic are taken.

ECT is safer than tricyclic antidepressants (TCAs) in patients with severe cardiovascular disease. (Zielinski *et al*, 1993) Modern ECT procedures significantly reduce the risk of adverse cardiac outcomes. (Rice *et al*, 1994)

Certain items should be checked off as part of a pre-ECT nursing check³³⁶³ and the completed record kept in the patient's notes.³³⁶⁴

Outpatients

Have a relative at the centre or one arranged for journey home

Should not drive, operate dangerous machinery, or otherwise take risks

The digit used for pulse oximetry should be free of nail polish. Medication³³⁶⁵ may be required to reduce the chances of inhalation in cases of oesophageal reflux. There should be a sheet on which the anaesthetist notes details of the drugs given and other procedures carried out, and the psychiatrist notes the effects of the ECT and the dose (millicoulombs) used. Two-thirds of the population have a seizure threshold of 100-200 mC, but the range is probably 20-800 or so. Scott (2005, p. 141) suggests that the initial dose be 50-100% and 300-500% above seizure threshold for bilateral and unilateral ECT respectively. Fochtmann *et al* (2003) suggest that optimum benefit with unilateral ECT requires stimulation that is 'at least' 5 to 6 times the threshold. Recovery from the treatment should also be noted regularly, as should response of the underlying disorder and cognitive status.

Fochtmann *et al* (2003) suggest giving beta-adrenergic receptor antagonists to minimise the risk of thyroid storm in patients with significant hyperthyroidism who are going to receive ECT; also, patients with myasthenia gravis or upper motor neurone disease should receive a reduced dose of succinylcholine³³⁶⁶.

Indications and contraindications

Patients who have responded to ECT in the past may seek ECT again should they suffer a relapse. Andrade and Kurinji (2002) reviewed the literature on continuation (direct continuation of ECT over a 6 month period following a course of ECT) and maintenance (6 months or more after a course of ECT) ECT and declared it safe and effective for relapse- and relapse/recurrence-prone patients who have responded to a course of ECT. (Frederikse *et al*, 2006; see Fink, 2007; Gupta *et al*, 2008) Continuation and maintenance ECT may be useful for otherwise refractory unipolar depressives³³⁶⁷, bipolar patients, and depressed schizoaffectives. (Russell *et al*, 2003; Vaidya *et al*, 2003) Unfortunately, patients who are unresponsive to antidepressant drugs may experience less benefit from ECT than drug-responsive subjects³³⁶⁸. (Prudic *et al*, 1996) ECT is indicated primarily for depression, especially if psychotic depression (especially with retardation and delusions – up to 90% of psychotic depressives respond). Buchan *et al*³³⁶⁹ (1992) found that deluded-retarded cases lost twice as many points on the Hamilton Depression Scale as did a group without these characteristics. However, Sobin *et al* (1996) concluded that ECT is a viable option for major depression regardless of the presence of psychosis, retardation or agitation. ECT works quickly, although its effect may not last more than an average of one month. According to Prudic *et al* (1993), the degree of residual symptomatology shortly after ECT is not different between cases of dysthymia plus major depression and

³³⁶³ Completed for each application.

³³⁶⁴ Name, age, unit, whether consent form signed, and date, psychological preparation, anaesthetic consent signed, ECT actually prescribed this time, patient fasting for 6 hours (2 hours for clear fluids; check with anaesthetist if in doubt), bladder empty (supervised – rupture is a rare risk, mainly in elderly, patients on TCAs, and prostatic obstruction), rings (on fingers) insulated (with tape), dentures removed (rare possibility of inhalation), metal objects removed (including hair pins), cosmetic removed (hair should be clean and free of cosmetics – latter can lead to singeing of hair and interfere with induction of seizure), shoes and stockings removed, personal hygiene, garments loosened, valuables safe, case notes to hand, treatment card to hand, temperature, pulse, BP, urine tested.

³³⁶⁵ E.g. ranitidine, metoclopramide, or sodium citrate.

³³⁶⁶ **Cholinesterase inhibitors prolong the effects of succinylcholine.**

³³⁶⁷ Kellner *et al* (2006) found that continuation ECT and lithium plus nortriptyline were better than placebo in preventing depressive relapse but that half the patients relapsed or dropped out of the study.

³³⁶⁸ Patients who are unresponsive to antidepressant medication should either have a change of antidepressant or augmentation with, say, lithium.

³³⁶⁹ This study combined results from the Leicester and Northwick Park trials.

major depression only. Patients with major depression plus personality disorder may respond less completely (more residual psychopathology) to ECT and relapse more readily after ECT than patients with uncomplicated major depression.(Lee & Coccaro, 2002; Feske ea, 2004)

Higher electrical dosage above seizure threshold results in more rapid response in major depression, and probably also in schizophrenia.(Sackeim, 2003, p. 536) However, it also causes more cognitive problems. ECT may still has a few important applications in schizophrenia,³³⁷⁰ catatonia,³³⁷¹ mania³³⁷² (de Macedo-Soares ea, 2005) and indeed any psychotic state where an early response is essential, when there is a danger of suicide, where there is much suffering, or when drugs are contraindicated as in the occasional case of extreme hypersensitivity, unacceptable side effects or non-responsiveness.(Duffett ea, 1999b) Combination of antipsychotic drug plus ECT may be more effective than either treatment given alone.(Sackeim, 2003; Painuly & Chakrabarti, 2006) ECT can be useful in epileptic patients who become disturbed but without developing a convulsion (often only one application is required). It may reduce the frequency of petit mal attacks and terminate *epilepsia partialis continua*. ECT appears to be safe when combined with anticonvulsant drugs, although the literature is composed mainly of case reports.(Sienaert & Peuskens, 2007) Dementia *per se* is not a contraindication to ECT although confusion after ECT can be severe and prolonged. White matter hyperintensities (and evidence of basal ganglia disorder) on MRI has been blamed for post-ECT delirium (Figiel ea, 1990), although Coffey ea (1989) achieved excellent results with ECT in older people despite the presence of such hyperintensities.(see also Coffey, 1996) Down's syndrome patients can be given ECT.

Negroes - may need screening for sickle cells (sickling crisis may be precipitated by hypoxia during anaesthesia)

High myopes - at risk of retinal detachment; ophthalmological opinion may be needed

Eye surgery – use ECT with caution during the first weeks; time is needed for wound healing; if ECT is used it is suggested that non-depolarising muscle relaxants are used, that adequate oxygen is given to decrease cerebral vasodilatation, and that the patient is hyperventilated to diminish hypercarbia; gross visual acuity and field-testing should be carried out after the first treatment (Saad ea, 2000)

*Open-angle glaucoma*³³⁷³ - ECT, although causing a transient rise in intraocular pressure, has not been reported to cause problems

Closed- (narrow-) angle glaucoma - although extremely unlikely to be referred for ECT, cases pose a much more serious proposition; expert advice should be sought;

Prescribed anti-glaucoma medications - in general these should be given before ECT (Fochtmann ea, 2003, p. 381)

Reserpine - contraindicates ECT (both treatments cause marked vagal stimulation with possibility of cardiac arrest: Bross, 1957)

Asymptomatic/stable coronary artery disease – do not stop long-term cardiac medications on morning of ECT because this will increase risk for myocardial ischaemia (Tess & Smetana, 2009)

Cerebrovascular accident – normally wait a minimum of 1-3 months³³⁷⁴ before considering ECT; poststroke depression may respond to ECT (Weiner ea, 2001, p. 13)

Anticoagulants – maintain INR of up to 3.5 unless there is an increased risk of intracranial bleeding (e.g. tumour or aneurysm: Tess & Smetana, 2009)

Brain tumour - ECT may be given if CSF pressure is normal, there is no surrounding oedema on CT, there are no indications of an organic brain syndrome, and neurological examination is normal; various manoeuvres (e.g. steroids, antihypertensives, and hyperventilation) may be used to minimise rises in intracranial pressure

³³⁷⁰ Especially acute onset, short episode duration (as distinct from illness duration), bewildered, or disturbed mood.(Sackeim, 2003) Fear (2005) suggests trying clozapine first. See Chanpattana and Andrade (2006) for a discussion of ECT for treatment-resistant schizophrenia and their response to the UK NICE report.

³³⁷¹ From almost any cause, although benzodiazepines are first choice for the less severe case. Fear (2005) suggests ECT as first-line treatment for malignant catatonia.

³³⁷² Especially mixed mania-depression and severe mania. Clozapine plus ECT may be the ultimate treatment for highly refractory mania.

³³⁷³ Anticholinesterases with long duration of action may prolong apnoea from succinylcholine and should be replaced by alternative drugs for a period before giving ECT.(Weiner ea, 2001, p.41)

³³⁷⁴ Depending on literature source and stroke severity. Every case requires an individual risk-benefit assessment.

Asthma or COPD – taper and stop theophylline; continue other medication; for exacerbations before ECT give inhaled beta-agonists and, if needed, corticosteroids (Tess & Smetana, 2009)

Chronic steroid patients – although often given extra ‘stress doses’ before general anaesthesia evidence from 27 patients (Rasmussen et al, 2008a) suggest that this is not necessary before ECT treatments, i.e. simply give the usual morning dose before ECT

ECT may improve *Parkinsonism* or associated depression, or both³³⁷⁵

The serum prolactin declines as ECT proceeds: it rises with each ECT but the rise is blunted with subsequent ECTs.

Relative contraindications³³⁷⁶ to ECT

Raised intracranial pressure

Aneurysms in awkward places or of large size (repair first if possible, but many cases have proved durable, e.g. Mueller et al, 2009; short-acting IV medications³³⁷⁷ may be used to control BP: Drop & Welch, 1989; Tess & Smetana, 2009)

Active chest infection

Recent myocardial infarction³³⁷⁸ or CVA³³⁷⁹

Non-demand pacemaker³³⁸⁰

Uncontrolled hypertension³³⁸¹

Untreated pheochromocytoma

Critical aortic stenosis³³⁸²

Unstable fracture

Odontoid process erosion (rheumatoid)

Threatened retinal detachment³³⁸³

Some authorities inhibit the defibrillator function of an implanted cardiac defibrillator during each ECT treatment³³⁸⁴ and some clinicians anticoagulate such patients to prevent mural thrombi being dislodged. Cardiac transplants do not contraindicate ECT if cardiac function is normal. (Weiner et al, 2001, p. 37) Renal dialysis patients requiring ECT should have their electrolyte levels normalised and, if possible, ECT should be given on the day following a dialysis session. (Pearlman et al, 1988)

³³⁷⁵ Patients on levodopa live longer but the treatment is associated with the ‘on-off syndrome’ of abrupt swings to marked relief of symptoms (‘on’) and to total immobility (‘off’). The latter responds to ECT (maintenance treatments may be needed – subcutaneous apomorphine is an alternative treatment). ECT in these circumstances might work by inducing effects on prolactin levels or via increased dopamine receptor sensitivity. Kellner and Bernstein (1993) have made several recommendations concerning the employment of ECT in Parkinson’s disease patients: use in severe, drug-refractory cases who give informed consent and understand that the effects are transient and limited; half the dose of levodopa and stop adjunctive medication (as prophylaxis against dyskinesia and delirium); unilateral ECT is tried (switch to bilateral if no response after three treatments); stop ECT after maximum effect is achieved or after six treatments if no improvement is noted; put the patient back on his pre-ECT medication and dosages after the course of ECT; and, finally, consider maintenance ECT.

³³⁷⁶ Depending on urgency of the case.

³³⁷⁷ E.g. beta-blockers, sodium nitroprusside, and hydralazine (Tess & Smetana, 2009). One should seek neurological/neurosurgical/anaesthetist consultation. Smaller aneurysms (< 10 mm in diameter) appear to be safer than larger ones.

³³⁷⁸ Cardiac reserve should be assessed because the heart works harder during ECT. Uncontrolled cardiac failure is a relative contraindication to ECT; try to avoid ECT within 3 months, especially if severe MI.

³³⁷⁹ In fact, many cases have been treated with ECT with low rate of complications. (Hsiao et al, 1987) Tess & Smetana (2009) suggest delaying ECT for at least 1 month post-stroke and that BP should be tightly controlled to minimise hypertension (haemorrhage) and hypotension (ischaemia).

³³⁸⁰ Some clinicians use a magnet to convert a demand pacemaker to a fixed mode to prevent triggering of a pacemaker during ECT.

³³⁸¹ Delay ECT advised by Tess & Smetana (2009). They would start antihypertensive treatment if BP is 140/90 or more (unless there was a recent CVA) but they would avoid beta-blockers lest there is interference with efficacy of ECT. Stable chronic hypertension with BP of < 140/90 is managed by continuing patient’s usual antihypertensive drugs through the morning of ECT.

³³⁸² Repair before ECT to avoid ventricular overload during seizure. However, O’Reardon et al (2008) gave ECT to a 96-year-old with this condition without untoward event (ventricular ejection was normal at 70%). Tess and Smetana (2009) suggest echocardiography to assess severity of stenosis; there is some data to suggest that ECT is safe with use of short-acting beta-blockers to reduce hypertension and tachycardia during ECT.

³³⁸³ Seek ophthalmologist’s advice, avoid head movement during ECT, and consider blunting rise in blood pressure during electroplexy.

³³⁸⁴ Taking care to preserve the pacemaker function. ECT may convert atrial fibrillation to sinus rhythm.

Patients with obstructive sleep apnoea (OSA) should ideally be subjected to adequate sleep laboratory investigation (including establishment of optimal continuous positive airway [CPAP]) and the employment of measures to counteract OSA (weight loss, CPAP, mandibular advancement device, ENT surgery) before giving ECT. However OSA may be discovered during emergency use of ECT (or the aforementioned tests and treatments may not be readily available or take too much time to work) and, in such cases, lengthy ventilation with 100% oxygen should precede general anaesthesia. Additional options are insertion of a nasopharyngeal airway, night-time CPAP, mandibular advancement device and, in extreme cases, tracheostomy.(McCall ea, 2009)

Monoamine oxidase inhibitors (MAOIs)

Various authors recommend stopping them for periods ranging from 10 days to 6 weeks

Most authorities do **not** now think that MAOIs (or TCAs) contraindicate ECT (e.g. Wells & Bjorkstein, 1989; Weller, 1992; Metzger, 1999; Weiner ea, 2001; Marangell ea, 2003, p. 1124; Alpert ea, 2004, p. 257; Scott, 2005, p. 111)

Do not give sympathomimetic drugs if the patient is taking an MAOI

Fochtmann ea (2003) suggest that concerns among anaesthesiologists regarding hypertensive reactions in patients on MAOIs arise from the use of indirect sympathomimetic agents during emergency surgery and they view this as being irrelevant in the case of ECT. However, the anaesthetist must be consulted. The largely North American practice of stopping antidepressants, such as TCAs, is currently 'undergoing reconsideration'.(Weiner ea, 2001, p. 89, Fochtmann ea, 2003, p. 380) Stopping such drugs during a course of ECT has not been popular in these islands. The present author has (thankfully) experienced no problems combining ECT with SSRIs, TCAs or lithium (see Jha ea, 1996; Kellner & Bourgon, 1998; Stewart, 2000; Papakostas ea, 2000) and there is some evidence that suicide risk (Brådvik & Berglund, 2000) and relapse (Sackeim ea, 2001) are reduced by continuing antidepressant drugs or lithium after ECT. This author continues antidepressants as long as they were or could be helpful, especially with in-patients. Less ill out-patients might commence a new antidepressant after a course of ECT is over. Sackeim ea (2009) found that the efficacy of ECT was increased by concomitant antidepressant medication with less cognitive dysfunction than when placebo was used; however, nortriptyline was superior to venlafaxine and tended to worsen cognitive function. There have been some concerns that lithium may be associated with delirium, catatonia or prolonged seizures, although opinion is 'divergent'.(Weiner ea, 2001, p. 83; Scott, 2005, p. 111, Fochtmann ea, 2003, p. 380) and Welch (2008, p. 638) states that lithium is 'usually safe'. Neither is there any good reason for stopping antipsychotic drugs during a course of ECT.(Weiner ea, 2001, p. 18; APA, 2002, p. 417; Braga & Petrides, 2005) Until more data is available, caution is suggested in patients taking bupropion because of reports of seizures in patients on high doses.

Some indications mentioned for ECT by year

1943. Intractable epilepsy³³⁸⁵

1945. Delirium

1950. Stauder's lethal catatonia

1953. Refractory delirium

1954. Anorexia nervosa³³⁸⁶

1967. Mental disorders associated with SLE

1972. Alcoholic delirium

1977. Mental disorders secondary to enteric fevers

1981. Phencyclidine delirium

1984. OCD refractory to medication

1987. In cases of intracranial shunt, shunt patency should be checked before ECT

1989. Mood congruent delusions or psychomotor retardation

1989. ECT used safely for major depression in AIDS.

1991. Catatonia secondary to a general medical disorder

1992. Depression in multiple sclerosis³³⁸⁷

1994. HIV-associated stupor

³³⁸⁵ ECT is effective for status epilepticus,(Cline & Roos, 2007) although it may also induce it.

³³⁸⁶ Series of 19 cases.

³³⁸⁷ Whilst ECT is effective in such cases, a minority, according to Krystal and Coffey,(1997) may show some neurological deterioration.

1995. Mental disorders in head injury patients

1996. Chronic pain due to affective disorders

1997. ECT can be given in presence of aortic stenosis if left ventricular function is normal

1999. NMS with psychotic symptoms (CPK range: 777-18,5000; normal = 0-70 IU/L)

2000. Eight cases in the literature where ECT was given to patients with intracranial masses, none with bad outcomes: an individual risk-benefit analysis should be performed; successful treatment of depression in the fortnight following CVA

2001. ECT in depressed patients with intracranial metal objects (e.g. shrapnel) or a metallic skull plate (place electrodes equidistant from defect)

2003. Forced normalisation as a possible indication³³⁸⁸; ECT improved depression in suspected cases (N = 7) of Lewy body dementia

2005. ECT to produce remission of tardive dystonia (blepharospasm) in a case of treatment-refractory schizophrenia

2008. Major depression with psychotic features in elderly female with advanced Parkinson's disease and in situ deep brain stimulator

2009. Bipolar affective disorder I with psychotic symptoms in Fahr disease

Complications

With adequate precautions significant problems are rare.

Possible complications

Manic/mixed state switch in bipolar depression³³⁸⁹

Headache³³⁹⁰

Myalgia³³⁹¹

Confusion³³⁹²

Amnesia

CVA

Status epilepticus³³⁹³

‘Scoline apnoea’³³⁹⁴

Aspiration pneumonia

Pulmonary embolism

TB flare up

Worsened neurological status in neurosyphilis

Subconjunctival haemorrhage

Epistaxis

Peptic ulcer bleed

Compression fractures of mid-dorsal vertebrae

Fractured limb bones

Dislocated jaw

Broken teeth

Bitten tongue

Fat embolism

Myocardial infarction, cardiac arrhythmias, angina, congestive cardiac failure

Aspiration pneumonia (rare) may be more likely in those patients who have gastroparesis due to diabetes mellitus, hypothyroidism³³⁹⁵, amyloidosis, connective tissue disorders or gastric tumours, and emptying the stomach with a nasogastric tube may be necessary prior to anaesthesia.

³³⁸⁸ The present author has used ECT successfully for this condition in a small number of cases.

³³⁸⁹ This occurs in about 7% of cases. One may either continue the ECT treatment or stop ECT and use medication to treat the mania/mixed affective state.

³³⁹⁰ May be vascular and may respond to intranasal sumatriptan, a 5-HT 1B/1D agonist.(Markowitz ea, 2001) However, in my experience, post-ECT headache is responsive to minor analgesics such as paracetamol. The same medication takes care of any muscle aches due to the muscle relaxant.

³³⁹¹ This responds to paracetamol. Rasmussen ea (2008b) found no correlation between myalgia following ECT and either convulsive movements or dose of succinylcholine.

³³⁹² Anticholinergic load of medication may contribute and may come from classical sources (e.g. TCAs) or less obvious ones (e.g. warfarin or prednisone).

³³⁹³ If seizure lasts > 2 minutes consider IV diazepam or more induction agent – Abrams, 1992; lorazepam is preferred by many authorities;(Weiner ea, 2001) Phenytoin or fos-phenytoin can be used if the former agents fail. The anaesthetic agent can also be used.

³³⁹⁴ Tests for pseudocholinesterase deficiency are too sensitive for screening purposes, giving many false positives.

³³⁹⁵ ECT raises TSH levels during treatment, but phototherapy does not affect thyroid function tests.(Sit & Rothschild, 2002)

If a beta-blocker³³⁹⁶ is used to control ECT-induced rises in blood pressure and heart rate it is advisable to add an anticholinergic agent such as atropine to prevent possible asystole³³⁹⁷. Some authorities use labetalol (Trandate), a short-acting blocker of both alpha and beta receptors, to prevent tachycardia. Nifedipine (Adalat), a calcium channel blocker given sublingually before anaesthetic induction, has been used in at-risk cases to prevent excessive rises in blood pressure during ECT.

Postictal delirium affects a minority of patients and usually abates in much less than an hour. It may occur with one or all treatments. Reassurance, gentle restraint, nursing in a quiet area, and, when necessary, medication (diazepam, midazolam, haloperidol) are the basis of management. Promethazine 25-50 mg orally two hours before ECT may prevent post-ECT agitation.(Vishne ea, 2005) A reduction in the electrical dose or frequency of ECT treatment may be required.

Postictal delirium

Agitation
Disorientation
Uncooperative with staff
Amnesia for the episode (usually)

Insulin requirements before and after ECT were not significantly altered in one study of diabetics.(Netzel ea, 2002) One approach is to hold the morning dose of insulin until after the treatment.(Welch, 2004, p. 107) Tess & Smetana (2009) suggest measuring blood glucose pre- and post-ECT, giving 50% of the usual dose of long-acting insulin the morning of ECT, withholding oral agents until the patient can eat, giving short-acting insulin to correct increases in blood glucose, and giving ECT early in the morning if possible. Burns, usually superficial, should be very rare. Rarely one may encounter unilateral (Mason, 1955) or bilateral (O'Shea ea, 1996; O'Shea, 2001) foot drop for which many theories have been proposed, e.g. pressure on the common peroneal nerve when the patient is held down under anaesthesia. Maximum output from an ECT machine delivers a current that could raise brain temperature by 10% of a degree centigrade. This is insufficient to cause electrical injury³³⁹⁸.(Swartz, 1989)

Mortality

Deaths are most often attributed to cardiovascular and cerebrovascular mechanisms.

ECT and death

Early Danish study - 1 death/22,000 treatments
1981 RCPsych (RCPsych) report - 1 death/2,600 courses (a course consisting of an average of 5-6 separate treatments; 8-9 for major depression in USA: Weiner ea, 2001)
1994 RCPsych estimate - 1 death/50,000 treatments (same figure as Fink, 1978)
ECT is 10 times safer than having a baby in the USA
Weiner ea (2001) - mortality rate from ECT declined over the years; suggested that it is currently likely to be 1/10,000 patients and 1/80,000 treatments
Lightening kills 6 times as many Americans as does ECT
Death rate from ECT estimated to be less than spontaneous death rate in USA (Abrams, 1997)

Nuttall ea (2004) conducted a review of ECT at the Mayo Clinic³³⁹⁹. 2,279 patients received 17,394 ECT treatments between 1.1.1998 and 31.12.2001 (median number of applications of ECT/patient = 7). 21 patients (> 1%) experienced complications during the first series of ECT treatments (mostly cardiac, especially arrhythmias), none leading to permanent sequelae. No one died immediately after ECT. 18

³³⁹⁶ Some authors avoid beta-blockers because of a couple of reports that it reduces the efficacy of ECT by shortening seizure duration.
³³⁹⁷ Asystole has been reported in resistant depression treated with venlafaxine (>300 mg/day) ECT and using propofol.(Gonzalez-Pinto ea, 2002)

³³⁹⁸ In cardioversion 200-400 joules are delivered in a second, and may be repeated. Typically, ECT requires 40-50 joules (max 110 joules) delivered over a number of seconds.(Maixner & Taylor, 2008, p. 72)

³³⁹⁹ Rochester, Minnesota.

people died within 30 days of the final treatment, “none related to ECT” (suicide, lung abscess, stroke, cancer, etc). The authors concluded that ECT was extremely safe.

A Danish study (Munk-Olsen *et al*, 2007) compared inpatients that had and had not received ECT: death from natural causes was reduced in those receiving ECT but they had a slightly higher suicide rate (especially in the first week after ECT).

Elderly

Old age as such does not preclude ECT (O'Shea *et al*, 1987; Tomac *et al*, 1997; Gormley *et al*, 1998; Tew *et al*, 1999; Scalia *et al*, 2007; O'Reardon *et al*, 2008) although confusion may last longer following ECT. This author normally gave ECT thrice weekly except in the elderly where he gave it twice weekly³⁴⁰⁰. There is some evidence that a thrice weekly frequency may be superior in terms of speed of clinical response. (Sackeim, 2003, p. 538) Recent guidance on optimal ECT frequency for the generality of patients is ‘twice per week’ and ‘probably twice per week’ for bilateral and unilateral ECT respectively³⁴⁰¹. (Scott, 2005, p. 141) It is the present author's experience that it is wrong to stop ECT if in the middle of a course the patient becomes confused, the depression has not yet lifted, and there is no other cause for the confusion (e.g. infection). Access to physiotherapy is important when giving ECT to old people or those with low respiratory reserve. Higher dose of muscle relaxant than usual may be needed in cases with osteoporosis. Although data is scarce, Andrade *et al* (2007) suggest that (at least younger) schizophrenic patients are not at increased risk of fracture from ECT. Elderly and arthritic patients may require spinal X-ray films before ECT.

Bowley and Walker (2005) suggestions:

ECG - cardiovascular disease, irregular pulse, heart murmur, hypertension, respiratory or kidney disease, diabetics aged over 40 years, and anyone over 50

Chest x-ray - suspected chest infection, cardiomegaly, congestive cardiac failure (CCF), pulmonary embolism, suspicion of fractured ribs (e.g. after a recent fall)

Association of Anaesthetists of Great Britain and Ireland (2000) require (mandatory):

Automated non-invasive blood pressure monitoring

ECG

Pulse oximetry

End-tidal carbon dioxide

More treatments are cancelled because of failure to fast (including sips of water) than through physical illness. (Bowley and Walker, 2005, p. 125)

Repeated courses of ECT, or even maintenance ECT³⁴⁰², may be necessary where maintenance pharmacotherapy does not prevent relapses.

Pregnancy

The Irish MHC (2006, 2009b) mandate that all pregnant patients be assessed by an obstetrician before receiving ECT, that resources are available to handle emergencies in mother and baby, and that foetal monitoring is used if the first trimester has passed. Aspiration is more likely in pregnant than in non-pregnant patients. Weiner *et al* (2001) suggest that a wedge be placed under the patient's right hip if the pregnancy is greater than 20 weeks duration in order to displace the womb from the great vessels. The antimuscarinic glycopyrrolate³⁴⁰³ appear to be relatively safe during pregnancy whereas atropine causes foetal tachycardia, variable heart rate, and may mask foetal distress. Sodium citrate may be used to reduce the risk of gastric regurgitation. ECT does not precipitate labour. Succinylcholine does not cross the placenta. The uterus is not involved in the muscle contractions of the seizure.

Mechanism of action

The antidepressant action of ECT increases with each application until a plateau is reached.

³⁴⁰⁰ The usual frequency of ECT is twice weekly in Britain and thrice weekly in the US.

³⁴⁰¹ In practice it is a trade off: twice weekly + slower response or thrice weekly + cognitive problems. (Kay & Tasman, 2006, p. 926)

³⁴⁰² Every 1-4 weeks, depending on individual response.

³⁴⁰³ Used, e.g., as topical cream for excess sweating in cases of diabetic autonomic neuropathy.

Possible mechanisms

Animal studies - ECT causes an increase in post-synaptic receptor sensitivity (see O'Shea *et al*, 1983)³⁴⁰⁴

Virtually all neurotransmitter systems are affected by ECT

Enhanced serotonergic responsivity - increase in fenfluramine-induced plasma prolactin levels after ECT; increases in CSF 5-HIAA and HVA; increase in plasma tryptophan

Stain-Malmgren *et al* (1998) stated that there may be an increase in platelet 5-HT₂ receptor density in drug-refractory depressives following ECT, i.e. up-regulation of such receptors, an effect opposite to that associated with antidepressant drugs, which downregulate 5-HT₂ receptors. Yatham *et al* (2010) reported a decrease in brain 5-HT₂ receptors in depressed individuals following ECT, an effect similar that caused by antidepressant drugs, and the authors suggest that ECT's ability to down-regulate brain 5-HT₂ receptors in drug-resistant depressives may explain its efficacy in such cases.

Decreased melatonin production

Many antidepressant drugs, and ECT, are known to downregulate postsynaptic beta-adrenergic receptors. Platelet alpha-2-adrenoceptors appear to be supersensitive in depression, and ECT seems to downregulate these receptors (Werstuck *et al*, 1996)

Fall in plasma noradrenaline levels may be associated with improved depression ratings in DSM-III-R melancholic or psychotic depression (Kelly & Cooper, 1997)

No association between non-suppression on DST and either immediate outcome or outcome at 6 months after ECT (Scott, 1998)

Whilst ACTH and plasma cortisol levels may rise acutely following ECT these levels may fall during the course of ECT, suggesting down-regulation of HPA axis (Grunhaus *et al*, 1987)

A relatively post-ECT high afternoon plasma cortisol level might increase risk of relapse (Cooper *et al*, 1995)

ECT may work by increasing brain-derived neurotrophic factor (BDNF) levels, a neuroprotective agent that promotes neuronal growth and synaptogenesis³⁴⁰⁵ (Reid, 2005; Taylor, 2008)

Neuropeptide release may also be therapeutic. ECT might act by augmenting inhibition by TRH and related peptides of hyperactive glutamatergic subcortical limbic neurones in depression

ECT may affect G-protein coupling to receptors, activity of adenylyl cyclase and phospholipase C, and the regulation of ionic calcium into nerve cells

Cerebral blood flow is increased immediately with ECT³⁴⁰⁶, followed by postictal hypoperfusion - the latter persists after a full course of ECT, and the degree of acute reduction in blood flow, especially in the frontal cortex, may predict response, non-responders showing no decline in flow (Trimble, 1996)

Anticonvulsant drugs are used as mood stabilisers and ECT increases the seizure threshold.³⁴⁰⁷ An anticonvulsant action may be important for the therapeutic potential of ECT, perhaps by augmenting glutamate-mediated synaptic transmission in the hippocampus by neuropeptide Y. Azuma *et al*, (2007) using 30 consecutive depressed in-patients who had not responded to standard medication, gave bilateral ECT in either sine or pulse wave mode and examined EEG parameters: postictal suppression was the only significant predictor of treatment outcome when baseline HAM-D and mode of stimulation were controlled for. Fink *et al* (2008) reported on 80 patients receiving continuation treatments after successful ECT: seizure threshold did not change in 70%, increased in 21%, and fell in 9% at remission, i.e. seizure threshold did not rise conclusively with remission; whilst results failed to support the anticonvulsant hypothesis for ECT the authors admit to 'numerous limitations' in procedures that may have limited their findings, e.g. seizure threshold was not measured for a week after the end of treatment.

³⁴⁰⁴ A refractory hallucinating patient on IM haloperidol decanoate developed EPS immediately following the seizure and stopped hallucinating. It should be noted that increased blood-brain barrier permeability is increased by ECT but returns to baseline within 24 hours. (Maixner & Taylor, 2008, p. 72)

³⁴⁰⁵ A number of studies indicate that electroshocks (ECS) increase synaptic connectivity. Chronic ECS more than single ECS causes mossy fibre sprouting and neurogenesis in hippocampus.

³⁴⁰⁶ Cerebral blood flow during ECT (using PET) for depression increases chiefly in basal ganglia, brain stem, diencephalon, amygdala, vermis, and frontal/temporal/parietal cortex – soon after ECT it increases in thalamus and decreases in anterior cingulate and medial frontal cortex. (Takano *et al*, 2007)

³⁴⁰⁷ Rasimas *et al* (2007) found that women had longer seizures than men (but only at first treatment session), that there was a strong inverse correlation between age and seizure length, and that the only significant drop in seizure duration was between the 1st and 2nd treatments, seizure duration remaining relatively constant thereafter.

In 10 people with psychotic depression given ECT, PET showed that relief of depression was associated with increased metabolism in the left subgenual anterior cingulate gyrus, and antipsychotic action correlated increased left hippocampal metabolism.(McCormick ea, 2007)

Cytokines IL-1 β and IL-6 are released after ECT, possibly due to neuronal depolarisation.(Lehtimäki ea, 2008)

Increased access to remote episodic memories, so aiding re-establishment of personal identity.(Frais, 2010)

In a small study (7 males, 2 females), inhibiting synthesis of both noradrenaline (using alpha-methyl-tyrosine) and serotonin (using tryptophan-free amino acid mixture) following successful treatment of major depression with ECT led to no significant changes in depression scores casting doubt on the theory that catecholamine and (the indoleamine) 5-HT availability is necessary for maintaining the initial antidepressant response to ECT.(Cassidy ea, 2010)

Three basic designs have been used to show that ECT works: controls given anaesthetic but no ECT, controls given nothing at all, and ECT compared with other treatments. Brill ea (1959) found repeated induction of unconsciousness to be as effective as real ECT. However, only 16 of 97 patients were depressed. The remainder of this mostly chronic group was suffering from schizophrenia or schizoaffective disorder.

Seizure activity in the brain is necessary for the clinical effectiveness of ECT.(Brandon ea, 1984; Freeman ea, 1978; Johnstone ea, 1980) Lambourn and Gill (1979) did not find real ECT better than sham ECT but their methodology has been criticised.(Weiner ea, 2001) A meta-analysis confirmed that ECT is superior to medication and simulated ECT.(Kho ea, 2003) The important component of the seizure is the *clonic* phase, and a jerk produced by the current should not be mistaken for a fit. Some authors (e.g. Malitz & Sackeim, 1986) and many clinicians believe that higher doses of electricity are more effective than lower doses despite the fact that both produce a seizure.(Dubovsky ea, 2003, p. 496) Also, simply having a generalised fit of adequate generation may not be sufficient to treat depression: the dose of electricity and the electrode positioning appear also to be important.(Sackeim, 2003, p. 536)

The seizure

The fit is equally effective no matter if just enough energy or more than enough energy is used to induce it. Therefore use the minimum amount of electrical energy required to induce a convulsion. One can reduce the amount of energy by a perpendicular rise and/or fall in stimulus amplitude to maximise the amount of energy transmitted at peak amplitude. An ECT instrument should be used which generates a discontinuous pulsatile waveform rather than a continuous sine wave³⁴⁰⁸. Constant current, brief pulse equipment giving a train of voltage pulses constitutes a more satisfactory physiological stimulus. An Indian study found that lower (50 pulses/second) was more efficient in inducing a seizure than was a higher (200 pulses/second) stimulus pulse frequency (the lower frequency caused a greater reduction in seizure threshold) and there were no significant cardiovascular responses between the two frequencies.(Girish ea, 2003) Most modern machines produce a uniphasic (one direction only) or biphasic brief-pulse current.³⁴⁰⁹ The ECTRON series 5 (a constant current apparatus) delivers an average effective stimulus of about 275 mC (Millicoulombs) over 3.25 sec. The stimulus intensity (i.e. mC/sec.) is therefore only about one-sixth that of the sine wave stimulus.

An 'adequate' seizure (on EEG) is said to last 25-30 (some say 20-50) seconds, although this author has seen many patients recover with much briefer seizures,(see Nobler ea, 1993; Kales ea, 1997) and there is increasing consensus that seizure duration is not be related to the efficacy of ECT.(Sackeim ea, 1991; Weiner ea, 2001, p. 83; Dubovsky ea, 2003, p. 496; Whitehouse & Scott, 2005, p. 161) As noted by Barnes,(2005) 'shorter seizures may be acceptable if the patient remains well'. Kho ea (2004) found that high seizure energy index³⁴¹⁰ predicted rapid response in major depression. Until this debate is resolved seizure duration of at least 15 seconds is desirable. EEG seizure activity is often of greater duration than observable motor convulsive activity. Non-convulsive seizures or status epilepticus may only be seen on the EEG. The EEG tracing may contain a lot of muscle artefacts³⁴¹¹ and suxamethonium-induced twitching

³⁴⁰⁸ A practice that, unfortunately, has not entirely caught on.(Sienaert ea, 2005)

³⁴⁰⁹ Today's ECT machines deliver very brief (1-2 msecs) pulses (< 70 pulses/sec) of direct current in series.

³⁴¹⁰ Mean integrated amplitude x seizure duration.

³⁴¹¹ Including those caused by the anaesthetist, e.g. when applying a face mask.

may be mistaken for the clonic phase of the seizure.³⁴¹² A successful ECT shows responses on the EEG tracing over both hemispheres³⁴¹³ indicating generalisation. The disparity between seizure adequacy as measured by observed motor activity or EEG activity is probably small.(Ratthalli et al, 2009)

Typical EEG response to ECT (chronology)

Latent phase - low amplitude, high frequency, polyspike activity

Increase in amplitude of polyspike activity and progressive slowing

Clonic phase

3 Hz spike and wave pattern

Progressive loss of spike and wave activity

Termination of seizure activity usually indicated by suppression: greatly attenuated activity following the high-amplitude sharp and slow seizure activity

Seizures with unilateral ECT are asymmetrical with higher ictal EEG amplitudes over the stimulated hemisphere than over the other hemisphere. Theophylline, an adenosine antagonist like caffeine, can prolong seizures in a patient undergoing ECT (as can caffeine, aminophylline, and several other drugs, incl. SSRIs), sometimes seriously so, but its use is confined to the research arena. When maximum electrical stimuli fail to produce a seizure ('missed or abortive seizure') etomidate (or possibly ketamine³⁴¹⁴) may be employed.(Patel et al, 2006) Hydration and hyperventilation are also useful strategies.(Datto et al, 2002; McCall, 2002) Electrode handsets with both electrodes joined onto a single stem have the electrodes placed far too close together. Shorting may occur due to excess scalp moisture and may be a reason for lack of a seizure. Rarely (Weiner et al, 2001, pp.19, 88) clozapine causes a prolonged seizure.(Bloch et al, 1996)

Procedure

A firm surface and private surroundings are required, as are assistants to hold the patient down at the shoulders and pelvis. An oxygen source (brain oxygen requirements increase during a seizure; oxygen lowers seizure threshold, i.e. amount of electrical energy needed to produce a grand mal seizure; and the fall in pCO₂ lengthens the duration of the seizure), Ambu bag, mouth gag and suction apparatus should be available. 100% oxygen is given before and after induction of the seizure. Hyperoxygenation does not harm the patient with chronic chest problems when given for brief periods only.

If the patient fails to have a good seizure after the initial stimulus, then the patient should be hyperoxygenated and consideration should be given to whether the settings on the machine should be increased by, say, 25% – but poor electrode contact with the scalp is the commonest culprit!

Interestingly, the APA Task Force on ECT (Weiner et al, 2001, p. 130) does not recommend the use of a plastic airway³⁴¹⁵ because of a perceived risk of dental or jaw injury. Instead they suggest the use of a bite-block.³⁴¹⁶

The dose of electricity is described in units of charge (Coulombs) rather than energy (Joules) because the former is independent of the variable impedance of patients and is more closely related to both the desired therapeutic and the unwanted cognitive effects. Ohm's law states that voltage = current x resistance; voltage varies as a function of resistance/impedance³⁴¹⁷. A constant current is recommended. Constant voltage or constant energy devices are not recommended.(Weiner et al, 2001) The convulsion is usually induced using a machine with automatic timing and a choice of waveforms. The minimum stimulus needed

³⁴¹² The initial tetanic stimulation of the masseter by the electrodes should not be mistaken for less than adequate muscle relaxation..

³⁴¹³ Therefore use two electrodes, one over each hemisphere.

³⁴¹⁴ There is some evidence that ketamine may cause less cognitive problems than other anaesthetics.(MacPherson & Loo, 2008)

³⁴¹⁵ E.g. Guedel.

³⁴¹⁶ The present author's former centre has employed a Guedel-type airway for years without adverse results. This author also remembers seeing psychiatrists using the heel of a shoe as a bite-block! Whatever is used there should be no sharing of the same item by patients.

³⁴¹⁷ Increased impedance necessitates an increased voltage to maintain a constant current.

to produce a generalised convulsion is applied, e.g. 140 volts for half a second. Passage of the stimulus should be accompanied by an audible or visual signal.³⁴¹⁸

A typical good ECT suite consists of waiting, treatment and recovery. Staff should be friendly, expert, and known to the patient. Piped music³⁴¹⁹ may help to calm a nervous patient.

Atropine

May or may not be given before anaesthesia

Given subcutaneously, atropine will not block the vagus and will simply dry the mouth

Usual dose (0.3-0.6 mg sc or 0.4-1.0 mg IV) gives some degree of vagal blockade but unreliable reduction in secretions

May exacerbate post-seizure hypertension and tachycardia

Large doses may cause confusion or psychosis, and uncomfortable dry mouth

Glycopyrrolate

0.2-0.4 mg IM, SC, or IV)

Does not cross blood-brain barrier

Dries secretions

Does not cause psychiatric symptoms

Leaves blood pressure unaltered

Attenuates deoxygenation and extreme bradycardia due to acute effect of ECT (Rasmussen ea, 2007)

Caffeine pretreatment is not recommended.(Scott, 2005, p. 113)

Resistance (impedance) is increased in line with skull thickness. Using information from a skull x-ray, it has been suggested that one place the electrodes over the thinnest part of the skull. Skin resistance must be reduced with a salt-water solution or electrojelly³⁴²⁰ rubbed into the area where the electrode pad is to be placed. Then an IV anaesthetic is given.

Dose titration (stimulus dosing)

Technique for determining correct amount of electricity required for a bilateral seizure

When using 'test' facility on ECT machine the apparatus is in test mode, i.e. it passes a small amount of electricity between the electrodes and informs about the static impedance of the head - if it is too high it is likely that the dynamic impedance is also too high, i.e. the machine will be unable to deliver the correct amount of electricity to the patient

Static impedance will be high if there is poor contact between electrodes and scalp

Electrodes should not be moved prior to delivering ECT after using the 'self-test' facility because the operator may significantly alter static impedance

Thiopentone (thiopental) causes a prolonged sleep (slow recovery) whereas methohexitone sodium has less anticonvulsant effects and has a lesser tendency to induce cardiac arrhythmias³⁴²¹. Methohexitone is associated with quick induction and recovery and was recommended by the RCPsych (RCPsych' Special Committee on ECT, 2002) and by Laidlaw (1995), but availability has been compromised; the dose is 0.75 mg/Kg; seizure threshold is increased at doses over 1.5 mg/Kg with the potential for non-therapeutic seizures. Methohexitone sodium (Brietal) was withdrawn from the Irish market in 1999, and it later became unavailable in the USA.(Kellner, 2003)

Propofol³⁴²² infusion syndrome

³⁴¹⁸ It should be noted that, unlike the situation in the USA, European machines are capable of high output, i.e. > 576 mC.(McCall, 2002) This is because the FDA limits the electrical output of ECT machines, a measure with particular implications for unilateral ECT.(Maixner & Taylor, 2008, p. 63)

³⁴¹⁹ Classical and soft.

³⁴²⁰ Similar to the jelly used for an ECG.

³⁴²¹ It should be noted that Rosa ea (2007) found no difference between etomidate, propofol, and thiopental when used as anaesthetics with ECT.

³⁴²² Causes of green/blue urine include propofol, biliverdin, pseudomonas UTI, Hartnup disease, cimetidine, amitriptyline, methylene blue, indomethacin, and food colouring.(Leclercq ea, 2009)

Various cardiac dysrhythmias Metabolic acidosis Hyperkalaemia Rhabdomyolysis Acute heart failure
--

In fact, postictal dysrhythmias may be less common with propofol than with thiopental. (Bowley & Walker, 2005) Controversially, (Laidlaw, 1995) the RCPsych opposed using propofol (Diprivan) in 1994 because of a tendency to increase the seizure threshold (Nally, 2002; Datto ea, 2002; but see Scott & Boddy, 2002; Geretsegger ea, 2007) or shorten the duration of seizures,³⁴²³ although these may not affect therapeutic outcome³⁴²⁴, (Fear ea, 1994; Datto ea, 2002; Scott & Boddy, 2002; Bauer ea, 2009) and it may be useful in patients who experience prolonged seizures from ECT and to minimise post-ictal nausea and vomiting. (Bailine ea, 2003) The findings of Okonkwo ea (2005) and Bauer ea (2009) suggest that propofol use may necessitate the employment of a somewhat higher dose of electricity that that needed when thiopentone³⁴²⁵ is used, and Patel ea (2006) report longer ECT courses with propofol than with etomidate. Also, the number of ECT applications per course may be increased. Scott & Boddy (2002) found no difference between propofol and methohexitone in terms of the median number of treatments (8) or the median initial seizure thresholds (75 mC) within courses. Nevertheless, propofol should be avoided in paediatric populations because of concerns raised over deaths in American ICU patients.³⁴²⁶ Not only does propofol reduce seizure length³⁴²⁷, it also reduces the extent of haemodynamic change accompanying ECT, e.g. blood pressure rises less than with methohexitone/methohexital. (Geretsegger ea, 2007) Addition of the ultra-short-acting opioid remifentanyl to propofol³⁴²⁸ reduces the required dose of the latter and increases the postictal suppression index³⁴²⁹. (Porter ea, 2008c) Rasmussen ea (2009) found³⁴³⁰ no real increase in seizure length when remifentanyl was added to thiopental, a finding echoed by Nasser ea. (2009) Concern has been raised concerning abuse of propofol, despite its narrow therapeutic index, by US healthcare professionals, sometime with fatal results. (Charatan, 2009) Abuse leads to a dissociative state with euphoria. Propofol was implicated in the death of singer Michael Jackson in 2009. As pointed out by Hartle and Malhotra (2009), the drug is safe when used for legitimate reasons.

Etomidate may increase seizure duration, increase extraneous muscle movements, cause local pain at the injection site, and rarely induce adrenocortical dysfunction after repeated dosing. (Benbow ea, 2002) Stadtland ea (2002) and Khalid ea (2006) suggest switching from propofol to etomidate if seizure duration is too short or seizure threshold is very high. The importance of seizure duration on the effectiveness of ECT is not now seen as being of such great importance as it was in the past (Weiner ea, 2001; RCPsych Special Committee on ECT, 2002) and, indeed, etomidate has been accused of prolonging seizures! (RCPsych' Special Committee on ECT, 2002) Also, Erdil ea (2009) found that the QT interval was shortened by propofol and lengthened by etomidate and propofol controlled the haemodynamic response better during ECT than did etomidate. A muscle relaxant is given after the anaesthetic via the same needle. The most commonly employed drug is the depolarising agent succinyl choline³⁴³¹ (Scoline) e.g. 25-40 mgs³⁴³². This should be drawn up late to avoid decay.

With depolarising muscle relaxants like succinylcholine, the button is pressed when muscle fasciculation³⁴³³ has **stopped**, e.g. at the chin or legs.

The most common sites for EEG recording during ECT are frontal-frontal³⁴³⁴ or frontal-mastoid montages.

³⁴²³ Measured 'from the end of electrical stimulation to the end of generalised convulsive muscular activity' by Scott & Boddy. (2002)

³⁴²⁴ Having to employ a higher electrical charge might increase the likelihood of cognitive dysfunction.

³⁴²⁵ Ingram ea (2007) found thiopentone to be associated with greater efficacy and less cognitive dysfunction when given with ECT to depressed patients (n = 30).

³⁴²⁶ The latter was to be investigated by AstraZeneca. (Irish Medicines Board, 2001)

³⁴²⁷ By up to 63% compared with methohexital.

³⁴²⁸ Or to methohexital for that matter. (Porter ea, 2008) If the clinician wishes to prolong a seizure he/she might consider using methohexital or short-acting opioid plus propofol. (Hooten & Rasmussen, 2008)

³⁴²⁹ Which might increase clinical response.

³⁴³⁰ Retrospective study of 56 cases.

³⁴³¹ Suxamethonium chloride.

³⁴³² Higher doses would obscure any clinical observation of seizure activity.

³⁴³³ Caused by the muscle relaxant.

³⁴³⁴ Frontal = at least one inch above midpoint of eyebrow.

Seizure threshold increases during a course of ECT by about 80% requiring, for example, an increase in mC requirement of 200 to 360.

Seizure threshold

Increased

ECT (bilateral > unilateral)

Males

Elderly

Reduced

Children and adolescents (Kellner et al, 1997)

Weiner (1994) suggests that the charge should exceed threshold by 150-250% and 50-100% for unilateral and bilateral ECT respectively. A stimulus just above threshold is less likely to be therapeutic than a higher intensity stimulus (especially with unilateral ECT), although very high intensities are more likely to cause adverse cognitive effects.

Excessive dose of an induction agent³⁴³⁵ will shorten seizure duration. BZDs, L-tryptophan, and centrally acting beta-blocking drugs may abbreviate a seizure. The time-honoured practice of giving one or two extra treatments after recovery is controversial but still practiced. The evidence does not support this practice. (Sackeim 2003, p. 538) ECT should be certainly stopped if a manic swing is discerned.

A post-ECT recovery suite should be available where the patient is nursed in the recovery position.

Preparation and after-care is the same as for any operation involving a general anaesthetic.

*Hamilton cuff method*³⁴³⁶

Sometimes used to ascertain that a fit has occurred

Blood pressure cuff is inflated well above systolic pressure (on the same side as the electrodes in unilateral ECT) after the anaesthetic is given and before the muscle relaxant is administered

Convulsive movements may be seen in the isolated arm

Opinion is divided its usefulness (Wise et al, 2000)

Physiological changes following ECT

After the first treatment there is a short period of episodic delta (δ) activity on the EEG. As the course progresses delta activity may become continuous with the addition of some theta (θ) waves. Persistence of prefrontal δ and θ activity may be associated with a good response to ECT. (Sackeim et al, 1996) After about 2-3 months from the time of the last treatment all patients will have normal EEG patterns, earlier for unilateral than bilateral ECT. Normalisation may only take a few days in some people, especially if they have received unilateral treatment.

ECT and sleep

Increased REM sleep

Decreased REM latency

Decreased total sleep time

If atropine is not used to block vagal activity there will initially be a bradycardia whilst the current is being passed and during the seizure which follows. This is due to vagal slowing of the heart and is followed, over the next 2-3 minutes, by a tachycardia. If atropine premedication is given there will be no slowing of the pulse and a lesser degree of tachycardia. Blood pressure changes mirror alterations in pulse rate. Routine premedication with a benzodiazepine should be avoided.

The circulation of blood in the brain increases tremendously during either a spontaneous fit or ECT.

Animal studies, where electric shocks are used to induce fits, have shown a great increase in the

³⁴³⁵ Especially propofol.

³⁴³⁶ This should not be used in people with sickle cell disease because sickling will occur distal to the inflated cuff. Also, care is required in the presence of other problems, such as peripheral vascular disease. It is important that the cuff pressure is well above systolic pressure because this rises during the seizure.

permeability of the blood brain barrier to a number of substances (e.g. horseradish peroxidase) while blood pressure is raised.(Duncan & Todd, 1991)

ECT and neurochemicals

Rapid rise in the serum cortisol for a few hours after ECT

Most, but not all, pituitary hormones increase in the plasma after ECT

Prolactin is the hormone most consistently and extensively released in response to ECT (bilateral > unilateral)

Although growth hormone is often elevated after noxious stimuli it is unresponsive to ECT and levels may even fall (these findings do not seem to be due to general anaesthesia)

Oestrogen-stimulated neurophysin (ESN) has no known physiological function but its plasma concentration provides an accurate guide to oxytocin release with the advantage of easier detection and a longer half-life.

Unilateral v bilateral

Unilateral treatment is given to the non-dominant hemisphere.³⁴³⁷ In practice unilateral ECT is nearly always given over the right cerebral hemisphere. Bilateral electrodes are placed in the bifronto-temporal position³⁴³⁸. Unilateral electrodes may be placed in a number of positions³⁴³⁹ but the recommended position is for the first electrode to be placed as for bilateral ECT and the second electrode to be placed just ipsilateral to the midline near the occiput.³⁴⁴⁰ The electrodes should be large enough not to cause a focal fit and wide enough apart to cause a generalised seizure. Firm contact is mandatory.³⁴⁴¹ A second person's help is needed when giving unilateral ECT: the head needs to be turned to the side so as make the parietal part of the head available and the head should be rested on a pillow.

Slightly more unilateral than bilateral treatments may be required in order to achieve a similar level of symptom relief. However, Sackeim *et al* (2000) found an equal response rate (65%) from *high dose* right unilateral ECT and bilateral ECT, and cognitive side effects were less with the former electrode settings. Memory impairment and post-ictal confusion are less pronounced with unilateral than with bilateral ECT. It was originally believed that right-sided ECT gave a better antidepressant effect but the same effect, from this viewpoint, is probably achieved no matter which hemisphere receives the treatment. Horne *et al* (1985) randomly assigned depressed patients to either bilateral or unilateral ECT on a double-blind basis and controlled seizure length by EEG. When seizures lasted less than 25 seconds in duration ECT was immediately given again. Both groups improved equally. If ECT had not been given again in these cases then the unilateral ECT group would have had significantly more missed seizures. Memory loss was obvious in the bilateral group but was not apparent in the nondominant unilateral group. Detailed examination of memory in severe depression before, during and after bifrontotemporal ECT (last assessment at 1 month post-ECT) using the CANTAB battery (Falconer *et al*, 2010) found significant impairments in visual and visuospatial memory during ECT and for the week following ECT, most impairment resolving within 4 weeks post-ECT, but significant impairment in spatial recognition memory were still there at the end of the study. It would be worth following up these patients (N = 24) to see if such problems persisted further and whether affected patients were at risk of relapse. Severely depressed patients who are treated without ECT should ideally be studied over the same time course for comparison purposes. On balance, the RCPsych (1995) favoured bilateral over unilateral ECT, but seemed to change its mind later.(Scott, 2005) From a purely practical point of view, one is surer of what one is doing and what one expects to achieve with the bilateral option (Kellner & Fink, 2002) and, as stressed by Copolov and Mitchell (2007, p. 575) one should not dispense with ECT before trying bilateral treatment. Maixner and

³⁴³⁷ **Methods of finding dominance** include unilateral ECT (first few treatments given on alternate sides – test verbal facility after recovery – less pronounced problems when given on non-dominant side), EEG (greater α rhythm suppression in dominant hemisphere during verbal thought), dichotic listening and visual techniques (simultaneous presentation of different, neutral information to both ears or visual fields – information presented to side opposite to dominant hemisphere is better received), handedness (ask a patient to catch a ball, use a scissors or eating utensils), position of holding a writing implement and injection of sodium amytal into the carotid artery on one side (**Wada test**: temporary speech loss when injected ipsilateral to dominant hemisphere). fMRI may eventually replace the Wada test.

³⁴³⁸ 2-4 cm above the midpoint of a line drawn between the lateral canthus of the eye and the external meatus/tragus of the ear.

³⁴³⁹ E.g. the Lancaster position.

³⁴⁴⁰ Or 4 cm on the right side of the head along a coronal line joining the tragi of the ears.

³⁴⁴¹ See RCPsych' Special Committee on ECT (1994) and Scott (2005) for further details.

Taylor (2008, p. 73) concluded that cognitive gains are insufficient to favour unilateral over bilateral ECT. If the patient fails to respond to unilateral ECT, try bilateral treatment. (Rosa ea, 2006) In one postal questionnaire study, Scottish psychiatrists (61% response rate) viewed bilateral ECT as more effective than unilateral ECT and placed remission ahead of other considerations. (Brown, 2009)

Predicting response

The more chronic the depression the less response is to ECT. ECT but not elective cholecystectomy increases ESN levels. It was suggested that a significant rise in ESN levels following ECT might predict recovery from depressive illness. (Scott, ea, 1986) Cooper ea (1985) found a fall in plasma noradrenaline following ECT was associated with improvement in depression. Depressed patients show a rise in blood glucose and plasma insulin levels after each treatment; insulin but not glucose response attenuates over the treatment course; and greater attenuation of insulin response at the fifth (final) treatment may predict relapse. (Williams ea, 1992) According to Devanand ea (1995) higher pre-ECT plasma GABA levels may predict a good response to ECT and these levels tend to fall with ECT. However, Esel ea (2008) state that depression is associated with low serum GABA and such levels are increased³⁴⁴² with ECT! Sackeim ea (1996) reported that the induction of prefrontal slow-wave activity correlated with symptomatic improvement in major depression. Kho ea (2004) found that high baseline HAM-D score and high seizure energy index³⁴⁴³ were each associated with rapid response in DSM-IV major depression.

Memory impairment

Benbow (2005, p. 172) lists associations with adverse cognitive effects of ECT: sine-wave, bilateral ECT, high stimulus intensity relative to seizure threshold, short interval between treatments, certain drugs (like lithium), and high-dose anaesthesia. Animal studies have shown brain damage due to electroshock but the method used was different from that used in psychiatry. Animal studies also demonstrate that ECT does not produce the same behavioural or neurochemical changes as spaced multiple ECT given in clinical practice. Fraser and Glass (1980) studied 29 elderly patients, aged 64-86 years, treated with ECT and found that they all had impaired memory function *before* treatment. Plotkin ea (1985) have demonstrated that poor subjective memory is significantly related to depressive symptoms in elderly patients. Improvement in depression paralleled improvement in memory regardless of whether they received tricyclics or group psychotherapy. People who recover from severe depression have impaired cognitive function irrespective of treatment. (Brodaty ea, 2001) Severe, untreated depression has a far more deleterious effect on cognition than that caused by ECT. (Wilkinson ea, 1993) ECT reduces knowledge about the world (**impersonal [public] memory**, e.g. events in the news) compared with knowledge about the self (**personal [private] memory**, i.e. autobiographical), for recent compared with remote events, and for less salient events; bilateral ECT has these effects more than right unilateral ECT, especially for impersonal events. (Lisanby ea, 2000) The change from sine wave to brief pulse ECT has been said to reduce amnesic effects (Lamprecht ea, 2005) although it has not removed the risk entirely and, whilst memory improves with time long-term data are needed. (Ingram ea, 2008) Abraham ea (2006), in a retrospective study, reported that maintenance ECT given to patients with refractory depression who had responded satisfactorily to a course of ECT only developed 'limited and tolerable' memory difficulties. The relationship between subjective reports and objective findings are weak, although methods of testing memory may not be optimal. A systematic review of articles with patients' views after receiving ECT found that at least one-third of patients reported persistent memory loss. (Rose ea, 2003) Mood state strongly influences the nature of reports. (Prudic ea, 2000) Despite discrepancies between subjective and objective memory complaints, it is important not to ignore either perspective. (Vamos, 2008) The UK Review Group, (2003) a part of the NICE³⁴⁴⁴ report, suggested that we do not have a clear quantitative estimate of the degree of short-term cognitive impairment associated with ECT or how much it may persist following symptomatic recovery.³⁴⁴⁵ A Kentucky woman of 89 who had received at least 1,250 ECTs during life showed no evidence of brain

³⁴⁴² Plasma GABA is a useful indicator of brain GABA because nearly all GABA production occurs in the CNS. Research suggests that a proportion of (major) depressed people have decreased plasma GABA levels and that ECT may increase GABA in sub-cortex or hippocampus, but tricyclic antidepressants may not change plasma GABA levels. See Dunlop and Nemeroff (2007) for review of review of reduced dopaminergic neurotransmission in major depression.

³⁴⁴³ SEI = mean integrated amplitude x seizure duration.

³⁴⁴⁴ National Institute for Clinical Excellence (NICE) in the UK.

³⁴⁴⁵ Kellner and McCall (2003) found the tone of the UK Review Group's interpretation to be 'cautious to the point of ambivalence' and wondered if 'we are still paying the price for the [over-] enthusiasm for ECT during the 1940s and 50s'. See also Rush ea (2007) who address the APA (consider ECT early) and NICE (strict reservations that may restrict access) guidelines.

damage at postmortem. In fact, her old leucotomy lesion had shown some attempt at healing! There is no significant association between past ECT and large ventricular-brain ratios. Neither does there seem to be a relationship between the rise in blood pressure after ECT and subsequent cognitive or affective change. Semkovska and McLoughlin (2010) conducted a systematic review and meta-analysis of 24 different standardised neuropsychological tests performed pre- and post-course of ECT and found that ECT-associated cognitive deficits were temporary and that performance on most tests were better after than before the treatment. Retrograde memory function was not included in this meta-analysis.

Summary of research on ECT and memory/cognitive function

1975. Use of brief pulse stimulation (instead of sine wave) can reduce memory impairment.

1980. Some patients have continuing memory problems that appear to be explained by continuing mood symptoms or substance/alcohol abuse.

1986. Reversible and transient memory loss for the 3-4 weeks around the period when ECT was administered was the most common finding.

1990. No evidence of cognitive dysfunction on any task in depressed patients tested at least 6 months post-ECT

Treatment factors increasing adverse cognitive sequelae: sine wave (brief pulse is preferred), bilateral ECT, very high stimulus intensity, excess frequency of ECT, more than one seizure/session, concomitant psychotropics, and high doses of anaesthetics.

1991. No measurable cognitive dysfunction found at longterm follow-up of patients given several courses of ECT.

Patients with normal pretreatment cognition retained this after ECT and those with poor pretreatment cognitive function showed improvement in such function after ECT.

Prospective MRI study finds no evidence of structural brain damage after repeated courses of ECT.

1993. Brain imaging pre- and post-ECT in depressed subjects find no evidence of brain damage attributable to ECT.

High electrical dosage associated with more rapid response, and unilateral ECT associated with less severe post-ECT cognitive dysfunction.

4-year follow-up of elderly major depressives: normal cognition pre-ECT associated with stable cognition over time and pre-treatment cognitive dysfunction improved over time.

1994. Review of CT, MRI, autopsy, animal studies, cell counts, etc – no evidence of structural brain damage from ECT. Cognitive deficits are transient, although ‘spotty memory loss’ may persist for events surrounding the ECT course.

ECT did not reverse the reduced cerebral blood flow found in major depression – ECT, in fact, reduced perfusion further.

TRH infusion given after third or fourth treatment may reduce cognitive deficits in depressed patients.

Basal ganglia disease, such as Parkinson’s disease, renders the patient prone to post-ECT confusion.

1995. Patients with major depression who manifest global cognitive impairment pre-ECT and who experience prolonged disorientation in the acute postictal period may be the most vulnerable group to the development of persistent retrograde amnesia for autobiographical information.

1996. Severe depression, especially in elderly, can affect memory; tests of memory pre- and post-ECT may show improvement.

1997. Single case study (> 400 treatments): cognitive effects no greater than with acute treatment and seem to be non-progressive.

1998. No significant difference between twice and thrice weekly ECT in ‘major depression, endogenous subtype’ but faster response and greater memory impairment with thrice weekly ECT.

2000. Bifrontal electrode placement is as efficacious as bitemporal electrode placement in the treatment of major depression and it causes less cognitive impairment.

Right unilateral ECT at up to 500% suprathreshold equals effect of bilateral ECT at 150% above threshold, but with less severe and persistent cognitive effects.

Antidepressant and cognitive effects of ECT increase with rise in stimulus dose relative to initial seizure threshold, up through 8-12 times that threshold.

Bifrontal ECT may have less cognitive side effects than bitemporal ECT: note that authors recommend giving ECT at threshold level.

2003. In a study of maintenance ECT v maintenance pharmacotherapy, no difference was found in neuropsychological functioning – cognitive function remained stable during maintenance ECT.

2004. Bitemporal electrode placement may be more efficacious than bifrontal placement, but it may cause modestly greater cognitive impairment.

Depressives treated with ECT in Australia did not show a deterioration in cognitive functioning.

Quality of life and function improved within first month after ECT in people with major depression in North Carolina; improved function relates to better cognition, and better quality of life is due to improved mood.

2006. Donepezil associated with quicker post-ECT cognitive recovery.

2007. Mangaoang and Lucey suggest treating post-ECT memory problems, e.g. compensatory strategies.

Postal questionnaire sent to 89 consecutive ECT patients at St Patrick’s Hospital, Dublin; 51 (57%) response; 44 would have ECT again; 35 reported at least modest improvement; 60% complained of subjective cognitive impairment.

Unipolar depressives: Bilateral ECT mainly influenced everyday memory (small decrease), which improved significantly at 3-month follow-up; semantic memory³⁴⁴⁶ had a fluctuating but recovering (more so in elderly) course; both types of memory are influenced by age and electrode placement.

2008. Autobiographical memory impairment follows ECT, objectively improving within 6 months but subjectively being more persistent.

³⁴⁴⁶ Semantic memory is a structured record of acquired facts, concepts, and skills.

ECT used safely and effectively for agitation in Alzheimer patients (chart review) – 9 of 11 had improvement or remission of agitated behaviour; 7 cases had no noted side effects; other cases showed urinary retention (1 case), atrial fibrillation requiring cardioversion (1), increased somnolence (1), decreased cognition (1), and idiopathic mild increase in serum amylase (1).

Research on bifrontal ECT to date is inadequate because non-specific cognitive measures (e.g. MMSE) have been employed and emphasis has been put on memory which is a temporal lobe function.

Tardive seizures may relate to use of lithium, paroxetine, thioridazine, theophylline, ciprofloxacin, and beta-lactam antibiotics (including piperacillin and cefotiam) although other factors may contribute, e.g. prolonged ECT seizure, electrolyte disturbance, neurological disorder, or benzodiazepine withdrawal.

Takotsubo cardiomyopathy (stress-induced acute coronary syndrome in absence of coronary artery stenosis associated with catecholamine surge) followed ECT (diagnosed by apical ballooning on cardiac imaging that resembles takotsubo [octopus fishing pot in Japan]; the patient also had Loeys-Dietz syndrome (inherited disorder of connective tissue predisposing to aortic dissection).

2010. Bitemporal (150% seizure threshold), bifrontal (150% seizure threshold) and right unilateral (600% seizure threshold) electrode placements are effective in treating depression when electrical dose is appropriate; bitemporal gives faster antidepressant response; there is little cognitive difference between the two bilateral placements.

Left and right hippocampi increased in size on MRI after ECT was given to depressed patients who received ongoing medication – they were a mixture of resistant cases, relapse despite medication, and a minority with only 2-4 weeks of medication.

It has been suggested that piracetam³⁴⁴⁷, given as 5 mg IV before ECT, may decrease memory loss and allow quicker recovery from the anaesthetic. However, Tang ea (2002) found no significant effect with piracetam on ECT-induced memory disturbance. A multivitamin preparation given IV (e.g. Pabrinex) has also been advocated for this purpose.

There is no agreement on the best way to monitor peri-ECT cognition. Options are discussed by Porter ea (2008a) who suggest baseline testing, after the third and sixth applications, and 2-3 months post-ECT. Testing should be performed at a standard interval following treatment. A mood rating scale (e.g. MADRS) should be performed at each of these time points, as should time to reorientation. Also, a cognitive battery is to be used that looks at global cognitive function (*MMSE*), retrograde memory (*Autobiographical Memory Questionnaire – short form*), new learning (*Hopkins Verbal Learning Test*), and psychomotor speed (*Digit-Symbol Substitution*).³⁴⁴⁸ The same group (Porter ea, 2008b) used a somewhat different group of tests to look for memory problems during ECT and, unsurprisingly, found significant problems ‘as early as 3 treatments’ but with ‘no evidence that these changes correlated with longer term changes’.

Repetitive transcranial magnetic stimulation (rTMS)³⁴⁴⁹

In rTMS pulses of high voltage current passed through an electromagnetic coil held against the scalp generates a rapidly alternating electric field which induces an electric current within the brain that can depolarise neurones to a depth of about 2 cm from the coil surface. The flow of current in the brain is parallel with but in the opposite direction to the current in the coil. This procedure has been used to transiently improve movement in Parkinson’s disease, to map cortical function, to inhibit overactive epileptogenic areas, and to decrease compulsive urges in OCD (with some dissenters on OCD, e.g. Sachdev ea, 2007). Whilst there is some evidence for an anxiolytic effect with rTMS, studies conducted to date have employed many different protocols and tend to lack a placebo-controlled design. (Zwanzger ea, 2009) There is evidence of improvement in depression,³⁴⁵⁰ (Klein ea, 1999; Loo ea, 1999; McNamara ea, 2001; Schutter

³⁴⁴⁷ Piracetam-2-oxo-1-pyrrolidine acetamide, a similar molecular structure to GABA.

³⁴⁴⁸ This seems to the present author to be onerous for both patient and doctor, although Porter ea (2008) suggests that ‘relatively non-specialized staff according to local resources’ might alleviate the latter problem! A shorter form but standard form of testing is needed.

³⁴⁴⁹ **TMS:** Electricity is converted to magnetic fields which the brain re-converts into electrical currents. Tissues, including bone, resist the flow of electrical current but not the passage of magnetic fields. Such fields meet cerebral neurones with resting potentials and the flow of electrical current is induced. Because the skull is highly resistant to electrical current a high dose of electricity causes only a small passage of current in the brain and may cause heat and pain *en route*. However, magnetic fields are unimpeded by the skull and changes to electric current in the brain.

³⁴⁵⁰ Is right prefrontal or left prefrontal rTMS superior for depression? Gershon ea (2003), in their overview of rTMS, suggest that left prefrontal treatment is most likely to be antidepressant. Whilst, Loo ea (2003) found rTMS to be no better than sham treatment in the treatment of resistant major depression, Fitzgerald ea, (2003) in their double-blind, sham-controlled study, found that treatment for at least four weeks is necessary to produce clinically meaningful benefits in depressed patients. Fitzgerald ea (2006) reported efficacy for the sequential application of high-frequency left-side rTMS and low-frequency rTMS to the right prefrontal cortex in patients with treatment-resistant major depression, treatment response accumulating to ‘meaningful level’ over 4-6 weeks of active therapy. Reid ea (1998) expressed concern that depression may reappear soon after stopping treatment and wondered if maintenance therapy might be needed. Martin ea, (2003) in their review and meta-analysis, found trials of rTMS to be of low quality and to provide insufficient evidence to support the use of rTMS in the treatment of depression. Patra and Coffey (2008, p. 502) stated that trials were of low quality and were not convincing, and that statistical significance (see Milev ea, 2009) might not translate into clinical significance, but

ea, 2009) but, at least for severe depression, perhaps not as good as that for ECT (Eranti ea, 2007) and rTMS may not augment or accelerate the response to antidepressant medication. (Herwig ea, 2007) Mogg ea (2008) found no difference between adjunctive rTMS to left prefrontal cortex and sham rTMS for depression. Fitzgerald ea (2008) state that most studies of rTMS in major depression have used high-frequency treatment to the left prefrontal cortex but that low-frequency rTMS to the right prefrontal cortex also has antidepressant effects, their work supporting these findings. Left temporoparietal cortical application may benefit hallucinations in schizophrenia especially if rTMS is applied to the dorsolateral prefrontal cortex (DLPFC). A single trial suggests that rTMS may have antimanic properties. (see McNamara ea, 2001 for review) Schulze-Rauschenbach ea, (2005) in a study comparing unilateral ECT (mean 9.9 treatments, s.d. = 2.7) and rTMS (the patient could choose between them), found no adverse memory effects from rTMS. Rasmussen (2008) reviewed the literature and reported that ECT was of superior efficacy to rTMS for major depression and called for larger RCTs directly comparing ECT with rTMS. rTMS may cause scalp pain from muscle spasm, hearing loss due to loud clicks (use ear plugs), possible subtle cognitive defects, possible manic switching, and seizures. (Sherman, 1998; George ea, 1999) However, Anderson ea (2006) exposed healthy young men to high doses (12,960 magnetic pulses/day for up to 3 days in one week) of rTMS without causing significant side effects and Loo ea (2007) used rTMS twice daily safely for major depression.

Contraindications (Milev & Mileva, 2010) include pregnancy (lack of data), ferromagnetic material (e.g. aneurysm clips) in the head (mouth excepted), increased intracranial pressure, epilepsy, cardiac pacemaker, severe cardiovascular or other disease.

Magnetic seizure therapy (MST)

This is rTMS deliberately given at high dosage in order to induce seizures (under anaesthesia), albeit more focal than those induced by ECT. MST-induced seizures are however generalised but with relatively low ictal EEG amplitude and postictal suppression. MST is generally well tolerated, has less adverse effects and faster recovery of orientation than unilateral ECT. 100 Hz MST over the vertex elicits seizures in most patient whereas the same procedure applied over the prefrontal midpoint is much less likely to do so. (Kirov ea, 2008) The cognitive impairments associated with MST are similar to ECT in some ways (verbal fluency, memory for temporal order – prefrontal functions) but less in others (e.g. memory for recent events and category fluency – temporal lobe). (Mantovani ea, 2008, p. 88) Further work is required to measure its antidepressant efficacy.

Transcranial direct current stimulation (tDCS, direct current polarisation)

This non-invasive method of electrically polarising cortical cells delivers a direct current (1-3 mA) via scalp electrodes. Cortical function is increased and decreased by anodal and cathodal stimulation respectively. Non-synaptic modulation of resting membrane potentials (involving NMDA among others) is the proposed mechanism of action. Changes in cortical excitability continue post-current for a period of time that is related to current duration. Tingling may be felt near the electrodes. There is some evidence that tDCS improves verbal fluency, word recall, and manual weakness in stroke cases. Anodal stimulation over the dorsolateral prefrontal cortex (20 minutes/day over 5 days) improved depression in one RCT. (Fregni ea, 2006) Further research is required.

Vagus nerve stimulation (VNS)

Vagal nerve³⁴⁵¹ stimulation (VNS), approved in the US for refractory partial-onset epilepsy and long-term management of treatment-resistant severe depression, is undergoing trials for refractory depression, bipolar cases (including rapid-cycling: Marangell ea, 2008), anxiety, bulimia, migraine and Alzheimer's disease. (Shuchman, 2007) As used for epilepsy, VNS is delivered with a device surgically implanted in the

that evidence for efficacy was growing. rTMS did not alleviate treatment-resistant OCD in a study involving daily left dorsolateral prefrontal cortex (over 10 sessions) stimulation. (Sachdev ea, 2007) Reductions in YBOCS scores may be related to relief of depression.

³⁴⁵¹ Vagal sensory afferent cell bodies in nodose ganglion send data to nucleus tractus solitarius. The latter sends information via ascending projections to forebrain (via parabrachial nucleus and locus coeruleus – these connect with many areas involved in mood modulation). It was noted early on that VNS given for epilepsy affected mood.

chest³⁴⁵² which delivers electrical impulses to the limbic system via the vagus nerve in doses of 0-3 mA for 30 seconds every 5 minutes. Neurologists noted that their patients felt better independent of improvement in seizures. (Mann, 2001) VNS changes blood flow in frontal, cingulate and thalamic areas. VNS seems to increase noradrenergic, serotonergic, and dopaminergic neurotransmission. Onset of action is slow and the therapeutic effect increases over time. There is evidence, albeit 'uncertain', (Patra & Coffey, 2008, p. 503) from open trials for its efficacy. (Rush ea, 2000; Corcoran ea, 2006) More rigorously conducted research is awaited, (Matthews & Eljamel, 2003b) and more needs to be learned about side-effects like vocal cord palsies. Because antidepressant effects tend to accrue over weeks to months, the use of VNS for maintenance treatment of chronic depression may be more fruitful than its use as an acute measure. (Patra & Coffey, 2008, p. 503)

VNS is not a contraindication to ECT. (Sharma ea, 2009)

Deep brain stimulation (DBS)

Low voltage electrical stimulation of target areas³⁴⁵³ via stereotactically placed electrodes³⁴⁵⁴ is used to modulate transmission in specified cerebral pathways. It has been used for movement disorders (e.g. essential tremor; Bilateral globus pallidus DBS (Damier ea, 2007) and DBS and bilateral posteroventral pallidotomy have produced useful results in severe tardive dyskinesia: Mattay and Casey, 2003, p. 567), Parkinson's disease (DBS of subthalamic nucleus has been used since the 1980s), pain syndromes, and epilepsy. DBS in the anterior limb of internal capsule offers a possible new way of treating refractory OCD (Nuttin ea, 1999: anterior limbs of internal capsules; ventral caudate nucleus) and depression (subgenual cingulate gyrus; ventral caudate nucleus). The mechanism of action is not known but might be related to enhanced activity of GABA. Potential adverse effects include intracerebral haemorrhage, peri-operative confusion, both related to surgery. During stimulation there may be problems with speech or eye movement, paraesthesia, and muscular contractions.

Sleep deprivation (wake therapy)

Both TCAs and MAOIs suppress REM sleep. Early research suggested that depressives did not improve if they failed to experience significant REM rebound. Depressives may improve with sleep deprivation. Deprivation of REM sleep³⁴⁵⁵ leading to alleviation of depression was reported in the late 1960s. If an animal was awakened before each episode of paradoxical sleep it began to show increased activity in all areas. Some reports suggested that total sleep deprivation could produce improvement in 'endogenous' depression. The duration of relief from depression varied. A faster response to clomipramine was found if the patient was deprived of sleep for one night before starting the drug.

During the late 1960s it was theorised that REM sleep was primed by metabolites of 5-HT and was triggered by ACh and noradrenaline. It is possible that sleep deprivation might work by increasing brain 5-HT. Clomipramine blocks 5-HT re-uptake into the presynaptic neurone. However, this is not a major function of many effective antidepressants.

Tests have shown that extroverts show greater amount of rebound after REM deprivation than do introverts. One of the major problems with attempts to treat mood disorders with sleep manipulation is the transient effect of any of the approaches employed to date. Also, staying awake requires motivation.

Psychosurgery/Neurosurgery

Reports of improvement in mental state date back to at least medieval times. Phineas Gage (1848) was respected railway foreman. Unfortunately, he had a crowbar driven through his frontal lobes. After this he became careless, uninhibited and unemployable. Ferrier, in his 1875 Croonian Lecture, reported that the removal of a large part of a monkey's frontal lobes led to tameness and docility with no sensorimotor deficits. In 1935 Fulton and Jacobsen reported that frontal lobectomy had a tranquillising effect in primates suffering from behavioural disorders due to an 'experimental neurosis'. In 1936 Moniz started to study ways in which

³⁴⁵² A small stimulus generator is placed beneath the clavicle and a lead from this is wrapped around the **left** vagus in the neck (the right nerve is avoided because it gives parasympathetic branches to the heart). The generator is programmed to deliver a fixed duration of stimulation, say 0.5 minutes every 5 minutes. The patient may cough or be hoarse during stimulation.

³⁴⁵³ E.g. the subgenual cingulate area (Brodman's area 25).

³⁴⁵⁴ Electrodes are connected to a battery or stimulator in the chest wall.

³⁴⁵⁵ Keep patient awake during second half of normal sleep span.

interruption of certain brain pathways (thalamo-frontal) could be used to control abnormal behaviour. Freeman³⁴⁵⁶ and Watts, a neurologist and neurosurgeon respectively, and others were responsible for refinements in technique. Modern stereotactic psychosurgery, such as Yttrium seed implantation, has two main aims: relief of severe, continuous or recurrent mental anguish due to psychiatric illness, and reduction of abnormal aggressiveness (as with amygdalectomy). The main indication in the past for psychosurgery was for intractable schizophrenia, but these people did least well, although schizoaffective disorder may be improved. The best results were achieved in depression with associated anxiety or in obsessional states. There is a 1-2% chance of one or more fits after the operation. The commonest procedure performed in Britain³⁴⁵⁷ was stereotactic subcaudate tractotomy.(Poynton ea, 1995) and was the only such intervention performed at the Geoffrey Knight Unit in London by the mid-1990s, with a total of 1,300 operations performed since 1961 (Freeman [1997] cites 501 operations between 1979 and 1995). Less commonly performed is limbic leucotomy and bilateral lesions in the cingulum bundle. (See Dougherty ea, 2002 for cingulotomy in OCD: a third or more of patients unresponsive to medication and behavioural treatments showed at least partial improvement at a mean of 32 months.) The commonest reasons for stereotactic subcaudate tractotomy according to a 1993 report were major depression (75%), bipolar disorder (15%), OCD (3%), and others (7%). In bipolar cases, episodes of mania may be better controlled than episodes of depression. Antisocial personality traits, drug and alcohol abuse, and absence of informed consent are contraindications. Significant changes in symptoms may occur over a six-month period following surgery, and such changes may have some predictive value. Poynton ea (1995) found no lasting effect of stereotactic subcaudate tractotomy on neuropsychological function during their prospective follow up of 23 patients, despite some initial minor decrement in cognitive abilities. Suicide risk may be reduced by psychosurgery but it is not completely eliminated. The zero suicide rate reported after capsulotomy by Fenton (1999) may relate to its more common use in OCD than in depression. Follow up of capsulotomy (for refractory anxiety) patients by Rück ea (2003) in Sweden revealed a significant amount of apathy and impaired executive function. A non-controlled long-term follow-up (mean 10.9 years post-surgery) of 25 consecutive OCD cases (Rück ea, 2008) found that capsulotomy is effective, has a substantial risk of adverse effects (weight gain, executive dysfunction, apathy, or disinhibition), that smaller lesions are safer, and that high radiation doses and multiple procedures should be avoided. Psychosurgery has been outlawed in a number of European countries and in 1996 Norway offered compensation to patients who had undergone such surgery in the past. Before considering a patient for psychosurgery he must have been suffering for a long time and all other appropriate treatments should have been given an adequate trial. Modern drug and behavioural treatments have drastically reduced the need for surgery. The use of psychosurgery is strictly regulated under British legislation and under the Irish Mental Health Act, 2001: psychosurgery requires written consent from the patient and authorisation from a Tribunal. Follow-up research must be of high quality.(Matthews & Eljamel, 2003a)

The use of the gamma knife (focused gamma rays), with no need to open the skull, may make psychosurgery more acceptable in the future. Psychosurgery remains a highly controversial intervention.(Persaud ea, 2003)

Insulin therapy

Manfred Sakel's famous 'coma treatment' for schizophrenia is now part of history, although it still has its advocates among those who used it (John Dunne, 1984, personal communication). Following the use of insulin to calm patients experiencing abstinence symptoms from opiates Sakel discovered that schizophrenics also benefited. Following an overnight fast an injection of insulin was used in the morning to cause coma. A couple of hours later glucose (NG or IV) was given to bring the patient out of coma. Some patients actually convulsed. Modified (non-coma) therapy with insulin has been tried for anorexia nervosa. Insulin coma therapy was shown not to be any better than barbiturate narcosis (Ackner ea, 1957) but it did not immediately go out of fashion.(Berrios, 2008, p. 27) The advent of neuroleptics offered a superior alternative. Nurses who were involved in 'coma therapy' tell us that vomiting was common and that the floors were often covered in a sugary solution.

Lithium and related treatments³⁴⁵⁸

Brian O'Shea

'The most important predictor of response to lithium is patient compliance'. (Shelley, 1995)

Lithium³⁴⁵⁹

Lithium³⁴⁶⁰

Does not occur freely in nature

The alkali metal³⁴⁶¹ has atomic weight of 3 (following hydrogen and helium) - it is always combined and is most often found in igneous rocks³⁴⁶²

Outer electron, unlike the two inner electrons, is easily displaced, hence, Li+ Lithium salts common in environment

Has no known function in human body, which normally contains about 0.1% of therapeutic level of lithium

Found in all body fluids, including saliva and semen

Side effects determined by peak level

Therapeutic effects relate to 12-hour level

Blood level should be taken before morning dose is taken (if the patient is on such a schedule)

Is quickly absorbed

Peak serum levels reached 1-2 hours after ingestion

Half-life is 14-30 hours

No protein binding

The lithium ion-selective analyser gives lithium level within 1 minute (whole blood)

Send³⁴⁶³ 5-10 ml clotted blood in plain tube, from which serum can be separated

Do not send anticoagulated blood³⁴⁶⁴

³⁴⁵⁸ O'Shea, (1993) reviewing pharmacological alternatives to lithium (Gk. *lithion*, stone) in bipolar affective disorder, found drugs more effective in preventing manic than depressive episodes. The commonest single drug implicated in British negligence claims is lithium: failure to appreciate the dangers of dehydration and concurrent use of diuretics, failure to monitor thyroid and kidneys, and poor communication between the laboratory and the clinician over serum lithium results. (Bradley, 1997) Lithium monitoring falls below guidelines in Ireland. (Udumaga & Mannion, 2010) Although there were isolated applications of lithium for affective disorders during the 19th century, (Schou, 1992) John Cade, who used lithium during the 1940s to treat mania in Australia and found it to be effective, is acknowledged as being responsible for its introduction to psychiatry. Patients relapsed when the lithium was stopped. Cade noticed that lithium had a slowing effect on animals. Before this, lithium had been tried in epilepsy (the bromide salt), gout, and, with disastrous results, as the sodium salt as a substitute in heart patients.

³⁴⁵⁹ Arfwedson and Berzelius discovered lithium sulfate in petalite in 1817, and elemental lithium was isolated in the mid-nineteenth century.

³⁴⁶⁰ Atomic number 3, atomic weight 6.94, 3 protons, 3 electrons, 4 neutrons.

³⁴⁶¹ Other alkali metals include sodium and magnesium.

³⁴⁶² Major sources of lithium include spodumene (up to 8% lithium oxide), brines (e.g. Great Salt Lake, Utah), amblygonite (up to 10% as complex phosphate), mineral spring waters (e.g. Perrier), lepidolite, and petalite.

³⁴⁶³ Lithium concentration can be measured by flame emission photometry or atomic absorption spectrophotometry. Ideally, serum should be separated as quickly as possible, preferably within an hour since lithium moves into erythrocytes after that time.

The kidney excretes lithium in favour of sodium, which it retains. A small amount of lithium appears in saliva and the use of saliva as a substitute for serum when estimating levels has been attempted. Red blood cell levels are a better reflection of intraneuronal levels and white blood cell levels may be better still. Brain lithium levels are typically about half those in serum. There appears to be little difference in the mean serum concentration-time plot between the available lithium preparations e.g. Camcolit and Priadel. Priadel liquid³⁴⁶⁵ is sugar-free. Phasal is another example of a lithium carbonate preparation.

Early studies suggested that patients with serum levels of 0.8-1.0 mmol/L have only a 13% relapse rate but experience side effects³⁴⁶⁶, whereas patients with serum levels of 0.4-0.6 mmol/L have a 28% relapse rate and much less of side effects. Older, higher suggested lithium serum level ranges tend to linger on in laboratory reports. Such levels are more suited to treatment of mania (with frequent measurements) than prophylaxis (with less frequent monitoring). Some, perhaps 28% (Marangell *et al.*, 2003, p. 1108), lithium-treated patients complain of memory impairment (e.g. forgetting a friend's name). Others complain of slowed reaction time and the feeling that life is now less colourful and interesting. These may respond to a lowering of the dose of lithium. Objective testing of memory is generally normal and some patients seem to miss their manic episodes. Lithium taken during ECT is thought to contribute to confusion, although this has not been a significant problem in this author's experience. Lithium can cause coarsening or partial loss of hair. Mild mood fluctuations are generally a warning not to stop lithium.

The recommended therapeutic lithium serum levels are the same for both adults and children.(Dulcan, 1996)

Key lithium studies summarised, including outcome

1979. Healthy volunteers on lithium show a small but consistent decrease in the ability to learn, concentrate and memorise.

1983. MRI (NMR) reveals longer proton T1 relaxation times in brain tissues of bipolar depressives, normalising with lithium therapy (similar results reported in red blood cells 3 years later).

1984. NIMH collaborative trial finds only one-third of patients remains well on lithium over 2-year period.

1989. Protein kinase C activation is blocked by lithium. Since protein kinase C (which potentiates neurotransmitter release) activation also potentiates 5-HT and noradrenaline release, this effect of lithium may be important in the treatment of mania and the prophylaxis of bipolar affective disorder.

1990. Response to lithium prophylaxis may depend on past course of bipolar affective disorder, e.g. better for sequence mania-depression-free interval than for depression-mania-free interval and rapid cycling with continuous circling course.

1991. 40% of bipolars had good outcome, 41% had fair outcome, and 19% had poor outcome. Poor outcome associated with frequent pre-lithium admissions, negative family affective style, lower social class, and current alcohol/substance abuse.

³⁴⁶⁴ Lithium heparin could be the anticoagulant and give false results.

³⁴⁶⁵ 520 mg lithium citrate/5 ml = 200 mg lithium carbonate. The citrate may cause less nausea and vomiting than the carbonate.

³⁴⁶⁶ Tremor, diarrhoea, urinary frequency, weight gain, and a metallic taste in the mouth.

Mania preceding depression predicts a better response to lithium than depression preceding mania.

1992. Lithium does not have an extreme mood normalising effect in well-controlled bipolar affective disorder patients i.e. normal moods remain.

Lithium may reduce suicidal behaviour even when it does not appear to control mood disorder.

Neurotoxicity at normal therapeutic levels is more likely if there are organic cerebral problems (incl. abnormal EEG), rapid dosage changes, or 'genetic susceptibility'.

1993. 26 cases of lithium-induced hyperparathyroidism³⁴⁶⁷ found in the literature – a reversible disorder.

1994. The chief reason for the difference between the efficacy of lithium prophylaxis in studies and its effectiveness in clinical practice is poor compliance in the latter context.

1995. Excess mortality in affective disorders is due to suicide and cardiovascular disease and lithium may reduce the likelihood of such events.

Relative risk of death among patients with mood or schizoaffective disorders is 1.7 times higher when off lithium compared to being on lithium; relative risk of suicide is 4.8 times higher if off lithium compared to that when on lithium.

1996. Improved psychosocial functioning for bipolar I patients on lithium above and beyond effects of relapse prevention v those not on lithium.

1998. High dropout rate among bipolars followed up after 5 years on lithium. Those on lithium had a lower hospitalisation rate but may be a self-selected group.

Poorer response to lithium with mixed episode, dysphoric mania, rapid cycling, many previous episodes, impaired functioning between episodes, and a depression-mania-euthymia course.

2000. Baldessarini and Tondo, looking at stability of response over 30 years, find that lithium benefits were not exaggerated in the past; nor has lithium lost efficacy. Poor results may be due to accumulation over time of complex, less treatment-responsive illnesses.

2001. Lithium monotherapy is as effective as lithium plus imipramine or paroxetine in bipolar depression; lithium levels below 0.8 mEq/L have a lower response rate than have lithium plus an antidepressant.

2003. Risperidone superior to placebo used in combination with lithium or divalproex in acute mania.

2004. Adding olanzapine to lithium or valproate for acute dysphoric mania improved depression, mania and suicidality.

2005. Danish study found that lithium reduces risk of suicide.

Lithium effective in preventing suicide, deliberate self-harm, and death from all causes in mood disordered patients (systematic review)

Divalproex was not more effective than lithium in longterm management of rapid-cycling bipolar disorder.

Young and Hammond (2007) point out that lithium use may be waning despite increasing knowledge about this efficacious tool. The key mechanism of therapeutic action is not known for sure. (Jope, 1999) Lithium is thought to increase presynaptic destruction of catecholamines, inhibit neurotransmitter release, decrease sensitivity of postsynaptic receptors, affect transfer of sodium and calcium and therefore affect both the release of neurotransmitters and the activity of receptor sites, cause sodium to be pumped out of the cell in depression (and possibly into the cell in mania), inhibit prostaglandin E³⁴⁶⁸, increase insulin release³⁴⁶⁹, increase permeability of membranes to magnesium and calcium, and cause EEG changes such as reduction in REM sleep duration. The

³⁴⁶⁷ Lithium reduces sensitivity of calcium-sensing receptor.

³⁴⁶⁸ Which is stimulated by cyclic adenosine monophosphate (cAMP).

³⁴⁶⁹ A possible reason for increased weight: glycogen formation in muscle.

corticosteroid rhythm is restored either as a direct affect of lithium or as a result of the effect on activity. Lithium moves out of cells more slowly than sodium. When receptors are affected by neurotransmitters there is then an effect on second messenger systems beneath the cell membrane. Effects on one of the latter systems, the phosphoinositide system, may explain the actions of lithium.(see box) Perhaps the ultimate effect is to attenuate protein kinase activity since a reduction in protein kinase C (PKC) levels parallels the time course for lithium's delayed onset of action. Both adenylate cyclase and phosphoinositol metabolism affect PKC levels which are known to facilitate release of a wide range of neurotransmitters. Valproate and carbamazepine also decrease PKC activity. In clinical doses, carbamazepine decreases cAMP production and CREB phosphorylation.(Chen et al, 1996)

Lithium – possible mechanisms producing therapeutic actions

Antimanic action – moderate attenuation of DA function, increased GABA neurotransmission, increases in or stabilisation of Ach function.

Arachidonic acid (an n-6 polyunsaturated fatty acid) and its metabolites (incl. eicosanoids and anandamide) are important second messengers that are able to modulate ion channels, neurotransmitter uptake, synaptic transmission, apoptosis, and so on. Rat studies show that lithium and anticonvulsant drugs decrease arachidonic acid turnover. Drugs targeting enzymes involved in the arachidonic acid cascade might therefore be beneficial in mania, e.g. cyclooxygenase 2 inhibitors. Competition between arachidonic and docosahexaenoic acid that occurs in the body suggests that docosahexaenoic acid or its precursors might also be useful therapeutic agents.(Rapoport & Bosetti, 2002) Many authorities suggest that lithium therapy for acute mania should not be considered to have failed unless plasma levels of 1.2-1.5 mEq/L have been reached and maintained for two weeks.

Antidepressant action – increased synthesis and turnover of presynaptic 5-HT (including increased tryptophan uptake), increased 5-HT release and reduced binding of function of 5-HT₂ receptors (especially hippocampal), increased responses mediated by postsynaptic 5-HT_{1A} receptors, increased metabolite of 5-HT in CSF, increased platelet 5-HT uptake, increased neuroendocrine responses to 5-HT agonists, reduced beta-adrenoreceptor-mediated stimulation of adenylate cyclase, and a tendency to downregulate alpha-2-adrenoreceptor function.

All of the above effects are modest, some have been found in animals, and some actions have been demonstrated in humans. It is likely that effects on second messengers and signal transduction systems are crucial. Lithium inhibits neurotransmitter-receptor-coupled adenylate cyclase activity and cyclic AMP formation *in vitro*. Lithium inhibits coupling of neurotransmitter receptors to G proteins, which inhibits G protein activation of adenylate cyclase. Lithium also inhibits the other major second messenger system, which involves phosphoinositide metabolism. Lithium may alter neuronal function via effects on ion distribution and kinetics.

Neural plasticity – lithium may affect this by actions on glycogen synthetase kinase-3 β ³⁴⁷⁰ (GSK 3 β), cyclic AMP-dependent kinase, and protein kinase C.

High doses required in the acute treatment of mania. The treatment needs to be monitored closely.(Kehoe & Mander, 1992) Treatment classically takes 7-10 days to have effect. Antipsychotic drugs bring behaviour under control quicker than lithium.

³⁴⁷⁰ Lithium has a tendency to elongate circadian periods and cause a phase delay of circadian rhythms and it prolongs the therapeutic effect of total sleep deprivation in depression. Inhibition of GSK 3 β , which modifies parts of the molecular clock, may account for lithium's actions in this regard.

Research in the 1970s on the lithium prophylaxis of bipolar disorder found a relapse rate of 23% on lithium compared to 68% with placebo, and 75% of relapses in lithium-prescribed patients were ascribed to non-compliance. Other possible uses include prophylaxis of schizoaffective disorder and some more doubtful applications. However, dipsomaniacs may respond, probably because of an affective underpinning. Lithium is not an antidepressant *per se* although its addition may³⁴⁷¹ augment antidepressant drug effects, and a lithium-imipramine combination may have superior prophylactic value in unipolar depression than either drug alone. Lithium reduces the intensity and duration of mood swings and full effect may require 6-24 months. Two manic episodes or one manic and two depressive episodes seem a reasonable guideline, although the length of time between episodes and the social consequences of attacks are equally important.³⁴⁷²

Sometimes one attack of mania is enough reason for prophylaxis. (Birch *et al.*, 1993) The patient's co-operation is all-important. Patient reliability is important. Family planning advice and a booklet outlining the basic facts of lithium therapy and its side and toxic effects are other important considerations.

Tests prior to commencement and at intervals during treatment include physical examination, serum creatinine, basic haematological work-up, thyroid function tests (especially TSH) and (if indicated, especially if patient > 50) an ECG. Serum lithium levels are usually tested weekly for 3-4 weeks and 3-monthly thereafter, and thyroid and renal functioning are tested twice a year over the long term, or more often if indicated. Lithium should not be stopped in cases of relapse of bipolar or unipolar affective disorder. The episode should be treated along orthodox lines³⁴⁷³.

Withdrawal of lithium, especially sudden withdrawal, is associated with a high relapse rate, increased number of inpatient days, increased doses of antipsychotic drugs, and, according to some but not all researchers, a withdrawal syndrome. Some patients may simply become irritable and emotionally labile on abrupt withdrawal from lithium. Post *et al.* (1992) contended that if effective lithium prophylaxis is stopped it may not work a second time although this argument is not convincing.

Page *et al.* (1987) investigated the fate of unipolar and bipolar affective disorder patients most of whom had taken lithium for at least 13 years. At follow-up 49% experienced a complete remission, 41% had a partial but significant response and 10% had no response to lithium. No specific individual or illness factor was found to correlate with a favourable outcome, and no correlation was discovered between the average serum lithium level and outcome. In a retrospective study of manic patients, Golney and Spence (1986) found a favourable response to be associated with bipolar status with a family history of depression or mania, unipolar status with endogenous illness, and with the absence of significant disturbance of personality. In the same study the response to lithium over 6 months in unipolar illness and over the first year in bipolar illness was strongly associated with long-term response. According to Prien and Gelenberg (1989), the average failure rate for lithium in preventive treatment studies was 33%, where a failure was defined as episodes needing admission or the addition of other drugs. Only one-fifth of patients suitable for lithium could expect no recurrences.

Lithium, usually combined with antidepressants, has been used successfully in the treatment of deluded depressives who refuse ECT, although a combination of antidepressant and antipsychotic drugs is favoured.

Lithium therapy may reduce the frequency of repeated aggression or self-mutilation in the mentally handicapped, psychotics, or delinquent subjects. One possible mechanism is that it may elevate 5-HT levels. There are no special features in such cases that would help one to predict a useful response.

Lithium causes a reversible nephrogenic diabetes insipidus with polyuria³⁴⁷⁴, especially with high serum levels. Polyuria is produced by inhibition of cAMP-dependent action of

³⁴⁷¹ Not all studies concur.

³⁴⁷² The present author has no rigid preconceptions about when to start lithium prophylaxis.

³⁴⁷³ With lithium dosage changes, ECT, antidepressants, or antipsychotics, etc.

1073

ADH on distal tubules and collecting ducts. Amiloride reduces lithium-induced polyuria without affecting lithium or potassium levels. This potassium-sparing diuretic increases ADH by blocking lithium entry to ADH-sensitive cells.(Martin, 1993) Amiloride 10-20 mg/day reduces lithium requirements, so check lithium levels more frequently. Adding hydrochlorothiazide (50 mg/day) to amiloride increases the risk of toxicity. Indometacin (indomethacin), 50 mg TID is only used when immediate normalisation of polyuria is required, and then only as a short course. It inhibits cyclo-oxygenase and prostaglandin synthesis. Other possible interventions include dose reduction, single daily dosing (trough assists renal recovery), and potassium supplements.

Depending on individual circumstances the present author usually starts patients on an average dose of 800 mg lithium carbonate at night, further dose changes being dictated by clinical state and serum levels. Short-acting preparations may cause nausea, whereas delayed-release preparations may be more likely to induce diarrhoea. The difference between the two preparations remains controversial³⁴⁷⁵.

Amdisen and Schou³⁴⁷⁶ of Denmark originally suggested serum levels (taken 12 hours after last dose) of 0.8-1.2 mmol/L. Hullin of Leeds has shown that lower levels are effective but high relapse rates occur below 0.4 mmol/L. The present author employs the range 0.6-0.9 mmol/L. (even lower in the elderly). Prophylaxis, this author believes, is generally for life.

Some factors increasing the likelihood of lithium intoxication

Overdose

High prescribed dose

Renal disease

Excess sweating

Dehydration

Hyponatraemia

Vomiting

Diarrhoea³⁴⁷⁷

Tropical heat

Sauna

Infection

Fever

Trauma/surgery³⁴⁷⁸

Diuretics³⁴⁷⁹

Indomethacin

Tetracyclines³⁴⁸⁰

³⁴⁷⁴ The patient should drink non-sweet fluids to compensate.

³⁴⁷⁵ The most important thing in practice is to avoid intoxication.

³⁴⁷⁶ Mogens Schou (b. 1918), son of psychiatrist and manic-depressive H. J. Schou.

³⁴⁷⁷ An SSRI added to lithium increases burden of diarrhoea.

³⁴⁷⁸ Stop lithium 1-2 days preoperatively, give IV fluids during surgery, and re-start lithium when oral fluids tolerated.

³⁴⁷⁹ Especially sodium-losing diuretics such as thiazides. Potassium-sparing and loop diuretics are relatively less likely to raise lithium levels.

³⁴⁸⁰ These usually only slightly increase lithium levels.

Digoxin

Alpha-methyldopa³⁴⁸¹

Phenylbutazone

Muscle relaxants³⁴⁸²

Cyclooxygenase-2 (APA, p. 583)

Pregnancy

Excess alcohol intake³⁴⁸³

Drastic slimming

The combination of lithium, a thiazide diuretic and digoxin can cause digoxin toxicity via induction of hypokalaemia. If a diuretic is necessary then a loop diuretic such as frusemide may be used. When treating a hypertensive patient who is taking lithium, consider a beta-blocker or clonidine, but avoid thiazide diuretics. Diclofenac, indomethacin, metronidazole, spectinomycin, ibuprofen and piroxicam have been reported to raise the plasma lithium concentration. Renal prostaglandins, especially PGE₂, are strong vasodilators of the renal circulation. NSAIDs may inhibit prostaglandin synthesis and lead to lithium intoxication via ischaemia³⁴⁸⁴. Renal function is most likely to be adversely affected by NSAIDs if it is already compromised, and prostaglandins become progressively more active with a deterioration in kidney function.

Some factors that give a falsely low lithium concentration in tissues include >13 hours since last dose ingested³⁴⁸⁵, brain damage, and phenytoin. AIDS patients are at increased risk of lithium toxicity, even with therapeutic serum levels.³⁴⁸⁶

Lithium intoxication usually develops over days or more quickly in the case of overdose. Lithium should be stopped for a few days during an intercurrent illness or suspected toxicity. Lithium intoxication has to be a clinical diagnosis because it results from high intracellular lithium concentrations, which may not be reflected in serum levels.

Features of intoxication

Sluggishness, drowsiness, dysarthria

Anorexia, diarrhoea, vomiting

Vertigo, coarse tremor, agitation, restlessness, hypertonia, hyperreflexia

Widespread shakes, muscle fasciculation, convulsions, transient hemiparesis

Irregular breathing, coma

ECG changes (flat or inverted T wave³⁴⁸⁷, U waves, and conduction delays, e.g. first degree heart block).

Intoxication may lead to full recovery, death, persistent renal symptoms, spasticity, cognitive impairment, or permanent cerebellar damage with loss of Purkinje cells. Polyneuropathy may require weeks or months to resolve. Lithium intoxication (even with therapeutic levels) can produce myoclonus and EEG changes resembling those found in

³⁴⁸¹ This can cause intoxication even with therapeutic lithium serum levels.

³⁴⁸² Succinylcholine and pancuronium are potentiated by lithium and may occasionally lead to prolonged apnoea.

³⁴⁸³ Leading to loss of salt and water.

³⁴⁸⁴ Aspirin, paracetamol, and sulindac (Clinoril) appear to be safe with lithium.

³⁴⁸⁵ Because of the slope in the graph, a sample taken after 12 hours is a better reflection of the 12-hour level than one taken before 12 hours.

³⁴⁸⁶ This may be due to damage to the blood-brain barrier.

³⁴⁸⁷ 50% of lithium-treated patients have benign/reversible T wave flattening.

CJD, but these are reversible.³⁴⁸⁸ Management of intoxication includes early diagnosis and treatment of overdose (initially stomach washout and activated charcoal left in stomach³⁴⁸⁹). In the usual case one can give oral or IV NaCl, Na₂SO₄, or MgSO₄³⁴⁹⁰, osmotic diuresis with acetazolamide (Diamox) or urea³⁴⁹¹, or renal dialysis.

A rebound rise in lithium levels may follow haemodialysis. Neurological recovery may lag behind decreases in serum lithium levels. This is explained by the relatively slow equilibration between intracellular (incl. neuronal) and plasma concentrations.

Dialysis patients do not eliminate Li⁺ naturally. Because lithium is readily dialyzable (and not excreted by kidneys in dialysis patients - it is only removed at dialysis), it is therefore given (300-600 mg lithium) to patients – orally or into dialysate - on renal dialysis who need lithium for their affective disorder *after* their dialysis sessions. Daily dosing is not required. Serum levels are measured some 3-4 hours after dialysis because serum levels may rise following dialysis due to equilibration with the tissues.

Contraindications to lithium therapy (vary with circumstances)

Patient unreliability

Early pregnancy³⁴⁹²

Elective surgery

Uncompensated renal disease

Severe cardiac disease³⁴⁹³

Diuretic therapy

Lithium may cause acute tubular necrosis.

The classic foetal anomaly reported with lithium is Ebstein's anomaly³⁴⁹⁴. The cardinal feature is the displaced tricuspid valve. Lithium should not be given to patients with myasthenia gravis³⁴⁹⁵, Addison's disease or untreated hypothyroidism.

Renal damage is most likely with intoxication. (Hetmar ea, 1991) Nephrotoxicity may relate more to the duration of exposure to peak lithium levels than to the absolute level of any peak, suggesting that once-daily dosing is the ideal prescription. Glomerular sclerosis, tubular atrophy, and interstitial fibrosis may occur in lithium treated patients and animals. However there is some evidence that the incidence is not particularly high when function is considered³⁴⁹⁶. Many authors have commented on the non-likelihood of death from lithium-induced nephropathy. Lithium can be used during maintenance haemodialysis where it has been given after dialysis in doses of 300-600 mg/day. Lithium-treated patients require more AVP (ADH) to maintain urine of a given osmolality than do non-lithium-treated cases. Some increase in serum creatinine concentrations and a lowering of maximum concentration capacity in lithium-treated patients over time is neither uncommon nor worrying. GFR may be normal in 85% or mildly decreased in patients on lithium. Serum creatinine may be normal in the elderly despite impaired renal function because of reduced muscle mass. The most prevalent renal effect of lithium is an impaired concentrating ability.

Estimated glomerular filtration rate (eGFR) (Morriss & Benjamin, 2008)

Calculated as:

³⁴⁸⁸ Lithium does not exacerbate epilepsy except for the induction of myoclonus during lithium intoxication.

³⁴⁸⁹ In fact, little lithium is absorbed from the stomach and there is a risk of worsening electrolyte imbalance.

³⁴⁹⁰ Cations exchanged for Li⁺ in the renal tubules.

³⁴⁹¹ Carbimide.

³⁴⁹² At parturition there is a diuresis with risk of intoxication, so reduce dose of lithium to prevent this.

³⁴⁹³ Unstable congestive cardiac failure or sick sinus syndrome. A recent myocardial infarction is a relative contraindication because of the risk of arrhythmias.

³⁴⁹⁴ Described by Wilhelm Ebstein in 1866.

³⁴⁹⁵ Because of blockade of Ach release and potentiation of neuromuscular blocking agents like succinyl choline.

³⁴⁹⁶ 5-10% of patients on long-term lithium experience impaired tubular function.

GFR = $175 \times [\text{seum creatinine } (\mu\text{mol/L})^{-1.154} \times [\text{age}]^{-0.203} \times [1.212 \text{ if Black}] \times [0.742 \text{ if female}], \text{ ml/min/1.73 m}^2$

eGFR is more sensitive indicator of stage 3 chronic (asymptomatic) renal disease³⁴⁹⁷

A single eGFR estimation is not a reliable estimation of stage 3 chronic (asymptomatic) renal disease

May be inaccurate if patient > 70 or < 18 years, pregnant, has an amputation, is malnourished/dehydrated, or of Afro-Caribbean origin

Falls, muscle injury, or injections can increase eGFR

Lithium can be given to renal transplant cases if frequent serum level monitoring is carried out. Cyclosporine can increase lithium serum levels by decreasing its excretion, thus necessitating a lowering of the lithium dosage. Live donor kidneys handle lithium better than cadaver kidneys.

Lithium interferes adversely with the iodination and release of thyroid hormones. It may interfere with their actions on target tissues in the same way that it reduces renal sensitivity to arginine vasopressin (AVP/ADH). After a few years on lithium some authors have found a 3-50% incidence³⁴⁹⁸ of goitre (larger size on ultrasound in smokers) and 4-21% incidence of hypothyroidism³⁴⁹⁹. Goitre appears to be more common the longer the patient is taking lithium. Pre-existing anti-thyroid antibodies or a family history of thyroid disease increase the chances of developing lithium-related hypothyroidism. Hypothyroidism and euthyroid goitre are managed with thyroxine supplementation³⁵⁰⁰ and the continued administration of lithium. Many therapists now give thyroid hormone supplementation for persistently raised TSH, even if T4 levels are normal. (Owens, 2004, p. 291) Thyroid function normalises in a couple of months when lithium is stopped. Whether uncommon cases of hyperthyroidism can be attributed to lithium is difficult to say. Rosser (1976) described the emergence of thyrotoxicosis after lithium was stopped and Byrne and Delaney (1993) reported a case where thyroid ophthalmopathy regressed after stopping lithium.

A raised leucocyte count may occur in people on lithium. The mechanism appears to be stimulation of granulocyte-stimulating factor and interleukin-6. It seems to be harmless and reverses soon after stopping lithium. It is suggested that lithium be withheld on chemotherapy days or during cranial (but not other) radiation in cancer patients. (Fawzy & Greenberg, 1999)

Exacerbation of psoriasis is common.³⁵⁰¹

Side effects include polyuria, thirst, nausea (take after food), loose stools, metallic taste, fine tremor, weight gain³⁵⁰², Parkinsonism³⁵⁰³, fatigue, and delayed reaction time whilst driving³⁵⁰⁴. Side effects may be more common in those patients who have EEG abnormalities. Rarely patients complain of itchy or burning eyes or blurred vision.

Pooled data from a number of studies (Goodwin & Jamison, 1990) found that the most frequent subjective complaints were (percentage of patients): thirst (36%), polyuria (30%), memory difficulties (28%), tremor (27%), increased weight (19%), drowsiness (12%), and diarrhoea (9%), with over one-quarter having no complaints. The most likely problems leading to non-adherence were memory difficulties, weight gain, temor, polyuria, and drowsiness.

³⁴⁹⁷ Grade 3 is associated with a 40% increase in cardiovascular mortality.

³⁴⁹⁸ The higher figures may not reflect clinical reality.

³⁴⁹⁹ Increased TSH occurs much more often than clinical hypothyroidism.

³⁵⁰⁰ E.g. 50 µg Eltroxin to start.

³⁵⁰¹ A full list of **cutaneous adverse effects** is daunting: folliculitis, proliferation of viral warts, hair loss, toe nail dystrophy, exfoliative dermatitis, acneiform eruptions, LE-like syndrome, and psoriasis (worsening; increased resistance to treatment; and conversion to pustular type). (Edwards, 1995)

³⁵⁰² Mean of 4 Kg; affects 75% of patients.

³⁵⁰³ Disputed by Factor (2004, p. 223) who suggests that it may not occur in the absence of anticonvulsants.

³⁵⁰⁴ The latter may lead to accidents, espc. in the elderly. (Etminan ea, 2004)

Dyspepsia may improve by dividing the daily dose or by changing the proprietary preparation. Tremor may improve with smaller and more frequent doses, avoidance of caffeine³⁵⁰⁵, or the addition of beta-adrenoceptor blocking drugs³⁵⁰⁶. Primidone (Mysoline) can also be used for lithium-induced tremor.(Factor, 2004, p. 219) However, primidone has been associated with psychosis and depression. Sudden cessation of caffeine intake can increase lithium blood levels by 24%.

Lithium can cause a golden discoloration of the distal nail plates. The combination of lithium and antipsychotic drug can lead to somnambulism, which should respond to dose reduction.

Cohen and Cohen caused a scare by reporting 4 cases of brain damage in subjects on both lithium and haloperidol, occurring in the one hospital, at the same time. When mania 'breaks',³⁵⁰⁷ heavy doses of these drugs cause EPS (extrapyramidal symptoms) which may be marked. If the patient is monitored closely and if doses are kept low it should be possible to prevent such problems. Cogwheel rigidity from lithium is unresponsive to anticholinergic drugs.

Lithium can potentiate the effects of muscle relaxants. It does not ordinarily change the effects of alcohol. Folate is considered necessary for 5-HT synthesis in the brain. A number of studies conducted during the 1980s found a slightly lower plasma folate concentration in lithium-treated patients. Coppen ea(1986) found that giving a supplement of folic acid (300-400 micrograms/day) to patients on lithium caused those with the highest folate levels to show a significant reduction in affective morbidity. Calcium blockers given with lithium can cause heart block and neurotoxicity. The chief culprit here is verapamil³⁵⁰⁸, whereas reports on diltiazem are less clear. Enalapril, an ACE inhibitor, can increase lithium levels to the toxic range. Verapamil can reduce lithium levels. Theophylline increases renal lithium excretion, thus lowering serum lithium levels.

Non-adherence with lithium therapy is associated with substance abuse and more admissions to hospital.

Non-response to lithium treatment in adherent patients is associated with female sex, young age, and a previously chronic illness course.

Other agents

Carbamazepine (e.g. Tegretol)

Carbamazepine, an iminodibenzyl and a relative of imipramine, is indicated for generalised tonic-clonic seizures, partial seizures, paroxysmal pain (e.g. trigeminal neuralgia), alcohol withdrawal, BZD withdrawal, mania, and prophylaxis of bipolar affective disorder³⁵⁰⁹. It may exacerbate petit mal (absence) seizures and is unlikely to be helpful in their management. According to Ballenger (1988), factors potentially predictive of antimanic response to carbamazepine include non-response to lithium, rapid or continuous cycling, more severe mania, depressed/anxious/dysphoric patient, more severely ill patient, schizoaffective disorder, evidence of organicity, primarily manic episodes, no family history, and early onset. According to Post ea (1997), an antidepressant response to carbamazepine might be associated with temporal hypermetabolism, but not the more typical frontal hypometabolism associated with depression.

Teratogenicity is not discussed. Carbamazepine should be avoided in those patients who have AV conduction defects³⁵¹⁰ or porphyria. The drug should be stopped if there is an

³⁵⁰⁵ Coffee, tea, cola, etc.

³⁵⁰⁶ E.g. propranolol 10-20 mg prn/bid/tid depending on circumstances.

³⁵⁰⁷ I.e. when the patient becomes euthymic.

³⁵⁰⁸ Bradycardia and movement disorders such as choreoathetosis may occur.

³⁵⁰⁹ And perhaps unipolar melancholic depression.(Stuppaek ea, 1994) Young ea (2010, p. 632) consider carbamazepine to be a third-line prophylactic agent.

³⁵¹⁰ Anything greater than first degree heart block.(Brown ea, 2000)

allergic skin reaction or deterioration in liver function. Routine liver function tests may be performed more often for legal reasons rather than for cost-effectiveness; Dubovsky *et al* (2003, p. 498) argues that hepatotoxicity, a rare phenomenon with anticonvulsants, may be picked up more readily by clinical examination than by laboratory examination. White cell counts and LFTs should be performed at baseline and, perhaps, at intervals thereafter. However, has been argued that routine WCC counts will miss agranulocytosis because of its rarity and sudden onset. (Dubovsky *et al*, 2003, p. 498; Marangell *et al*, 2003, p. 1112) It is probably safer to tell the patient to report pyrexia, pharyngitis, other infection, petechiae, or weakness and pallor. (Marangell *et al*, 2003, p. 1112) A non-progressive or fluctuating leucopaenia (and anaemia), often early in treatment, is common and usually harmless. However, should the leucopaenia be severe or be accompanied by clinical signs (e.g. pyrexia or sore throat) the drug should be stopped and the WCC checked. Post *et al* (1997) estimated that serious side effects, such as agranulocytosis and aplastic anaemia, occur in only 1 in 10,000 to 120,000 treated patients³⁵¹¹. It may be necessary to cover sudden withdrawal with a BZD. Carbamazepine may interfere with driving and it can cause folate deficiency. The half-life of carbamazepine is 13-17 hours and there is 70-80% protein binding. Drugs such as cimetidine, dextropropoxyphene, diltiazem, erythromycin, INAH, viloxazine³⁵¹², and verapamil inhibit the metabolism of carbamazepine. Nifedipine (e.g. Nifed) does not have this effect. Fluoxetine may increase carbamazepine levels. Valproate raises the concentration of the toxic 10,11-epoxide metabolite of carbamazepine; therefore, whilst carbamazepine levels may be normal the patient may be toxic as the metabolite is not being measured. Carbamazepine induces liver enzymes and can reduce the effectiveness of certain drugs, e.g. antipsychotics, steroids (including oestrogen), theophylline, warfarin, and other antiepileptic drugs. TCA plasma levels may be reduced by 40-45% for the same reason. The dosage of anticoagulant drugs may need to be changed. Anovulant drugs may show reduced efficacy and there may be breakthrough bleeding or spotting; it is recommended that a pill containing at least 50 mcg of oestrogen is used or that another method of contraception is employed. It is not recommended that carbamazepine be given with or within 2 weeks of MAOI therapy because of the danger of a hypertensive crisis. This is because it is a tricyclic drug. However, the combination has been safely employed. (Ketter *et al*, 1995) The side effects of carbamazepine, usually most marked early in treatment, are listed in the box. The usual recommended range for the prophylaxis of bipolar affective disorder is 4-12 mg carbamazepine/L plasma.

Side effects of carbamazepine

CNS – dizziness, diplopia, blurred vision, headache, somnolence, ataxia, confusion (with agitation in elderly), dystonia, worsening of multiple sclerosis symptoms
 GIT – dry mouth, nausea, diarrhoea, constipation, anorexia
 Metabolic – water intoxication, hyponatraemia
 Endocrine – low T4 level with normal TSH level³⁵¹³
 Skin – reversible generalised erythema in c 3%, and (rarely) severe reactions like exfoliative dermatitis, Stevens-Johnson syndrome (rash with symptoms equivalent to a severe burn – may kill from superimposed bacterial infection or lead to disfigurement), toxic epidermal necrolysis, hair loss

³⁵¹¹ Some authors put it at 1 in >575,000 treated patients/year.

³⁵¹² Withdrawn from market.

³⁵¹³ Clinical hypothyroidism is unusual and may be due to reduced TSH response to TRH. Whilst lithium causes a decreased thyroxine with increased TSH, carbamazepine causes a decrease in thyroxine with normal TSH.

Haematology – leucopaenia (may be reversed by lithium), thrombocytopaenia, agranulocytosis, aplastic anaemia, thromboembolism
 Others – oedema (dose-dependent), fever, proteinuria, lymphadenopathy, acute renal failure, cardiac conduction disorders³⁵¹⁴, hepatitis³⁵¹⁵, immunoglobulin deficiency (Hayman & Bansal, 2002)
 Overdose³⁵¹⁶ – tremor, excitement, seizures, hypo- or hypertension, diminished consciousness, EEG and ECG (including arrhythmias) changes

Carbamazepine-lithium combination: In general this combination is safe and well tolerated despite some reports of neurotoxicity, especially if the treatment is initiated at lower doses and increased with care. (Ballenger, 1988) Carbamazepine-induced leucopaenia may be reversed by lithium.

Valproate

Valproate (sodium valproate/Epilim) is useful in the treatment of mixed affective states and it may be safer than carbamazepine in those patients who have cardiac disease. (Brown ea, 2000) Low dose valproate (mean level of 32.5 micrograms/ml) may help the milder rapid-cycling patient or the person with cyclothymia but more severe bipolar cases may need antiepileptic doses (50-120 micrograms/ml). Other anticonvulsants will reduce valproate plasma levels and should such drugs be stopped the levels of valproate levels will increase. Valproate does not do this to other anticonvulsants because it doesn't induce liver enzymes. The combination of valproate and the carbapenems³⁵¹⁷ is not recommended because its leads to a rapid and significant drop in valproate levels. The same may apply to a combination of valproate and chitosan³⁵¹⁸, a common dieting agent. The combination of clonazepam and valproate may induce absence status in those patients with a history of absence seizures. Unlike carbamazepine, *valproate does not cause oral contraceptive failure*. Valproate has been combined with lithium and even with a combination of lithium and carbamazepine. (Denicoff ea, 1997) However, valproate can increase the levels of the 10,11-epoxide metabolite of carbamazepine to toxic levels. (Brown ea, 2000) Valproate can also increase lamotrigine levels, thereby increasing the risk of rash. The half-life of valproic acid is 6-16 hours, and there is 95% protein binding. Sodium valproate causes less GIT side effects than does valproic acid. It should be taken on a full stomach. Valproate can increase serum amylase and ammonia levels³⁵¹⁹, the latter being potentially important if there is liver disease. Aspirin should be avoided³⁵²⁰ in favour of paracetamol. The combination of valproate with antipsychotic drugs can potentially cause an encephalopathy with diffuse EEG slowing or an exacerbation of Parkinsonism. Erythromycin increases valproate levels. (Brown ea, 2000)

Divalproex³⁵²¹ sodium (Depakote) is an anticonvulsant drug that is absorbed into the bloodstream as valproate. It has been found to improve responsivity of refractory affective disorders (not necessarily including rapid cycling: Calabrese ea, 2005) to lithium or carbamazepine when it is added to the regimen. Divalproex sodium is probably safe in combination with lithium. (Granneman ea, 1996)

³⁵¹⁴ Quinidine-like action of this tricyclic drug: consider valproate for patients with heart disease who have bipolar affective disorder.

³⁵¹⁵ Less than 5% of patients experience a benign rise in liver enzyme levels and perhaps less than 1 in 10,000 patients experience a serious acute hepatic necrosis and then usually during the first weeks of therapy.

³⁵¹⁶ Following massive overdose, peak plasma concentrations may be reached on second or third day after ingestion.

³⁵¹⁷ Doripenem, ertapenem, meropenem, and imipenem (antibiotics).

³⁵¹⁸ Chitosan is found in crab exoskeleton and in fungal cell wall.

³⁵¹⁹ Inhibition of urea synthesis.

³⁵²⁰ Increased total and free valproate levels by displacing the drug from binding proteins.

³⁵²¹ This is a dimer molecule that dissociates in the GIT to form free valproate. It causes less GIT upset than valproate.

Side effects of valproateHair loss³⁵²²Severe nausea, vomiting³⁵²³, diarrhoea

Tremor (responds to beta-blockers), dizziness, sedation, ataxia, dysarthria, memory impairment

Weight gain

Persistent increase in liver transaminases (usually asymptomatic and normalises on stopping the drug)

Fatal liver damage (children under 10 years of age)

Pancreatitis (young children)

Thrombocytopaenia³⁵²⁴, inhibition of platelet aggregation, abnormal coagulation parameters³⁵²⁵Interference with thyroid function tests³⁵²⁶

Back pain

False test for ketones in urine

Valproate should be avoided in the presence of hepatic failure.

There may be CNS depression, especially in combination with agents such as alcohol. The association between valproate and polycystic ovaries (PCOS)³⁵²⁷ is complex and incompletely resolved, one study showing no association.(see Schatzberg ea, 2005, pp. 271, 272) However, Joffe ea (2006) found that over 10% of bipolar women on valproate had oligomenorrhoea or hyperandrogenism versus almost one-and-a-half percent bipolar females taking lithium or a different anticonvulsant. Ostacher and Tilley (2008, p. 663) present evidence for an association between PCOS and valproate and advise against employing valproate as a 'first-line' treatment of bipolar disorder in women of childbearing age.

There may be displacement of other protein-bound drugs, e.g. phenobarbitone, aspirin, phenytoin, and carbamazepine. Schaff ea (1993) suggest aiming for 50-100 mg/ml of serum.

Lamotrigine (Lamictal dispersible tablets)

A phenyltriazine that was noted to improve mood in epileptics, lamotrigine is thought to work in bipolar disorder by inhibiting excitatory presynaptic neurotransmitter release, especially glutamate. It also blocks sodium channels and 5-HT₃ receptors. Peak plasma concentration occurs 2-3 hours after ingestion, the half-life is about 30 hours, 55% is protein bound, bioavailability is 98%, first-pass metabolism is minimal, and an inactive glucuronide metabolite is formed in the liver and excreted in the urine. Lamotrigine crosses the placenta and is found in foetus and breast milk. Side effects include nausea, sedation, dizziness, headache, and diplopia. It seems to be weight neutral. Diarrhoea and

³⁵²² Rarely there may be loss of all body hair. Give vitamin preparation containing zinc and selenium. Severe alopecia may necessitate stopping the drug and hair re-growth (tends to be curly) may then take several months.

³⁵²³ Can be quite marked – give low dose to start, increase dose slowly, use enteric-coated tablets; H₂ antagonists may alleviate persistent GIT distress.(Stoll ea, 1991)

³⁵²⁴ Usually mild and reverses on reducing dose or stopping drug.

³⁵²⁵ E.g. low levels of fibrinogen.

³⁵²⁶ Disputed by Sit & Rothschild.(2002, p. 765)

³⁵²⁷ Also associated with obesity and epilepsy.

tremor are less than with lithium. Most lamotrigine-related rashes (occurring in 10% of patients) are of little clinical importance, but because rare cases can be very serious³⁵²⁸, such as Stevens-Johnson syndrome or toxic epidermal necrolysis, it has been suggested that rash is an indication for stopping the drug. Certainly, where the face is extensively involved, where there is evidence of mucous membrane involvement³⁵²⁹, or where there are systemic symptoms³⁵³⁰ there is no choice but to stop the drug and to treat the case as an emergency. Slow titration of dosage may reduce the likelihood of serious rash developing. There are rare reports of blood and liver problems, which cannot as yet be directly attributed to lamotrigine. A few cases of breakthrough seizures, unexpected pregnancies³⁵³¹ and of menstrual bleeding disorders³⁵³² have been reported to GlaxoSmithKline in women on a combination of lamotrigine and the contraceptive pill. Anovulants decrease serum levels of lamotrigine and such levels may there rise on stopping the contraceptive pill. The half-life of lamotrigine is doubled by valproate³⁵³³ and halved by phenytoin and carbamazepine. Lamotrigine dose should be halved in the presence of valproate. Duncan ea (1998) called for more detailed studies of lamotrigine use in the affective disorders. A small, open, non-randomised report of lamotrigine being effective when added to clozapine in partially clozapine-responsive patients was conducted by Dursun and McIntosh.(1999) Goldsmith ea (2003) reviewed the lamotrigine literature and found that it may be good for bipolar depression but that it was without demonstrated efficacy for acute mania. Also, it was of limited efficacy in delaying time to manic/hypomanic episodes but it significantly delayed time to intervention for a depressive episode. Junker and Stodieck (1997) reported a case of lamotrigine-responsive clozapine-induced myoclonus. The starting dose is 25 mg daily for 2 weeks, followed by 50 mg daily for 2 weeks, gradually increasing to 200 mgs daily over 6 weeks (range in bipolar disorder: 50-300 mg/day). Higher doses give no additional efficacy. If the patient is also on valproate, start with 25 mg every second day (max. dose 100 mgs daily); if on carbamazepine, give 50 mgs daily to start (max. dose 400 mgs daily). Divided dosing can be used. If it is decided to stop lamotrigine the drug should be withdrawn slowly.

Verapamil (e.g. Isoptin, Verap)

Verapamil, a class I calcium antagonist, may be a useful treatment in acute mania.

Gabapentin (Neurontin)

Despite positive case reports, trials do not support use of this drug in the treatment of bipolar disorder³⁵³⁴.(Frye ea, 2000; Pande ea, 2000) However, it might be considered in the augmentation of other mood stabilising drugs in very anxious patients or in rapid-cyclers. It has found a niche in the management of anxiety, pain, and substance use disorders.

Antipsychotic drugs

Esparon ea (1986) performed a double blind crossover trial of depot flupenthixol (flupenthixol) in recurrent manic-depression. All patients stayed on lithium. Eleven patients completed the two-year trial. Flupenthixol appeared to have no prophylactic effect. Flupenthixol is nevertheless employed in depot injectable form in non-compliant patient with recurrent affective disorders by many clinicians.

Clonidine (Catapres, Dixarit)

Giannini ea(1986) found lithium to be more effective than clonidine in manic patients. Some patients on clonidine developed depression and hypotension.

³⁵²⁸ 0.1% of treated cases; especially in **children** or in **those also taking valproate**.

³⁵²⁹ As indicated by oral or lingual lesions or by complaints of dysuria.

³⁵³⁰ E.g. pyrexia or enlarged lymph nodes.

³⁵³¹ Lamotrigine may be associated with oral clefts in the offspring.

³⁵³² E.g. breakthrough bleeding.

³⁵³³ Increasing the rate of non-serious rash.

³⁵³⁴ Pfizer had to pay \$430 million for inappropriate marketing of gabapentin!

Clonazepam (Rivotril³⁵³⁵)

Clonazepam reduces lithium clearance. Sachs (1990) reported early claims that clonazepam reduced cycle frequency in bipolar affective disorder, was associated with fewer depressive episodes than when antipsychotic drugs were employed, and that neuroleptic-lithium combinations could be switched to a clonazepam-lithium combination without leading to an acute relapse.

Drug use in the elderly

This important subject is dealt with here for convenience. Various factors affect drug disposition in old people: age-related physiological changes, pathology, and therapeutic and environmental factors. Age-related physiological changes include absorption³⁵³⁶, distribution³⁵³⁷, metabolism³⁵³⁸, and excretion³⁵³⁹.

Some guidelines for prescribing drugs in the elderly

Take a careful drug history and check for use of over-the-counter drugs
Be familiar with the effects of age on the pharmacology of drugs
Strive to make a diagnosis before instituting therapy
Use smaller starting doses
Adjust the dose according to response
Review the drug treatment plan regularly and keeping it simple
Be alert to the possibility of iatrogenic illness
Beware interactions between disease states and drugs.

Antidepressant drugs³⁵⁴⁰

Brian O'Shea

'...successful treatment may require patients to tolerate side effects'. (APA, 2002)

'Before modern treatments, depressed patients typically spent one-fourth of their adult lives in the hospital and fully one-half of their lives disabled'. (Loosen & Shelton, 2008, p. 325)

Most antidepressants take 7-21 days before they cause subjective lifting of depressed mood. Sleep may improve immediately when a sedative antidepressant is given at night. Stimulating³⁵⁴¹ antidepressants (AD) should be given early in the day to prevent interference with sleep. Older people and children should normally commence on one-half to one-third of the adult starting dose³⁵⁴². A trial using adequate doses of antidepressants must be undertaken before describing depression as refractory, e.g. 300 mgs/day of imipramine or its equivalent³⁵⁴³. A therapeutic trial of an antidepressant should last for at least 6 weeks, with at least 4 weeks on the highest tolerated safe dose. Side effects will be better tolerated if it is explained that these are usually transient and that the drug will be reduced if significant improvement does not occur in about 6 weeks. Relapse may be due to non-compliance. (O'Shea, 1995) The initial dose is built up gradually. Maintenance treatment at the therapeutic dose for at least 6 months and then slowly reduced in case the episode of depression has not abated. The early stages of recovery from depression may be accompanied by a sufficient return of volition³⁵⁴⁴ to make suicide a real possibility³⁵⁴⁵. Some patients make the mistake of taking antidepressants on a p.r.n. basis. Studies of suicides suggest that antidepressants are either not prescribed at all or are given in sub-optimal dosage in many cases of depressive illness. The serum concentrations of antidepressants show a wide individual variation, are increased by antipsychotic drugs and are decreased by barbiturates. Depression in the elderly requires for its proper treatment a consideration of its wide variety of associated aetiological factors. Drug metabolism is less efficient in the elderly. The reader is advised to check an up to date data sheet from the manufacturer before prescribing a drug, especially where he or she is not very familiar with the product – this advice applies to all pharmaceuticals³⁵⁴⁶. Drugs that block noradrenaline uptake, like maprotilene, or 5-HT, like fluoxetine, appear to have equivalent antidepressant potency. Downregulation of

³⁵⁴⁰ A study of psychiatrists' outpatient prescribing practices in Rhode Island during 2001-2 (Zimmerman et al, 2004) showed that their main considerations were avoiding specific side effects (esp. sexual dysfunction and weight gain), comorbidity (esp. GAD and panic disorder), and the presence of specific symptoms (esp. high anxiety, insomnia and fatigue). Prior response to treatment came next. Drug interactions or discontinuation syndromes were much less influential. In order of frequency, the prescribed drugs were citalopram (23.3%, N = 265), bupropion, sertraline, venlafaxine, mirtazapine, fluoxetine, paroxetine, nefazodone, TCAs, others/missing, and, in 0.4% (N = 4), MAOIs.

³⁵⁴¹ Often synonymous with non-sedating.

³⁵⁴² TCA effectiveness in children has been shown to equal that of placebo.

³⁵⁴³ Imipramine is the best studied of the TCAs and is often used for comparison with newer antidepressants.

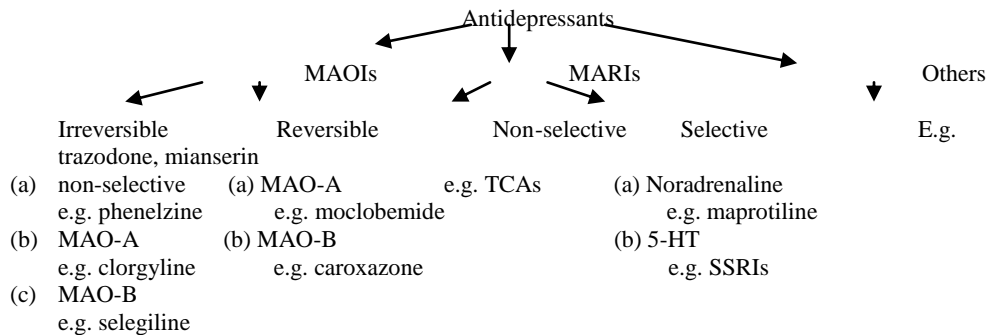

³⁵⁴⁴ Conative is synonymous with volitional.

³⁵⁴⁵ Simon et al (2006) found little evidence to suggest that newer antidepressants increase risk of suicide or serious suicide attempt.

³⁵⁴⁶ Zimeldine (Zelmid, derived from chlorpheniramine), the first SSRI, was removed from the market because of neurological problems (Guillain-Barré syndrome). The SSRI Femoxetine failed to reach the market. Another SSRI, indalpine, was withdrawn due to hepatotoxicity. Nomifensine was in use for seven years before its toxicity became apparent. Viloxazine, a bicyclic derivative of β -blockers that inhibits 5-HT uptake, was also withdrawn. Bupropion was temporarily withdrawn because of concerns over seizure induction. (Leonard, 2003, p. 190)

postsynaptic β -receptors is a very consistent finding after antidepressant treatment, and the same phenomenon has been reported with ECT and sleep deprivation. Researchers hold that one-third of patients placed on antidepressant drugs are non-responders, one-third are placebo responders, and the final third constitute responders.³⁵⁴⁷

Classification of antidepressant drugs

MAOI, monoamine oxidase inhibitor; MAO- monoamine oxidase; MARI, monoamine reuptake inhibitor; 5-HT, 5-hydroxytryptamine or serotonin; TCA, tricyclic antidepressant; and SSRI, specific (or selective) serotonin reuptake inhibitor.

Actions of antidepressant drugs (schematic)

Action on central serotonergic +/- catecholaminergic systems by reducing breakdown, blocking presynaptic (re-) uptake, or agonist/antagonist effects at receptor: **immediate** effect is increased availability of 5-HT +/- catecholamines

Down-regulation of presynaptic autoreceptors, alpha- and beta-noradrenergic receptors, and 5-HT₁ receptors: closer in time to **delayed** onset of clinical response (However, Mitchell [2006] and Tylee and Walters [2007] contend that antidepressants produce maximum improvement during the first 2 weeks, with some improvement in the first 3 days; also, Taylor et al [2006] found that SSRIs improved symptoms of depression by the end of week one with a decreasing rate of improvement for at least six weeks.)

Modulation of G proteins, second messenger systems, and gene expression: probably the **real reason** for efficacy/effectiveness*

*Protein phosphorylation within the cell is increased by chronic treatment with antidepressant drugs and this results in increased microtubule formation, which in turn may alter intraneuronal signal transduction. (Leonard, 2003, p. 166)

Tricyclic antidepressants (TCAs)

TCAs were still the most popular first preference antidepressants among senior Irish psychiatrists in 1991. (O'Shea, 1991) In fact, they may still be the most commonly used antidepressants world-wide. (Caturvedi, 1999) Tricyclics have no beneficial effects in euthymic subjects. TCAs are re-uptake inhibitors of monoamines (MARIs), preventing the re-uptake of neurotransmitters into the presynaptic neurone. Desipramine is a very strong re-uptake inhibitor of nor-adrenaline whereas clomipramine is a powerful

³⁵⁴⁷ The last third are said to occupy the 'efficacy window'. The narrowness of this window suggests that increased or decreased efficacy in comparative studies have to be large in order to be detected.

serotonin re-uptake inhibitor. The clinical utility of an IV infusion of clomipramine is debatable.(Loudon, 1993)

Following absorption, TCAs are metabolised by methylation and hydroxylation in the liver before they pass into the circulation where they are strongly bound to proteins. There is little to distinguish so-called slow release preparations from standard forms of TCAs.

TCAs can be subdivided into two groups on the basis of their sedative potencies: sedative (tertiary amine tricyclics - chiefly block 5-HT re-uptake; the higher the plasma concentration the greater is their antidepressant effect) and activating (secondary amine tricyclics - chiefly block noradrenaline re-uptake; the 'therapeutic window' effect leads to a situation where serum levels above or below a certain range fail to be therapeutic³⁵⁴⁸). Side chain demethylation converts tertiary amines to secondary amines and the latter to (inactive) primary amines.³⁵⁴⁹ Sudden cessation of tricyclics can lead to restless agitation, insomnia, headaches, vomiting and hyperhidrosis. A better guide to TCA toxicity than plasma level is the ECG. Excessive doses of TCAs can cause hypertension³⁵⁵⁰, cardiac arrhythmias, hallucinations, excitement, and seizures. TCAs impair conduction in the Bundle of His, causing tachycardia, arrhythmia, and heart block. Cardiac monitoring as well as stomach washout is indicated in cases of overdose.

O'Brien and Oyeboode (2003) have discussed the Brugada syndrome, a disorder of the Na⁺ channel and a cause of death (espc. during sleep) in Thai males.³⁵⁵¹

Donovan and Freeman (1990) believed that toxicity in TCA overdose has been over-emphasised when the benefits to patients from TCAs is considered.³⁵⁵² During the period 1993-7 in England and Wales 20% of all deaths from overdose and poisoning were antidepressant related. Whilst the number of such deaths increased by 18% during the same period, prescriptions for these drugs increased three times. 95% of antidepressant deaths were due to TCAs, especially dothiepin (dosulepin) and amitriptyline³⁵⁵³.

Lofepramine was relatively safe. The highest death rates were in males aged 30-44 years and in females aged 45-59 years. Very interestingly, such deaths were 2.5 times higher in the more socially deprived areas. In 28% of cases more than one drug was taken.(Shah ea, 2001)

Another study (Hawton ea, 2010), gathering data from disparate sources, found that TCAs (dosulepin [dothiepin] and doxepin were potentially more lethal than amitriptyline) were potentially more lethal than venlafaxine or mirtazapine, SSRIs being the potentially least lethal antidepressants (with citalopram having the highest case fatality among SSRIs).

³⁵⁴⁸ E.g. nortriptyline 50-150 ng/ml. The statistical strength of the therapeutic window concept is generally too weak to have much influence on clinical practice.

³⁵⁴⁹ Amitriptyline (Tryptizol, Lentizol, Triptafen, Laroxyl – half-life 9-36 hrs; active metabolite nortriptyline has half-life of 18-44 hrs), dothiepin (dosulepin: Prothiaden – half-life 14-24 hrs; active metabolite desmethyl-dothiepin has a half-life of 23-46 hours), trimipramine, and clomipramine (Anafranil) are sedative TCAs. Examples of activating TCAs are protriptyline (Concordin - most activating TCA) and nortriptyline (e.g. Aventyl).

³⁵⁵⁰ Inhibition of reuptake of adrenaline and noradrenaline; inhibition of uptake of guanethidine, bethanidine, clonidine and debrisoquine increases blood pressure by antagonising the hypotensive drug effect.

³⁵⁵¹ Mutation of the SCN5A gene leads to a reduction of inward Na⁺ depolarising currents. The main complication is ventricular fibrillation. The heart is structurally normal. The ECG shows right bundle-branch block and S-T segment elevation in chest leads V1-V3, but a normal QT interval. Overdose of TCAs (and possibly of antipsychotic drugs) may present with these features.

³⁵⁵² The UK fatal toxicity index (FTI: deaths/million prescriptions) for various antidepressants, according to Buckley and McManus(2002) are (FTI in brackets) TCAs in general (34.8), desipramine (200.9), amoxapine (93.5), dothiepin (53.3), amitriptyline (38.0), declining to nortriptyline (5.5), lofepramine (1.3), and protriptyline (0); for serotonergic drugs the FTIs are venlafaxine (13.2), clomipramine (12.5, a TCA), fluvoxamine (3), citalopram (1.9), sertraline (1.2), fluoxetine (0.9), paroxetine (0.7), and nefazodone (0 – withdrawn 2003: liver failure); FTIs for MAOIs are tranylcypromine (43.6), phenelzine (14.9), and iproniazid and isocarboxazid (both 0); and those for flupenthixol (0.4), tryptophan (0), and lithium (7.2). In a report by Cheeta ea,(2004) the standardised proportionate mortality rate (SPMR) for amoxapine was 10 compared to SPMRs of, for example, protriptyline 5, amitriptyline 1.8, dothiepin 1.7, lofepramine 0.1, moclobemide 2.2, tranylcypromine 2.5, phenelzine 1.1, SSRIs 0.1-0.3, venlafaxine 1.6, and trazodone 0.3.

³⁵⁵³ Deaths/100,000 prescriptions for TCAs, MAOIs and SSRIs were 5.3, 4.4 and 0.4 respectively.

Apart from nortriptyline, there are no definite therapeutic ranges for TCA plasma levels.³⁵⁵⁴ Such levels may still be useful to monitor compliance or to confirm toxicity. TCA levels should be measured when the drug has reached steady state, usually after 5-7 days, and about 10-14 hours (aim for 12 hours) after ingesting the last dose.

TCA's

(a) TCA groups

Tertiary amines (terminal methyl group on side chain; potent antagonists of alpha-1-adrenoceptors and muscarinic cholinergic receptors – more sedating and anticholinergic) – amitriptyline (a very effective drug with low tolerability), imipramine (Tofranil)³⁵⁵⁵, doxepin (originally seen as safe in heart disease, but low doses used, withdrawn November 2006), trimipramine, clomipramine

Secondary amines – desipramine, nortriptyline, protriptyline

Note: Tertiary amines are converted to secondary amines, so that the effect of the derived compound has to be added to the effect of the parent compound, e.g. imipramine, amitriptyline, and clomipramine are converted to desipramine, nortriptyline, and desmethylclomipramine respectively. Desmethylclomipramine is a more potent inhibitor of noradrenaline uptake than of 5-HT uptake.

(b) Side effects of TCAs

Anticholinergic: dry mouth³⁵⁵⁶, blurred vision³⁵⁵⁷, oesophageal reflux³⁵⁵⁸, constipation, urinary retention. Anticholinergic drugs can cause delirium.³⁵⁵⁹

Biliary: cholestatic jaundice

Cardiovascular: postural hypotension³⁵⁶⁰, tachycardia³⁵⁶¹, arrhythmias³⁵⁶², conduction defects, hypertension, cardiac failure, myocardial infarction,³⁵⁶³ ECG changes (prolonged PR + QRS, flat T, depressed ST), cardiomyopathy, and sudden death. Lofepramine (Gamanil) is *relatively* safe. Cardiotoxicity reaches significant proportions in people with pre-existent heart problems and in overdose. Some authors suggest that psychiatric illness may play a role in myocardial infarction and that this fact confounds the undoubted increase in adverse myocardial events in treated patients. (Thorogood *et al.*, 1992) Cannon *et al.* (1994) found that imipramine improved symptoms in patients with chest pain and normal coronary angiograms. They point out that 10-30% of patients undergoing cardiac catheterisation because of chest pain are found to have normal coronary angiograms. Astemizole (Hismanal), an anti-allergic drug (selective H₁ antagonist) that prolongs the QT interval, may cause adverse events if combined with arrhythmogenic drugs like TCAs, antipsychotic drugs, and antiarrhythmics. TCAs may prevent uptake of adrenaline in local anaesthetics with consequent rise in blood pressure. Methylphenidate plus a TCA can cause hypertension.

Epilepsy: lowering of seizure threshold; it is suggested that clomipramine daily dosage be kept below 250 mg for that reason

³⁵⁵⁴ Therapeutic imipramine (plus desipramine) and desipramine levels of greater than 200 ng/ml and 125 ng/ml have been suggested.

³⁵⁵⁵ Imipramine (Tofranil), withdrawn 2006.

³⁵⁵⁶ Artificial saliva or hard sweets may help and attention to dental hygiene must be emphasised.

³⁵⁵⁷ Antidote: pilocarpine drops.

³⁵⁵⁸ Inhibited cardiac sphincter.

³⁵⁵⁹ 'Central anticholinergic crisis', e.g. with TCAs; use of an IV injection of physostigmine to bring about a rapid resolution of this crisis has been advocated, but the safety of such a treatment has been questioned because of possible adverse cardiac effects. In fact, physostigmine should only be used as a last resort.

³⁵⁶⁰ Relatively less likely with nortriptyline. (Roose *et al.*, 1981)

³⁵⁶¹ Rarely a significant problem with therapeutic doses, (Glassman & Bigger, 1981) but may be disconcerting.

³⁵⁶² Anoxia has been postulated to change TCAs from being antiarrhythmic to arrhythmogenic agents.

³⁵⁶³ Especially if TCA + age + stress. (Cohen *et al.*, 2000)

Eyes: increased intraocular pressure in narrow angle glaucoma; reduced lacrimation (antimuscarinic -predisposition to corneal infection/damage, esp. if contact lenses used)

Genitourinary: impotence, orchitis, hesitancy, retention, anorgasmia, and inability to ejaculate

Haematology: eosinophilia, leucocytosis, leucopaenia, and thrombocytopaenia with purpura; agranulocytosis is a rare hypersensitivity reaction to TCAs found most commonly in elderly females in the second month of treatment

Metabolic: gynaecomastia, amenorrhoea, engorged breasts and galactorrhoea, hypoglycaemia, changes in AVP (ADH) output

Nausea: try changing commercial preparation

Neuropsychiatric: sedation³⁵⁶⁴, confusion, headache, insomnia, aggressiveness, agitation, nightmares³⁵⁶⁵, hallucinosis, EPS, dysarthria, nystagmus, myoclonus³⁵⁶⁶, peripheral neuropathy, tinnitus, exacerbation of schizophrenia due to excess dopamine (DA), hypomania* (The increase in DA may improve Parkinson's disease but a TCA + L-DOPA can cause agitation, tremor and rigidity.) Tremor may respond to beta-blockers.(Bharucha & Sethi, 2004, p. 243)

Liver: elevated transaminases and alkaline phosphatase

Rapid cycling of mood disorders

Sexual: diminished libido, delayed or absent orgasm, and absent or retrograde ejaculation.³⁵⁶⁷

Skin: sweating, rashes (mild rashes might be treated symptomatically but anything more significant should lead to withdrawal³⁵⁶⁸ of the drug – avoid drugs that are metabolites of the offending agent, i.e. desipramine/imipramine or nortriptyline/amitriptyline)

Weight gain: chiefly associated with amitriptyline, chlorpromazine, clozapine, olanzapine, and lithium; it might be due to an increased appetite due to effects on noradrenergic pathways, thirst and the drinking of 'soft' or other drinks, or resistance to ADH. Ideally, the patient should be weighed regularly, including a baseline measurement before starting treatment. Dietician should advise on a low-carbohydrate diet (watch sodium in lithium preparations). Patient should drink water (not sugary drinks). If possible, reduce the dose of the drug. It has been suggested that depot haloperidol may cause less increase in weight than other depot antipsychotic drugs. It has also been suggested that trifluoperazine and haloperidol are superior in this regard than are chlorpromazine, thiothixene or thioridazine. Avoid anorectic drugs if possible (may exacerbate psychosis and cause valvular heart disease). H₂-blocking agents have been suggested for weight gain with olanzapine, as has amantadine.(Symmetrel, up to 300 mg/day: Graham ea, 2005)

Note: If the antidepressant mainly inhibits noradrenaline reuptake, as is the case with desipramine, relapse may follow addition of the noradrenaline synthesis inhibitor α -methyl paratyrosine.

*Lewis and Winokur (1982), and a number of later authors, believed that TCAs probably did not 'cause' a manic switch and that it was really a spontaneous swing that was being observed. Stoll ea (1994) found that mania secondary to antidepressants to be milder and of shorter duration than spontaneous mania and they suggested that MAOIs and bupropion may be associated with milder manic states than either TCAs or fluoxetine.

Contraindications to TCAs include prostatism, glaucoma, ischaemic heart disease, epilepsy, mania, and a history of recurrent ODs - risk must be weighed against likely benefit in individual cases. Bunney (1978) estimated that the risk of occurrence of hypomania is 11% with MAOIs (particularly with tranylcypromine) and about 8% with TCAs.

³⁵⁶⁴ This can be antihistaminic with doxepin or amitriptyline, or α -1-adrenergic blockade as with trazodone.

³⁵⁶⁵ Perhaps due to an anticholinergic action.

³⁵⁶⁶ This is usually mild. In problematic cases reduce TCA dose or add clonazepam.

³⁵⁶⁷ Dry orgasm.

³⁵⁶⁸ Preferably slow to avoid cholinergic rebound.

Of lofepramine (half-life of 2-3 hrs), an imipramine analogue and a tertiary amine with little anticholinergic potential, one third is broken down to desipramine³⁵⁶⁹. Lofepramine acts like a secondary amine³⁵⁷⁰. It has and a *relatively* low cardiotoxicity potential compared to other TCAs. Uncommonly, patients on lofepramine have become icteric during the first two months of treatment, and this disappears if the drug is stopped.

Clomipramine, a powerful cause of impotence, is useful in phobic and obsessional states³⁵⁷¹; high doses may activate withdrawn schizophrenics. Imipramine is useful in the short-term management of enuresis.(see later)

Amoxapine (Asendis - a demethylated metabolite of loxapine)³⁵⁷² is thought to block noradrenaline reuptake and to a lesser extent it may block 5-HT reuptake. There is also DA blockade by its metabolite.³⁵⁷³ There are minimal anticholinergic effects. Side effects include seizures, minor ECG changes, hypotension, hyperprolactinaemia³⁵⁷⁴, malignant neuroleptic syndrome, EPS and tardive dyskinesia. According to Buckley and McManus (1998) amoxapine had the highest fatal toxicity index³⁵⁷⁵ of all antidepressants! Children bind less TCA to protein and have less fat, into which the lipid soluble drug can penetrate, and hence are at greater risk than adults of toxic effects.

TCAs may reduce the antihypertensive effects of guanethidine, debrisoquine, bethanidine, a clonidine by interfering with the reuptake mechanism of noradrenergic neurones.

Patients with delusional affective disorder seem to respond less well to TCAs or to lithium than do those without delusions.

Sudden withdrawal from TCAs³⁵⁷⁶ can lead to a 'cholinergic rebound syndrome'³⁵⁷⁷ consisting of anxiety, dizziness, nausea, vomiting, gastric upset, diarrhoea, sweating, headache, and neck pain. TCA abstinence symptoms in children who were on moderate or high doses include flu-like symptoms with nausea, vomiting cramps, headaches, and muscle pains. Also described are social withdrawal, hyperactivity³⁵⁷⁸, depression, agitation, and insomnia. Withdrawal symptoms from TCAs may be prevented by very gradual tapering of dosage or by adding low doses of an anticholinergic drug³⁵⁷⁹. Nicotine and carbamazepine lower plasma TCA levels. Oestrogens, cimetidine, sodium valproate, and many antipsychotic drugs and SSRIs increase TCA levels.

Notes on the management of enuresis: This problem is more often one for paediatricians and child mental health care workers than for general adult psychiatrists. Nevertheless, the adult prevalence of this problem is about 1%. Behavioural methods of treatment include restricting fluids before bedtime, scheduled nocturnal waking to pass urine, and awards (praise, stars, etc) for dry nights. The bed and pad method (wetting sets off an alarm) is very effective (in children it is important that parents arise as well). TCAs,

³⁵⁶⁹ Desmethylinipramine or desipramine, a secondary amine with a half-life of 12-24 hrs.

³⁵⁷⁰ Inhibits noradrenaline re-uptake but not 5-HT.

³⁵⁷¹ Obsessional traits predict good response to fluvoxamine.(Ansseau ea, 1991)

³⁵⁷² **Amoxapine:** A dibenzoxazepine tetracyclic (sometimes described as a secondary amine TCA – it has a tricyclic structure with a fourth ring attached by a –N bond) that is said to be relatively safe from the cardiovascular point of view. It is said to be less likely than other TCAs to cause hypotension. Amoxapine is rapidly absorbed after oral ingestion. Amoxapine is converted to loxapine by the liver. Its main metabolite, 8-hydroxy-amoxapine, which has antipsychotic properties, has a 30-hour elimination half-life (8 hours for amoxapine).

³⁵⁷³ Relative antidepressant affinities for D2 receptors range from 5.6 for amoxapine to 0 for venlafaxine.(Richelson, 2001) The D2 antagonism of amoxapine may exacerbate Parkinson's disease.(Fava & Papakostas, 2008, p. 607)

³⁵⁷⁴ Galactorrhoea, amenorrhoea, and impotence.

³⁵⁷⁵ Surpassed by desipramine in their 2002 paper.

³⁵⁷⁶ Or low potency phenothiazines.

³⁵⁷⁷ Exposure of upregulated postsynaptic Ach receptors. However, this explanation has been challenged and serotonergic mechanisms may be involved.

³⁵⁷⁸ Hypomania with sudden withdrawal.(Schatzberg ea, 2005, p. 111)

³⁵⁷⁹ E.g. diphenhydramine 25 mg bid-tid.

especially imipramine about 2 mg/Kg nocte (avoid desipramine), are effective, although relapse is common in practice on stopping the drug, particularly if the dose is reduced too quickly. Desmopressin (DDAVP, an antidiuretic hormone/vasopressin analogue: Desmospray, Desmotabs), MAOIs, and carbamazepine have also been shown to help. Oxybutynin (Cystrin, Ditropan, Renamel), an anticholinergic-antispasmodic, may improve daytime enuresis by relaxing the detrusor muscle. Anticholinergic drugs per se are not effective. There are many other approaches, e.g. ultrasound detection of bladder size.

Monoamine oxidase inhibitors (MAOIs)

The classical indications for MAOIs are atypical depression or reverse negative symptoms: mood reactivity, irritability, rejection hypersensitivity, hypersomnia, hyperphagia, and psychomotor agitation. Early studies of MAOIs used low doses. Higher doses are superior to placebo and, whether or not the depression has endogenous features, MAOIs are equivalent in effectiveness to TCAs.

Two subgroups of MAOIs

*Hydrazine*³⁵⁸⁰ e.g. phenelzine (Nardil)

Non-hydrazine e.g. tranylcypromine (Parnate)³⁵⁸¹

MAOIs inhibit MAO. This process starts in the gut wall, continues in the liver, and ends in the brain. The dose needs to be increased until CNS side effects occur, such as sedation with phenelzine or postural hypotension with tranylcypromine. Tranylcypromine is stimulant and euphoriant. Phenelzine (Nardil), which is sedative, is started in a dose of 15 mgs BID and cautiously increased if required to 15 mgs QID (dose range 45-90 mgs/day).

Hepatocellular damage with jaundice from hydrazines is rare except in alcoholics. If an adequate trial of one MAOI does not work, other MAOIs probably won't work either. (Schatzberg et al, 2005, p. 123) MAOI serum levels are not related to therapeutic effect. A platelet MAO suppression of more than 80% may be necessary for optimal therapeutic response, although this requirement is not universally accepted dogma. Slow acetylators have low levels of acetylase, an autosomal recessive trait. The clinical relevance of acetylator status is less certain than it was. (Leonard, 2003, p. 85)

Side effects of MAOIs

Abuse for feeling of euphoria, e.g. tranylcypromine³⁵⁸²

Dry mouth, constipation, nausea, postural hypotension³⁵⁸³, blurred vision, colour blindness³⁵⁸⁴, tremor, peripheral neuropathy, electric shock-like sensations³⁵⁸⁵, impotence, urinary retention, weight gain, leucopaenia, sweating, migraine made worse or initiated, hypomania, hepatocellular jaundice (especially iproniazid³⁵⁸⁶ and other hydrazines³⁵⁸⁷),

³⁵⁸⁰ NH₂NH₂.

³⁵⁸¹ A cyclopropylamine formed by substitution of isopropyl side chain of amphetamine with a cyclopropyl one.

³⁵⁸² Amphetamine is one of the metabolites of tranylcypromine. Marangell et al (2003) suggest a two-week interval between stopping phenelzine and starting tranylcypromine because of the amphetamine-like nature of the latter drug.

³⁵⁸³ Possibly due to DA accumulation in sympathetic cervical ganglia where it acts as an inhibitory neurotransmitter with consequent reduction in peripheral vascular tone. (Leonard, 2003, p. 170) Salt tablets or fludrocortisone may help.

³⁵⁸⁴ This is uncommon. Pheniprazine, an early MAOI, was withdrawn because it caused transient red-green colour blindness from Retrobulbar neuritis.

³⁵⁸⁵ These may respond to clonazepam. Peripheral neuropathy usually responds to vitamin B6 50-100 mg/day.

³⁵⁸⁶ Fox, a chemist, at Hoffmann-La Roche Labs in New Jersey, looking for anti-TB drugs, synthesised iproniazid from isonicotinic acid; iproniazid was synthesised from isoniazid; Irving Selikoff (1915-92) reported the improved mood induced by the latter as a toxic effect!

³⁵⁸⁷ Hydrazine: two linked NH groups.

exacerbation of liver disease, exacerbation of gluten enteropathy with gluten-containing preparations.

Peripheral oedema of the dependent type³⁵⁸⁸ may occur with TCAs, MAOIs, or with phenothiazines.

Phenelzine may lower pseudocholinesterase and prolong neuromuscular blockade.³⁵⁸⁹

Hypertensive crisis – hypertension, headache, vomiting, sweating, and, potentially, intracranial haemorrhage or myocardial infarction.

Notes: Constipation should be treated with a bulk laxative, such as methylcellulose (Celevac) or bran.

Avoid SSRIs, clomipramine, fenfluramine, and buspirone.

Patients on non-selective MAOIs who are stung by a bee (causes MAO-A inhibition in GIT) may develop a hypertensive crisis (increased tyramine absorption leading to pressor effect).

It has been suggested that patients taking MAOIs carry a 10 mg nifedipine (calcium channel blocker) tablet to chew or dissolve under the tongue at the first sign of hypertensive reaction (sudden fatigue or a pounding bilateral occipital headache). Some workers believe that the risks associated with nifedipine are irrelevant compared with a hypertensive crisis. Others point out that nifedipine use in such circumstances may cause myocardial infarction and would strongly suggest that it not be used. The best drugs are still chlorpromazine, 25-50 mg IM, or phentolamine (Rogitine), 5 mg IV. Marangell *et al* (2003) suggest that due to risks of cardiac arrhythmias or severe hypotension phentolamine should be given in a place where such adverse outcomes can be managed (e.g. A & E department).

Ginseng, found in herbal remedies, may cause headache, tremor, insomnia, or mania if taken with MAOIs.

Drug interactions may occur with sympathomimetics³⁵⁹⁰, TCAs³⁵⁹¹, α -methyl dopa and reserpine may cause central excitation, insulin and oral hypoglycaemic drugs³⁵⁹², alcohol and barbiturates³⁵⁹³. MAOIs block the metabolism of phenytoin, which may put the patient at risk for phenytoin toxicity. Antihistamines can be co-prescribed with a MAOI as long as there are no accompanying sympathomimetics. Narcotic analgesics are a different story. Pethidine³⁵⁹⁴ should always be avoided because of the risk of a fatal excitatory reaction, but morphine is safe to use. There are two distinct forms of MAOI/narcotic interaction: excitatory³⁵⁹⁵ and depressive³⁵⁹⁶. The only analgesics to have elicited the excitatory response are pethidine (meperidine/Demerol) and, possibly, dextromethorphan³⁵⁹⁷. Remick *et al* (1987) found no evidence of hazard with the combination of a general anaesthetic with a MAOI. They also felt that it was unwarranted to stop MAOIs for two weeks before ECT. Peden (2000) saw little evidence for stopping psychotropic drugs before anaesthesia, but advises forewarning the anaesthetist.

³⁵⁸⁸ Fluid retention causes puffy hands and swollen ankles (an effect on local blood vessels has also been postulated). Salt restriction may help.

³⁵⁸⁹ When the anaesthetist requires it, stop phenelzine 10-14 days before elective procedures requiring succinylcholine. However, phenelzine therapy is no longer seen as a contraindication to surgery or ECT. (Alpert *et al*, 2004, p. 257)

³⁵⁹⁰ Ephedrine, nasal decongestants, cough and cold cures – asthma inhalers can cause problems, except for pure steroid preparations.

³⁵⁹¹ Hypertensive crisis – especially imipramine, desipramine, and clomipramine.

³⁵⁹² Increased sensitivity to these drugs may cause severe hypoglycaemia.

³⁵⁹³ Increase in central depression.

³⁵⁹⁴ Meperidine [Demerol] in USA.

³⁵⁹⁵ Sudden agitation, unmanageable behavior, headache, hypo- or hypertension, rigidity, fits, pyrexia, and coma - possibly due to central serotonergic overactivity.

³⁵⁹⁶ Respiratory depression, hypotension, and coma - inhibition of hepatic microsomal enzymes by MAOI with consequent accumulation of non-metabolised narcotic.

³⁵⁹⁷ Present in OTC cough syrups.

1092

The *cheese reaction* (Blackwell *et al.*, 1967) is due to the presence in food of the indirect sympathomimetic tyramine³⁵⁹⁸. Any foods subject to decomposition may contain pressor amines. Tyramine releases adrenaline and NA and causes severe headache, fever, muscle spasm, and even cerebral or subarachnoid bleeding. Among foods to be avoided are cheese, meat (i.e. if not fresh) and meat and yeast extracts (Oxo, Bovril, and Marmite) fortified wines, any non-fresh food, broad bean pods (not the beans themselves), pickled herrings, and venison. Fava beans contain L-dopa and should be avoided. Chianti is an oft-quoted offender. Small quantities of some wines, non-tap beers (bottled and canned) and sherries may be taken in safety. Avoid tap beers. Tyramine can be present in processed drinks involving yeast, even if alcohol is absent. Therefore, patients on MAOIs should avoid tapped alcoholic and non-alcoholic beers. The list of restricted foods is potentially very long (banana skins, caviar, etc) and an up-to-date warning card must be obtained from the dispensing pharmacist. Tyramine content of food varies by sample, country and region. (Pies & Shader, 2003, p. 262) Schatzberg *et al.* (2005, p. 119) advise against eating Chinese food because of ingredients such as sherry and soy sauce.

Management of a hypertensive crisis

Oral nifedipine (calcium channel-blocker): 10 mg, often normalises blood pressure within minutes

Chlorpromazine

Phentolamine (Rogitine) 5 mgs IV: this alpha-adrenergic blocker should only be used in a suitable hospital setting because it may be associated with cardiac arrhythmias or significant hypotension

Other steps: suxamethonium, a ventilator and tepid sponging

On stopping a TCA one should wait at least three days before starting a MAOI. The opposite switch demands an interval of at least seven days³⁵⁹⁹ (5-6 weeks when stopping tranylcypromine). When starting a MAOI + TCA combination wait for one week after stopping either class of drug. Each drug is given in small doses and slowly increased together (some authorities start the TCA first and gradually add the MAOI). Only some combinations are relatively safe, e.g. phenelzine (Nardil) and amitriptyline (Tryptizol) or trimipramine (Surmontil). *Tranylcypromine and clomipramine is an extremely dangerous combination*. Changing from a MAOI to a TCA is more dangerous than is the opposite manoeuvre (one may need suppression of much MAO for a reaction). Adding a MAOI to a TCA is safer than the opposite manoeuvre. When switching from a hydrazine MAOI like phenelzine to a non-hydrazine MAOI like tranylcypromine (a derivative of amphetamine) one should wait at least 2 weeks after the first drug is withdrawn because the latter drug inhibits noradrenaline uptake and causes dextroamphetamine-type sympathomimetic effects which may cause toxicity if the second drug is instituted too early. (Nies, 1982) SSRIs should never be prescribed with MAOIs and fluoxetine takes 5-6 weeks to leave the system (leave about 2 weeks for other SSRIs). Not everyone considers the risks of combined antidepressants to be as serious as these notes suggest. For example, Pare *et al.* (1982) felt that a TCA/MAOI combination may be safer than prescribing MAOIs alone as it seems to reduce the risk of causing a 'cheese' effect. However, there is no universal consensus on the usefulness of TCA/MAOI combination therapy. (Kennedy & Joffe, 1989)

Moclobemide: Classic MAOIs bind very strongly and irreversibly to MAO, resulting in a complete and prolonged inhibition of MAO. Moclobemide (Manerix³⁶⁰⁰) is a selective MAO-A inhibitor and substituted benzamide. Tyramine can compete with it for the enzyme, making moclobemide much less likely to cause a hypertensive crisis, although

³⁵⁹⁸ Or other offenders such as DOPA.

³⁵⁹⁹ For moclobemide and selegiline leave 1 week after stopping either drug before giving another antidepressant. (Lam & Mok, 2008, p. 54)

³⁶⁰⁰ Aurorix in USA.

some authors (e.g. Livingston, 1995) would suggest full MAOI precautions as for the non-selective drugs. Full MAO activity is restored within 24 hours. Some authors do not accept that moclobemide is as effective as TCAs and the classic MAOIs (e.g. Howland & Thase, 2002). It is said to be non-toxic to the liver. Moclobemide plasma levels are increased by cimetidine (Tagamet). Moclobemide has little effect on body weight, reaction times (as in driving), short-term memory, or arousal. Its action lasts for 8-16 hours, the elimination half-life is 1-2 hours, and it is 50% bound to plasma proteins. Moclobemide may be associated with raised levels of liver enzymes of no clinical relevance. The usual dose is 300 mg/day in 2-3 divided doses (max. 600 mg/day³⁶⁰¹). Lower doses are given in the presence of severe hepatic disease or drugs that inhibit microsomal mono-oxygenase activity (e.g. cimetidine). Do not use it with pethidine, SSRIs (danger of serotonin syndrome) or 5-HT precursors, or in the presence of thyrotoxicosis or phaeochromocytoma. The combination of clomipramine and moclobemide has been reported to cause a serotonin syndrome. Hypertensives should avoid a large amount of old ripe cheese³⁶⁰². Indirectly acting sympathomimetics and pethidine should be avoided during anaesthesia. Side effects include insomnia, headache, dizziness, nausea, and confusion (rare). Controversially, (Freeman, 1993) Fahy (1993) suggested that moclobemide-treated patients may become very excited and have experiences of unreality. Moclobemide causes increased effects of opiates and ibuprofen. Very little appears in breast milk and a washout period is not required before starting TCAs. Overdose causes agitation, aggressiveness and behavioural changes. The efficacy of the RIMAs has questioned. (Leonard, 2003, p. 171)

Brofaromine, selegiline, toloxatone and chlorgyline are other selective MAOIs.

Selegiline (Eldepryl or -deprenyl) is a selective and irreversible MAO-B inhibitor that potentiates brain DA function. Selegiline is derived from metamphetamine; indeed, like tranlycypromine, it is metabolised to L-amphetamine and L-methamphetamine in the body. It was not viewed as a useful antidepressant and was used for Parkinson's disease. However, it has become available as a patch-delivered antidepressant (Emsam: 6 mg/24 hr) in the US. It is said not to cause a tyramine reaction with no need therefore for dietary restrictions³⁶⁰³. The most important adverse effects are confusion and psychosis. Selegiline protects against methyl-phenyl-tetra-hydro-pyridine (MPTP) in animals. MPTP is converted by MAO-B to MPP that selectively destroys nigrostriatal DA neurones. *Do not use SSRIs or add an MAO-A³⁶⁰⁴ inhibitor (moclobemide) if the patient is taking selegiline*, and be cautious in the use of TCAs. Lauterbach (2000) suggests discontinuation of selegiline for at least two weeks (5 weeks for fluoxetine) before starting another antidepressant because of reported fatalities due to drug interactions. Abrupt discontinuation of selegiline may lead to nausea, dizziness, and hallucinations. (Schatzberg et al, 2005, p. 125)

DA and tyramine are common substrates for both types of MAO (-A and -B). Noradrenaline and 5-HT are substrates for MAO-A, and phenylethylamine and benzylamine are substrates for MAO-B. Non-selective MAOIs like tranlycypromine exert significant effects on both types of MAO and are therefore more likely to give rise to a cheese reaction. Because moclobemide preferentially inhibits MAO-A it interferes less with the metabolism of tyramine.

Because irreversible MAOIs form a permanent covalent bond between the MAO enzyme and the inhibitor their duration of action is equal to the time required for renewal of the enzymes. A single dose can last for several days.

³⁶⁰¹ At very doses, such as 900 mg/day, moclobemide also inhibits MAO-B.

³⁶⁰² Otherwise there is not the same embargo as with the older MAOIs.

³⁶⁰³ However, other authorities suggest that dietary precautions are required for higher (9 or more mg) but not lower (6 mg) doses of selegiline.

³⁶⁰⁴ RIMA + selegiline = non-selective MAOI!

In the case of reversible MAOIs, the duration of action is dose-related to the elimination half-life. High affinity substrates can displace the inhibitor from the enzyme. Also, MAO-B is still left to metabolise the ingested tyramine³⁶⁰⁵.

Selective/specific serotonin reuptake inhibitors (SSRIs)

The SSRIs (unlike TCAs) do not share a common structural moiety. They have a range of structures encompassing monocyclic, bicyclic, tricyclic and tetracyclic configurations. The most potent SSRI (at inhibiting 5-HT uptake) is paroxetine, and the most selective (for serotonin) SSRI is citalopram followed by sertraline.³⁶⁰⁶ The therapeutic action of SSRIs may not be as simple as inhibition of reuptake of serotonin at the presynaptic receptor.³⁶⁰⁷

Tamoxifen may reduce serum TCA levels and the activity of tamoxifen itself may be reduced by SSRIs.(Jin ea, 2005) Paroxetine used in association with tamoxifen may be associated with an increased risk of death from breast cancer, at least in older women.(Kelly ea, 2010)

Nausea may limit compliance with SSRI therapy,(Dowling ea, 1990) and taking the drug with food may help in this regard. Also, nausea often diminishes with time on the drug.

Low dose cisapride may relieve such nausea, perhaps via antagonism of 5-HT₃ receptors³⁶⁰⁸. Ginger tea is found helpful by some patients. Ondansetron³⁶⁰⁹ may also be helpful³⁶¹⁰. SSRIs, fluoxetine more than paroxetine, may interfere with sleep and taking the bulk of the dose in the morning may reduce this effect. Longterm use of SSRIs may be associated with side effects that are not obvious during acute treatment, e.g. sleep problems, sexual dysfunction, and weight gain,(Sherman, 1998) and perhaps amnesia.(Joss ea, 2003) Prolactin levels may rise in SSRI-treated patients, more often in women than in men, which has implications for fracture risk, especially in older people.(Fava & Papakostas, 2008, p. 600) *Never combine an MAOI with an SSRI.(vide supra)* Procarbazine³⁶¹¹ and linezolid³⁶¹² are MAOIs and therefore should not be given to someone on an SSRI. SSRIs may cause EPS such as Parkinsonism or even TD.(Gerber & Lynd, 1998) The reason why TCAs and SSRIs can induce EPS may relate to the fact that 5-HT normally and tonically inhibits brainstem DA function. There are suggestions that SSRIs can 'reveal' tardive dyskinesia in those patients previously exposed to antipsychotic drugs or to exacerbate such disorders. SSRIs can worsen the tremor of lithium as well as the EPS caused by antipsychotic drugs, bupropion, and psychostimulants. The minimum effective dose of the SSRIs produces about 80% inhibition of platelet serotonin uptake in most patients. Agents increasing serotonin availability³⁶¹³ can, especially if combined with an SSRI, potentially lead to a serotonin syndrome with delirium, agitation, restlessness, diarrhoea, hyperthermia, rapidly changing vital signs, ataxia, dysarthria, rigidity, myoclonus, hyperreflexia, and possibly

³⁶⁰⁵ As well as MAO-A from which the RIMA - reversible inhibitor of MAO-A - moclobemide is displaced.

³⁶⁰⁶ Relative affinities for blocking the 5-HT transporter among selected antidepressants are: paroxetine 800, clomipramine 360, sertraline 341, fluoxetine 120, citalopram 86, fluvoxamine 45, venlafaxine 11, and doxepin 1.5.(Richelson, 2001)

³⁶⁰⁷ Other actions that may be important include blockade of somatodendritic autoreceptors (an early effect is downregulation/desensitisation of such receptors), reduced impulse flow in the axon, a delayed increase in presynaptic release of 5-HT (a candidate for the true therapeutic action), and downregulation of postsynaptic receptors (perhaps conferring tolerance to side effects).

³⁶⁰⁸ **Cisapride** (Prepulsid) can cause QT elongation and, according to Mitchell ea (2002, p. 1199), it was taken off the US market for this reason. It was formally employed in anorexia nervosa.

³⁶⁰⁹ 5-HT₃ receptor antagonism.

³⁶¹⁰ Mirtazepine blocks 5-HT₃ receptors and causes less GIT upset than SSRIs. Some practitioners co-prescribe mirtazepine with SSRIs for a short period.

³⁶¹¹ A treatment for blood malignancies.

³⁶¹² Linezolid is an antibacterial oxazolidinone that is a non-selective MAOI.

³⁶¹³ Lithium, MAOIs such as chlorgyline or phenelzine, tryptophan, clomipramine, etc.(Keck & Arnold, 2000)

coma and death³⁶¹⁴. (Edwards, 1992) Fluoxetine may cause a serotonin syndrome even when the patient stops taking it if another serotonergic drug is added! Overdose³⁶¹⁵ of MAOIs has caused serotonin syndrome, as have carcinoid and oat cell carcinomas. The drug(s) should be stopped (resolution usually follows quickly). BZDs or a cooling blanket may be required. 5-HT antagonists (e.g. cyproheptadine, 8-32 mg/day) or (for its 5-HT_{1A} antagonism) propranolol may be indicated in some cases.

Headache, occipital and pounding, is associated with SSRIs, and may occur more frequently with continued use. (Frazer, 1997) Pharyngitis, dyspnoea, serum sickness and alopecia are uncommon adverse effects of SSRIs. All SSRIs can cause hyponatraemia (see Ul Haque *et al*, 2010) via inappropriate ADH secretion (in one series SIADH mainly occurred in the over-65s on SSRIs, usually starting on day 13; TCAs, such as lofepramine, have also been reported to cause hyponatraemia). SIADH usually resolves over several weeks after stopping the offending drug. As well as stopping the offending drug, fluids should be restricted. Symptoms of SIADH include headache and lethargy. Apart from hyponatraemia there is an increase in renal excretion of sodium and the urine is hyperosmotic. In severe cases (delirium, seizures, or coma) IV sodium chloride is required.

SSRIs inhibit CYP2D6 and there increase TCA and antipsychotic drug concentrations. SSRIs may increase the effects of warfarin with a tendency to bleed without a change in prothrombin time. Nemeroff *et al* (1996) warn that inhibitors of cytochrome P450 3A4³⁶¹⁶ should preferably be avoided in patients on terfenadine, astemizole, alprazolam or triazolam or in patients receiving midazolam as a component of anaesthesia. Side effects are very similar for each SSRI and are most pronounced early in treatment. Sexual dysfunction is common in patients on SSRIs³⁶¹⁷. Moclobemide has less sexual side effects, the opposite applying to SSRIs and venlafaxine. However, clomipramine and SSRIs can be used to treat premature ejaculation, and trazodone has been used to treat erectile dysfunction. Sexual side effects of antidepressants might be approached by dose reduction, changing the drug, a drug holiday, or remedial therapy. (Mir & Taylor, 1998) The latter may take several forms.³⁶¹⁸

Strategies for managing sexual side effects of antidepressants (Rothschild, 1999)

Reduce dose
Weekend drug holidays for short half-life drugs
Change the antidepressant
Take medication after coitus
Cyproheptadine
Bethanacol
Amantadine
Yohimbine
Buspirone
Bupropion

Seizures may occur with any SSRI. Rash in SSRI-treated patients is usually urticarial and may rarely include fever, arthralgia, and lymphadenopathy. If a rash occurs the SSRI should be stopped. Mydriasis has been reported with paroxetine and a combination of

³⁶¹⁴ That being said, this author (or many others, e.g. Hendrickx & Floris, 1991) has experienced no significant problems among patients treated with lithium and an SSRI.

³⁶¹⁵ Beware of the patient who takes an overdose of multiple antidepressants, e.g. SSRI + TCA or MAOI!

³⁶¹⁶ Especially fluoxetine, fluvoxamine, and nefazodone.

³⁶¹⁷ Consider changing to trazodone.

³⁶¹⁸ If the problem is increased serotonergic transmission (e.g. SSRIs) one could try the antihistamine cyproheptadine (which has 5-HT₂ antagonist activity). However, according to Meston & Frohlich, (2002) cyproheptadine can interfere with the antidepressant effects of SSRIs. Granisetron (5-HT₃ antagonist) may improve SSRI-induced anorgasmia. Yohimbine (α_2 antagonist and α_1 agonist) for fluoxetine-induced impotence or anorgasmia. Amantadine (DA agonist) for ejaculatory difficulties or (taken 5-6 hrs before intercourse) anorgasmia secondary to SSRIs.

mydriasis and uneven pupils³⁶¹⁹ with paroxetine and sertraline.(Barrett, 1994) SSRIs inhibit hydroxylase enzymes and may thus increase TCA plasma levels by a factor of four. The combination (TCA + SSRI) can cause hypertension and/or the serotonin syndrome. Yawning and spontaneous orgasm are rare side effects of SSRIs. Overdose of SSRIs may cause agitation, vomiting and seizures. The SSRIs are finding an ever-expanding list of applications, e.g. depression³⁶²⁰, depression associated with anxiety, obsessional states, social phobia, bulimia nervosa, and premenstrual syndrome. Efficacy is similar for all the SSRIs³⁶²¹.(Edwards & Anderson, 1999) SSRI discontinuation rates may be no different from those for newer TCAs and heterocyclics.(Hotopf ea, 1997) although they compare favourably in this regard with the older TCAs. The SSRIs are expensive compared to TCAs (Song ea, 1993) although their side effect profile seems more acceptable to consumers. Withdrawal (discontinuation) symptoms are least likely with fluoxetine³⁶²² and most likely with paroxetine. Such symptoms potentially include short-lived (usually start after 48 hours and resolve within 3 weeks³⁶²³) dizziness, nausea, vomiting, diarrhoea, myalgia, fatigue, anxiety, headache, agitation, insomnia, unusual dreams, sweating, tremor, vertigo, hallucinations, electric shock-like sensations, and depersonalisation. There has also been a report of a neonatal withdrawal reaction. SSRIs should be withdrawn gradually, especially those with shorter half-lives. Some authors suggest giving one dose of fluoxetine to attenuate withdrawal from shorter acting serotonergic antidepressants.(Marangell ea, 2003) Short-term use of a benzodiazepine is another possible strategy.(Marangell ea, 2003)

An increase in anxiety early on in treatment with an SSRI often proves to be transient. It may be due to hypersensitive 5-HT_{1A} receptors that normalise with continued treatment. Use of low starting doses (e.g. fluoxetine 10mg mane) may avoid much of this problem, but the patient should be forewarned. The patient should be monitored for agitation.(Geddes & Cipriani, 2004)

An *apathy syndrome*, which may be subtle, has been ascribed to SSRIs. There is an inability to 'experience feeling', good or bad.(Price ea, 2009) It may respond to dose reduction or switching to a non-serotonergic antidepressant such as bupropion. When depression lifts but anhedonia persists, drug-induced apathy should be considered. **Fluoxetine**³⁶²⁴ (Prozac, Prozamel, Norzac, Fluzac, Bellzac) is an SSRI that is unrelated chemically to either TCAs or tetracyclics. It is not to be combined with MAOIs or tryptophan. The starting and usual therapeutic dose for depression dose is 20 mgs/day.³⁶²⁵ Fluoxetine is taken in the morning. The parent drug has a long elimination half-life of 2-3 days. So also has its major active metabolite, desmethylfluoxetine (7-9 days), also a potent and specific 5-HT re-uptake inhibitor. In the elderly the clinician can prescribe 10 mg/day or 20 mgs every second day.

³⁶¹⁹ Anisocoria.

³⁶²⁰ Many clinicians view them as indicated in 'mild/moderate' cases only – some studies have reported superior efficacy for TCAs(, e.g. Danish University Antidepressant Group[1990; Roose ea, 1994]) – but see Montgomery ea's meta-analysis(1994), who found similar efficacy between both groups with greater dropout rates for TCAs secondary to side effects; see also Montgomery & Johnson.(1995)

³⁶²¹ Kirsch ea (2008) meta-analysed data on randomised, double-blind, placebo-controlled trials conducted on patients with DSM major depression (measured with HRSD) treated with fluoxetine, venlafaxine, nefazodone, and paroxetine submitted to the FDA for licensing purposes. Drug-placebo differences increased as a function of initial severity: no difference at moderate levels and a relatively small difference at the very severe end of the severity scale. Timonen and Liukkonen (2008), on the other hand, whilst acknowledging that 'most' of the trials are sponsored by the pharmaceutical industry, suggest that there is 'robust' evidence for the efficacy of these drugs, and NICE recommends that we try SSRIs first for depression.(National Institute for Clinical Excellence, 2004) A possible reason for the Kirsch ea (2008) result might be an excessively wide variety of problems under the heading of 'depression' or, more fundamentally, an excessively short follow-up of 6 weeks.

³⁶²² Long half-life of parent and norfluoxetine/desmethylfluoxetine.

³⁶²³ Different sources give different timescales (e.g. starts within 24 hours, peaks days 5 to 6, and resolves within a fortnight) so it is difficult to be exact.

³⁶²⁴ The dose of the sustained release formulation of Prozac (Prozac Weekly) was 90 mg once weekly.(Schmidt ea, 2000; Miner ea, 2002) However, Eli Lilly announced its withdrawal from the market in mid-2008.

³⁶²⁵ Prozac liquid contains 20 mg/5 ml.

Five weeks must pass after stopping fluoxetine and starting a MAOI and more than 2 weeks after stopping a MAOI and starting fluoxetine, probably up to 6 weeks for tranylcypromine.

Fluoxetine inhibits the metabolism of TCAs and BZDs. Seizures have been reported in those patients receiving both a TCA and fluoxetine. Fluoxetine is extensively metabolised in the liver and excreted by the kidneys. Fluoxetine can reduce weight (albeit transiently), and can cause anorexia, agitation, and insomnia. Paton and Ferrier (2005) discuss the differential affinities of various antidepressants on the serotonin transporter: high for clomipramine, fluoxetine, sertraline, and paroxetine; intermediate for citalopram, fluvoxamine, and venlafaxine; and low for doxepin, mirtazepine³⁶²⁶, moclobemide, and nortriptyline. Fluoxetine decreases granular storage of serotonin in platelets that can lead to an increase in bleeding time.³⁶²⁷ Rarely there may be bruising or melaena. Upper GIT bleeding is a potential problem with SSRIs and venlafaxine, made much more likely if NSAIDs, ticlopidine or aspirin is added to the regimen.(Anonymous, 2004; de Abajo & Garcia-Rodriguez, 2008) It is suggested that the bleeding time be checked before elective surgery if the patient is on fluoxetine³⁶²⁸. Caution has been urged when prescribing SSRIs in any patient on a treatment that increases the risk of bleeding.(Anonymous, 2003a) Paton and Ferrier (2005) suggest using gastroprotective agents³⁶²⁹ in certain groups of SSRI-treated patients, e.g. history of bleeding, elderly, those on NSAIDs or aspirin, but not in those on SSRIs alone.

Starting in 1990, reports started appearing alleging that fluoxetine caused the emergence of serious suicidal preoccupation in depressed patients³⁶³⁰. The evidence is that fluoxetine probably is no more likely to be culpable in this regard than any other antidepressant(e.g. Murphy & Kelleher, 1994; Khan et al, 2003; Jick et al, 2004; Geddes & Cipriani, 2004; Martinez et al, 2005; Tauscher-Wisniewski et al, 2007) especially in adults. Not all studies agree, however.(Fergusson et al, 2005) An important point is that suicidality may increase transiently in depressives when volition returns as depression lifts and self-harm may be related to variables other than depression or its treatment, e.g. family discord or substance abuse.(Brent et al, 2009) Interestingly, it has been advocated for agitated depression. However, the debate continues about the suicidogenic and withdrawal propensities of SSRIs in general.(Anonymous, 2003b; Leonard, 2004; Cato, 2005; Gunnell et al, 2005; Hall, 2006; Gibbons et al, 2006) Hypomania or mania occurs in a few percent of treated patients. There is less agreement that fluoxetine doesn't cause increased levels of hostility and aggression.(Anonymous, 1992) although the same has been said of TCAs. Also, SSRIs can cause akathisia, itself associated with suicidal ideation. Fluoxetine can cause hypoglycaemia and its side effects can mimic hypoglycaemia. According to Katona et al,(1995) the combination of lithium and fluoxetine causes neurotoxicity no more often than the combination of lofepramine. The combination of pimozone and fluoxetine can lead to bradycardia and/or delirium. Withdrawal of fluoxetine can potentially lead to hyperglycaemia. The anorectic and weight reducing properties and reduced incidence of anticholinergic side effects of fluoxetine may be of use in diabetes mellitus. Nevertheless, its use in diabetics should be carefully monitored.

³⁶²⁶ This 6-azo derivative of mianserin has more potent effects on the 5-HT system than has mianserin.

³⁶²⁷ 5-HT release from platelets augments their aggregation.

³⁶²⁸ But see Irish Medicines Board(2000) for a broader warning about SSRIs.

³⁶²⁹ H2 antagonists, proton pump inhibitors, or misoprostil.

³⁶³⁰ The American FDA warns of suicidality in relation to all antidepressants, but the risk of suicide is much higher in untreated depression.(Friedman & Leon, 2007) The Irish Medicines Board (2008) states that young adults in particular should be warned that they may feel suicidal during antidepressant treatment and that they should seek help immediately if they begin to feel that way; also a friend or close relative should be in the know and keep an eye on them; also, this precaution applies even if the reason for prescribing an antidepressant is for a disorder other than depression, e.g. anxiety.

Fluoxetine, controversially (Pfeffer, 2007), is the only SSRI recommended by the FDA³⁶³¹ and the Committee on Safety of Medicines for use in children³⁶³². (Ramchandani, 2004; Geddes & Cipriani, 2004; Bennett ea, 2005)

Paroxetine (Seroxat, Parox, Meloxat; Paxil in USA) plasma levels are increased by phenytoin. The half-life is 21-24 hours. There are no active metabolites and little effect on weight. The starting dose is 20 mg daily (10, 20 and 30 mg tablets are available; the liquid form contains 20 mg/ml). Paroxetine, a phenylpiperidine, is relatively sedative (paroxetine is the most sedative SSRI, fluoxetine the least sedative) and, because of its relatively short half-life, it has a stronger propensity to be associated with withdrawal symptoms (dizziness, sweating, tremor) on cessation of therapy relative to fluoxetine. Paroxetine should not be stopped abruptly except on medical advice. Serotonin syndrome, akathisia, gastrointestinal bleeding, and hyponatraemia are possible with paroxetine. Dystonia has been recorded, especially early in treatment. As is common with many antidepressants, sweating can occur early in treatment. A few cases of stupor have been reported in the literature, (Lewis ea, 1993) as has transient or chronic hepatitis, (Benbow & Gill, 1997) and digitalis intoxication. (Yasui-Furukori & Kaneko, 2006) Ghaemi (2003, p. 243) cautions against the use of paroxetine in the elderly because of its anticholinergic potential. GlaxoSmithKline issued letters in June 2003 and July 2005 stating that paroxetine was not to be used in persons under 18 because of adverse events³⁶³³ and problems during tapering of paroxetine³⁶³⁴, all being reported at a frequency of at least 2% of patients and occurring at a rate of at least twice that of placebo. However, already successfully treated under 18s could complete a course a course of paroxetine. It should be noted that Jick ea (2004) who found no difference in suicidal behaviours in paroxetine-treated 10-19 year olds compared to those given fluoxetine, amitriptyline, or dothiepin. GlaxoSmithKline issued a communiqué in May 2006 to the effect that paroxetine use during the first trimester of pregnancy is associated in some epidemiological studies with a small increase in cardiovascular malformations (VSD and ASD).

Fluvoxamine³⁶³⁵ (Faverin) is said to inhibit the neuronal uptake of 5-HT with little or no effect on catecholamines. It has a low incidence of side effects, apart perhaps from GIT upset. Unlike TCAs, it has no clinically important cardiovascular effects.

Side effects of fluvoxamine

Nausea, vomiting, indigestion, diarrhoea
Dizziness, somnolence
Headache
Anxiety
Palpitations
Rash

The dose is 2 tablets taken at night to start. Plasma levels of drugs metabolised by the P450 system³⁶³⁶ may be increased. Fluvoxamine is a particularly potent inhibitor of CYP1A2, thus increasing plasma levels of drugs such as TCAs and mirtazapine. *It can increase clozapine levels at least 5 times.* (Olesen & Linnet, 2000) Silver ea (2003) reported improvement in primary negative symptoms of schizophrenia with fluvoxamine.

³⁶³¹ This led to reduced SSRI use in adults (Valuck ea, 2007) and children (Libby ea, 2009) and an increase in SNRI use in adults. (Libby ea, 2009)

³⁶³² Children and adolescents metabolise SSRIs faster than adults and may require doses in excess of those given to adults to achieve a clinical response. Gibbons ea (2006) found that higher rates of SSRI prescribing was associated with lower suicide rates in children and adolescents. See Gavin ea (2008) for discussion and Emslie ea (2008) for evidence for fluoxetine preventing relapse of major depression in children and adolescents.

³⁶³³ Decreased appetite, tremor, sweating, hyperkinesia, hostility, agitation, emotional lability (crying, mood fluctuations), self harm, suicidal thoughts, and attempted suicide.

³⁶³⁴ Nervousness, dizziness, nausea, emotional lability, and abdominal pain.

³⁶³⁵ An aralkyl ketone with a half-life of 22 hours.

³⁶³⁶ E.g. TCAs, phenothiazines, type Ic anti-arrhythmics, debrisoquine and sparteine.

1099

Sertraline³⁶³⁷ (Lustral, Seretral, Serlo, Bellsert) is said to little or no sedative effect. Plasma half-life is 26 hours. 98% is bound to plasma proteins. Its active metabolite, N-desmethyl-sertraline, has a half-life of 2.5-4.5 days. Starting dose is 50 mg/day and the maximum dose is 200 mg/day. Sertraline may be the least likely SSRI to be stopped by the patient.(Edwards & Anderson, 1999)

Citalopram (Cipramil, Citalopram Teva, Citrol, Cipralam, Ciprapine, Belcital), a bicyclic with a half-life of 33 hours, is a 5-HT re-uptake inhibitor that is given once daily in 20-60 mgs doses, or 10-30 mgs in the elderly. The metabolites of this racemic compound are desmethycitalopram (one-third the level of the parent compound in plasma) and didesmethylcitalopram (lower levels). Citalopram is a weak inhibitor of CYP2D6 and drug interactions do not appear to be a major problem. In particular, there seems to be no interaction with alcohol. The clinical effect is thought to be due mainly to citalopram itself. Its metabolites are less potent and enter the brain less readily.

Side effects of citalopram

Dry mouth
Somnolence
Nausea, diarrhoea
Sweating
Tremor
Ejaculatory failure

There have been some fatalities, especially when combined with alcohol or sedative drugs.(Edwards & Anderson, 1999) Citalopram prolongs the QTc in dogs.

Escitalopram oxalate (Lexapro) is the S-enantiomer of citalopram³⁶³⁸. The S-enantiomer of citalopram is an SSRI whereas the R-enantiomer is thirty times less active on the transporter.(Hyttle ea, 1992) It is as powerful an antidepressant as citalopram (Burke ea, 2002; Kennedy ea, 2006) and is better than placebo.(Wade ea, 2002) It binds to a specific site on the 5-HT receptor and to a site common to other SSRIs.(Leonard, 2007) Nausea may occur, but it tends to subside with continued use. Escitalopram appears to have a low potential for drug interactions via impaired P450 enzymatic activity.(Wade ea 2002) Depression is treated with 10 mg once daily (max. 20 mg). Panic disorder is treated with 5 mg per day for one week, then 10mg daily (max. 20 mg).

Sibutramine (Reductil) is a monoamine re-uptake inhibitor active against noradrenaline and 5-HT and to a lesser extent against dopamine, and it rapidly down-regulates both beta-adrenergic receptor binding as well as the noradrenaline - stimulated adenylate cyclase system. Sibutramine is structurally related to amphetamine and is marketed as an anti-obesity drug. The hypophagic effect may stem from activation of 5-HT_{2C} receptors. In trials, this putative antidepressant, at doses of 60 mgs, which is considered to be high, increased the mean arterial blood pressure by 7.8 mm. Hg. (p < 0.01) and the heart rate by 7.9 beats / minute (p < 0.01). There is some evidence that sibutramine may alleviate weight gain in patients treated with olanzapine.(Henderson ea, 2005)

Other new antidepressants

Venlafaxine (Efexor XL, Efaxil XL, Ireven, Venlafaxine Teva, Vedixal, Venlofex, Venlift, Vedixal XR, Venex XL, Velift XL, Vensir XL)

³⁶³⁷ 1S,4S-N-methyl-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-1-naphthylamine.

³⁶³⁸ It comes as 5 mg, 10 mg, 15 mg and 20 mg tablets.

1100

The phenylethylamine venlafaxine, a SNRI (serotonin and noradrenaline reuptake inhibitor) has an elimination half-life of 3-7 hours. It is O-demethylated to the active metabolite O-desmethylvenlafaxine, which has a half-life of 8-13 hours and is equipotent to the parent compound. Most psychotropic drugs are 80-95% bound to plasma proteins, except venlafaxine (15-20%) and O-desmethylvenlafaxine. In descending order of potency venlafaxine inhibits reuptake of 5-HT, noradrenaline, and DA.³⁶³⁹ Venlafaxine appears to be primarily serotonergic in lower doses and dopaminergic in doses over 300 mg daily.

Side effects of venlafaxine

Nausea (36% at first, 12% or placebo level at 3 weeks)

Headache

Insomnia (esp. in higher doses)

Somnolence

Dry mouth

Dizziness

Constipation

Asthenia

Postural hypotension (disputed)

Nervousness and sweating

Syncope (rare: may relate to a genetic sodium channel mechanism: Schatzberg ea, 2005, p. 78)

Extrasystole during ECT³⁶⁴⁰

Dose-dependent sustained hypertension (3% of treated patients)

Seizure (0.2%)

Rash (4%)

Impotence (7%)

Reversible increases in liver enzymes (0.5%)

Weight gain (<1%)

GIT bleeding (especially if also taking NSAIDs: de Abajo & Garcia-Rodriguez, 2008)

Venlafaxine, with the exception of escitalopram (Fava & Papakostas, 2008, p. 603), may be more potent than the SSRIs. It may have better efficacy and be better tolerated than imipramine. Venlafaxine may be superior to fluoxetine for anxiety associated with depression. It may be more effective than SSRIs for depression.(Smith ea, 2002) The usual starting dose is 37.5 mg bid. This can be increased after some weeks to 75 mg bid if needed. It should be taken with food. There are intermittent (IR) and extended (XR – given once daily) release preparations. Efexor XL is a once daily dosage formulation (recommended dosage, 75 mg/day; can be increased to 150 mg/day; max, 225 mg/day). The dose should be halved in the presence of moderate renal or hepatic failure. Reduced doses are not usually required in the elderly. Because of lack of data, venlafaxine is contraindicated in pregnancy (give advice to women about contraceptive measures), during lactation, and with MAOIs (*wait 2 weeks after stopping a MAOI and 7 days after stopping venlafaxine*). It is contraindicated in persons less than age 18 years (because a small number have developed hostility and suicidal ideation), uncontrolled hypertension, and in cases with a very high risk of ventricular arrhythmia.³⁶⁴¹ Lithium reduces the renal clearance of venlafaxine. There have been a number of reports of venlafaxine withdrawal symptoms.(Anonymous, 2003b) There is a suggestion that venlafaxine should be prescribed only by practitioners with a special interest in mental health.(Eaton, 2004)

³⁶³⁹ Cf. Stahl(2000) for illustrated account of how these actions might be translated into mRNA production.

³⁶⁴⁰ In patients with treatment-resistant depression on > 300 mg/day and receiving propofol.(Gonzalez-Pinto ea, 2002)

³⁶⁴¹ It should be noted that Martinez ea (2010) found that pharmacological doses of venlafaxine are not associated with an increased risk of potentially fatal arrhythmias.

NICE suggests that an ECG and blood pressure measurement be carried out before starting venlafaxine.

*Desvenlafaxine*³⁶⁴² (Pristiq)

Also known as O-desmethylvenlafaxine, this new SNRI is available in the USA as a 50 mg extended-release tablet. It is a synthetic form of the venlafaxine metabolite O-desmethylvenlafaxine. It has been found to be effective and tolerated in the treatment of major depression (DeMartinis et al, 2007) and may be useful for vasomotor menopausal symptoms. The blood pressure should be monitored and the dose reduced or the drug withdrawn if a persistent rise in pressure is found.

Adverse effects of desvenlafaxine

Nausea, dry mouth, anorexia, constipation, asthenia, insomnia, somnolence, nervousness, dizziness, sweating, problems with ejaculation/orgasm

Rare: hyponatraemia/SIADH, interstitial lung disease, eosinophilic pneumonia, serotonin syndrome, mydriasis

*Reboxetine*³⁶⁴³ (Edronax)

This selective noradrenaline reuptake inhibitor (NARI) has a low affinity for alpha-adrenergic and muscarinic receptors and no effect on DA uptake. It has low toxicity in animals. Because the half-life is 13 hours, reboxetine is given twice daily (4 mg twice daily to start and this may be increased to 10 mg/day after 3-4 weeks). A lower dosage is indicated in the frail elderly (2 mg bid) and in those with severe renal impairment, excretion being mainly via the kidneys. Reboxetine is rapidly absorbed after ingestion and food does not affect its bioavailability. Reboxetine is 97% bound to plasma protein, 92% in the elderly. 78% is excreted in the urine. Avoid reboxetine with MAOIs, macrolide antibiotics, fluvoxamine and azole anti-fungals. CYP2D6 is only involved at very high doses of reboxetine.

Side effects of reboxetine

Dry mouth
Headache/migraine
Dizziness
Gastrointestinal upset
Constipation
Sweating
Orthostatic hypotension (at higher doses)
High blood pressure³⁶⁴⁴
Tachycardia
Insomnia

³⁶⁴² 50 mg daily in adults. Adjust for renal/hepatic dysfunction.

³⁶⁴³ Structurally similar to viloxazine (withdrawn from market) and fluoxetine.

³⁶⁴⁴ It occurs in some cases, especially in people with SCL6A2 variant of noradrenaline transporter.

Paraesthesiae

Impotence (with higher doses)

Spontaneous ejaculation (very rare)

Urinary hesitancy/retention (latter with higher doses)

Less common: agitation, nervousness, anxiety, somnolence, and tremor

Cardiac rhythm problems (especially increased rate) and conduction disorders (small percent of elderly patients)

Seizures (rare – stop the drug)

There is some evidence that reboxetine may attenuate weight gain in olanzapine-treated schizophrenic patients. (Poyurovsky et al, 2003) It may be particularly useful in apathetic, anergic depressives.

Mirtazapine (Zispin, Zispin SolTab³⁶⁴⁵, Mirap, Mirap Orodispersable, Mirtall, Mirzaten, Mirtazapine TEVA, Zismirt Orotab³⁶⁴⁶, and, in US, Remeron)

Mirtazapine is a noradrenergic and specific serotonergic (NaSSA) antidepressant and a 6-aza derivative of mianserin. Mirtazapine increases noradrenergic transmission by blocking α_2 -autoreceptors. It also enhances 5-HT transmission via two synergistic mechanisms: increased serotonergic cell firing and blockade of alpha-2-adrenergic heteroreceptors. It specifically increases 5-HT1-mediated transmission because it blocks 5-HT2 and 5-HT3 receptors, leaving 5-HT1 receptors unhindered. The usual dose is 30 mg (15-45) nocte.

Adverse effects of mirtazapine

Sedation³⁶⁴⁷

Dry mouth

Increased appetite and weight (probably due to blockade of 5-HT2C receptors)

Constipation

Rare: orthostatic hypotension, mania, seizures, tremor, myoclonus, oedema, acute bone marrow suppression (neutropaenia is commoner than agranulocytosis³⁶⁴⁸), and increased serum levels of transaminases

Increased psychomotor effects of BZDs and alcohol

Raised serum cholesterol and triglyceride levels in some patients (APA, 2002, pp. 497 & 513)

The literature is somewhat conflicting regarding whether mirtazapine mitigates the sexual side effects of SSRIs (Schatzberg et al, 2005, p. 89) but it is generally seen as helpful in such situations. (Lloyd, 2007, p. 78) Binding to plasma proteins is only 85%. Mirtazapine should not be given for the first two weeks after stopping MAOIs. It has a similar effect on sleep architecture to amitriptyline. REM latency and stages 3 and 4 sleep are increased. Overdose leads to prolonged sedation and is treated by gastric lavage and support.

Duloxetine (Cymbalta)

³⁶⁴⁵ Zispin SolTabs (15 mg and 45 mg) dissolve in the mouth.

³⁶⁴⁶ Orodispersible 15 mg, 30 mg, 45 mg tablets.

³⁶⁴⁷ Because of recruitment of noradrenergic effects at higher doses, sedation may lighten as the dose rises to 30 mg/day or more.

³⁶⁴⁸ Avoid concomitant clozapine or carbamazepine.

This combined 5-HT and noradrenaline reuptake inhibitor³⁶⁴⁹ is metabolised by CYP1A2 and the polymorphic CYP2D6, followed by conjugation. 96% is bound to plasma proteins. Metabolites are excreted principally in the urine. Like venlafaxine, it may diminish diabetic neuropathic pain³⁶⁵⁰.

Potential side effects of duloxetine

Nausea, dry mouth, constipation, diarrhoea

Sweating

Reduced appetite and weight

Insomnia, fatigue, somnolence/sedation/dizziness

Decreased libido, hot flushes³⁶⁵¹, anorgasmia, erectile dysfunction, ejaculatory delay/dysfunction

Tremor

Blurred vision, mydriasis (*risk of narrow-angle glaucoma*³⁶⁵²)

Hyponatraemia (rare, esp. elderly)

Tinnitus

Strong CYP1A2 inhibitors³⁶⁵³ raise duloxetine plasma levels. Smoking reduces duloxetine plasma levels by 50%. Use of duloxetine in pregnancy has to be based on a careful risk-benefit analysis; its use in breastfeeding women is not advised. The starting and therapeutic dose is 60 mg o.d. (dosage shown to be effective in prophylaxis of major depression: Perahia *et al.*, 2006) and the maximum dose is 120 mg, given in divided doses. There are 30 mg and 60 mg capsules. Little is known about use of duloxetine in the elderly. Since it is extensively metabolised (oxidation followed by conjugation and then the metabolites are excreted in urine) significant hepatic³⁶⁵⁴ and renal disease (creatinine clearance < 30 ml/hr) are contraindications to duloxetine use. Blood pressure should be monitored in cases of hypertension or cardiac disease. Avoid duloxetine with non-selective, irreversible MAOIs³⁶⁵⁵. It is not advisable to combine duloxetine with St John's Wort. Caution is required with concomitant use of SSRIs, clomipramine, venlafaxine, triptans, tramadol, pethidine, and tryptophan. The sucrose in the capsule can cause problems in people with fructose intolerance, glucose-galactose malabsorption, or sucrose-isomaltase insufficiency.

Discontinuation symptoms with duloxetine

Dizziness

Nausea

Vomiting

Insomnia

Nightmares

Headache

Anxiety

Irritability

Paraesthesia

³⁶⁴⁹ Venlafaxine is mainly serotonergic at lower doses but duloxetine strongly inhibits 5-HT and noradrenaline transporters in all clinical doses.

³⁶⁵⁰ Leonard (2006) has described duloxetine as 'venlafaxine at a lower dose'.

³⁶⁵¹ Interestingly, venlafaxine and SSRIs may decrease hot flashes due to tamoxifen.

³⁶⁵² Avoid use of duloxetine in patients with uncontrolled narrow-angle glaucoma.

³⁶⁵³ Fluvoxamine, ciprofloxacin, and enoxacin.

³⁶⁵⁴ There have been reports of hepatitis, hepatomegaly, raised liver enzyme levels, and cholestatic jaundice. It is suggested that duloxetine be avoided in heavy drinkers.

³⁶⁵⁵ Risk of serotonin syndrome: wait 2 weeks after stopping MAOI/at least 5 days after stopping duloxetine/lesser, but not absent risk with selective, reversible MAOIs like moclobemide.

Duloxetine (*Yentreve*)³⁶⁵⁶ appears to be efficacious for female stress urinary incontinence. Manufacturer's data suggests that duloxetine causes urinary hesitancy in less than 1% of males. Elderly males should be monitored for this. (Schatzberg et al, 2005, p. 78) Naturally, one duloxetine preparation should not be combined with a second such preparation!

Review of duloxetine (Anonymous, 2007)

Published evidence for comparative efficacy insufficient in depression or diabetic peripheral neuropathic pain

Regarding stress incontinence - only prescribed for cases with 14 or more episodes/week where pelvic floor exercises are poorly effective or where surgery is unsuitable/undesirable

Duloxetine in elderly (recurrent) major depressives v placebo (Raskin et al, 2007)

Improved cognition, depression, and some pain measures; safe and well tolerated

Escitalopram v duloxetine in major depression (Wade et al, 2008)

24-week, randomised, double-blind, fixed dose

Escitalopram 20 mg/day vs duloxetine 60 mg/day

Greater improvement in symptoms at week 8 with escitalopram

Both drugs equal efficacy at 24 weeks

Withdrawal from study due to adverse effects greater with duloxetine

Milnacipran (Ixel)

This inhibits 5-HT and noradrenaline reuptake to an equal degree. 25 mgs twice daily or 50 mgs once daily is given during the first week, the recommended dose thereafter being 50 mgs twice daily for adults and elderly. It is glucuronidated and is not metabolised by P450 enzymes. It is comparable in efficacy to TCAs and, at least in severe cases, possibly better than SSRIs in major depression. (Montgomery, 2003) The main adverse effect is dysuria due to adrenergic receptor stimulation in the urinary tract. It should therefore be used with care in people with prostatic obstruction. (Kasper et al, 2001)

Tianeptine (Stablon)

This atypical tricyclic may have anxiolytic effects in major depression. (Lepine et al, 2001)

It modulates the HPA axis and glutamate and doesn't affect 5-HT uptake. (Leonard, 2007)

The dose is one tablet thrice daily (twice daily in elderly or with renal insufficiency). It should not be combined with MAOIs.

Side effects (uncommon and generally not severe)

Pain (epigastric, abdominal, precordial, muscular, back)

Dry mouth, anorexia, nausea, vomiting, flatulence

Insomnia, drowsiness, nightmares, asthenia

Tachycardia, extrasystoles

Vertigo, headache, faintness (lipothymia), tremor

Respiratory discomfort

Lump in the throat

Hot flushes

Agomelatine (Valdoxan)

Agomelatine³⁶⁵⁷ (Valdoxan) is a melatonergic (M1 and M2)³⁶⁵⁸ agonist and selective antagonist of 5-HT_{2C} receptors³⁶⁵⁹ and is active in several animal models of depression.

³⁶⁵⁶ 40 mg b.i.d., or 20 mg b.i.d. if side effects are troublesome.

³⁶⁵⁷ See vol. 21, suppl. 1, February 2006 (Montgomery SA, ed.) of *Internat Clin Psychopharmacol* 2006 for a fuller discussion.

Loo et al (2002) used a double-blind design comparing three different doses of agomelatine (1, 5 and 25 mg once daily) with placebo over an 8-week treatment period. Paroxetine was used as the study validator. 711 patients with a baseline mean score of 27.4 on the 17-item HAM-D were included. On the pivotal analysis, the mean final HAM-D total score demonstrated agomelatine 25 mg to be statistically more effective than placebo.³⁶⁶⁰ Agomelatine 25 mg alleviated anxiety associated with depression, as measured on *Hamilton Anxiety Scale*. Paroxetine was found to be effective on pivotal analysis and most of the secondary criteria used to validate the study methodology and population. Agomelatine, whatever the dose, showed good acceptability with a side-effects profile close to that of placebo. The starting dose in adults is 25 mg/day, increasing to 50 mg nocte after 2 weeks if response is inadequate. Patients on agomelatine should have *LFTs done at baseline, 6 weeks, and 24 weeks, and thereafter when clinically indicated*. Agomelatine is metabolised by CYP1A2 and to a lesser extent by CYP2C9. Fluvoxamine and ciprofloxacin, both being CYP1A2 inhibitors, increase agomelatine levels. Therefore, CYP1A2 inhibitors should not be co-prescribed with agomelatine. Lesser CYP1A2 inhibitors, such as oestrogen, should be prescribed with caution. Nausea and dizziness are common and usually transient ADRs associated with agomelatine. Other side-effects include migraine, headache, adverse effects on sleep, GIT upset, fatigue, sweating, and back pain. Erythematous rash and hepatitis are rare ADRs. Insufficient information is available concerning pregnancy and breastfeeding.

*St John's Wort*³⁶⁶¹

St John's Wort (SJW) contains at least 10 diverse chemicals that may possess psychotropic effects, such as hypericin. SJW probably works on several neurotransmitters, including serotonin³⁶⁶². It is unlikely to possess MAOI activity, but caution is advised if the patient is taking MAOIs and other antidepressants because of the rare possibility of a serotonin syndrome. A serotonin-like syndrome or hypertensive reaction, generally non-fatal, is possible when SJW is combined with serotonergic drugs as varied as SSRIs, venlafaxine, nefazodone, dextromethorphan, and pethidine. SJW is generally well tolerated. Mania may be induced in bipolar patients. Possibly by inducing P450 (CYP3A4) enzymes, it can reduce the plasma levels of the anti-HIV protease inhibitor³⁶⁶³ indinavir, warfarin, theophylline, and cyclosporin. (see Mills et al, 2004) Interactions between SJW and cyclosporin may lead to transplant rejection. Oral contraceptive efficacy may be diminished by SJW. Woelk (2000) compared SJW with relatively modest doses of imipramine (150 mgs. /day) in a randomised, multicentre, double blind, parallel group study involving mild to moderate outpatient depressives.

Kennedy (2010) suggested that M1 agonism leads to circadian phase advance and resynchronisation of disrupted rhythms whereas M2 agonism affects prefrontal DA and norepinephrine release by blocking the inhibitory action of GABA. He stated that agomelatine promotes neurogenesis by increasing cell proliferation and aiding cell survival in the ventral dentate gyrus. DA release in the accumbens is unaffected. Glutamate release may be reduced. Transcription factors and BDNF are increased. There is evidence for acute and sustained antidepressant activity. It reduces symptoms of GAD. Dizziness was the adverse effect that separated best from placebo. ALAT and ASAT liver enzymes may rise reversibly but Kennedy does not view agomelatine as a hepatotoxic drug. It appears to be weight neutral. It has a better sexual function profile than venlafaxine and is non-sedating and has no appreciable effect on GIT function, blood pressure, heart rate or QTc.

³⁶⁵⁸ Leonard (2007) suggested that the main effect is antagonism of 5-HT₂ receptors and questions the relevance of its effects on melatonin receptors. Agomelatine does not suppress REM sleep.

³⁶⁵⁹ Blockade of 5-HT_{2C} receptors is thought to enhance fronto-cortical dopaminergic and adrenergic pathway activity. (Millan et al, 2003)

³⁶⁶⁰ This was confirmed by other analyses and criteria: responders, remission, sub-population of severely depressed patients, *Montgomery-Asberg Depression Rating Scale*, *Clinical Global Impression-Severity of Illness*.

³⁶⁶¹ SJW (*Wort*, *Rose of Sharon*, *goat weed*, *Klamath weed*: herb or vegetable), or extracts of the plant *Hypericum perforatum*, is of ancient vintage. It was used in classical times as a diuretic and as an aid to wound-healing. It received its name from the story that it grew from ground upon which the blood of John the Baptist fell when he was beheaded. An alternative story is that it blooms on June 24th, the traditional birthday of John the Baptist. It can cause a rash in humans and in goats and sheep.

³⁶⁶² The serotonergic effects of SJW are weak.

³⁶⁶³ Carbamazepine can render protease inhibitors less effective.

Both preparations were equally effective although SJW was better tolerated. This study cannot answer the question as to whether an inert placebo would have performed as well under the circumstances. Shelton *et al* (2001) and Lecrubier *et al* (2002) found it ineffective and effective for major depression respectively, a contradiction reflected in a meta-analysis of RCTs.(Linde *et al*, 2005)

Other antidepressants

Mianserin (e.g. Tolvon³⁶⁶⁴) is a sedative tetracyclic that inhibits presynaptic α -2 receptors and thereby 'fools' the cell into liberating extra neurotransmitter. It can cause blood dyscrasias in 1:4,000 treated patients³⁶⁶⁵, and therefore, monthly blood counts have been advised, at least during the initial period of treatment. Mianserin is relatively safe in overdose. Girard (1988) believes that hepatotoxicity from mianserin is not a significant problem. Mianserin has been recommended for the treatment of depression in cancer patients.(Van Heeringen & Zivkov, 1996)

Trazodone (Molipaxin), a sedative triazolopyridine more often employed as a sedative-hypnotic, can rarely cause priapism (1 in 6,000 males treated³⁶⁶⁶) or arrhythmias in those patients with heart disease (pre-existing premature ventricular contractions or mitral valve prolapse). According to the APA (2002, p. 500) the evidence for trazodone's arrhythmogenicity is anecdotal only. Trazodone increases slow wave and total sleep time and has little or no effect on REM sleep.(Yamadera *et al*, 1998) Trazodone is a mixed 5-HT agonist-antagonist. Its active metabolite, m-chlorophenylpiperazine (m-CPP), is a potent direct serotonin agonist. Trazodone is available in capsular, tablet and liquid (50 mg/5 ml) form. It has a half-life of 3-9 hours. It is often used to manage insomnia during early SSRI or bupropion treatment, but use as an antidepressant is reduced by the need for multiple daily doses and sedation. Avoid trazodone with MAOIs. Side effects include sedation (in low doses it is a useful hypnotic – may cause daytime drowsiness), orthostatic hypotension, dizziness, headache, nausea, and gastric irritation. It can occasionally cause dry mouth via α -1-adrenergic blockade. There is some risk of GIT bleeding.(Po, 1999) Spontaneous orgasms in a postmenopausal woman on trazodone have been reported. It has minimal anticholinergic side effects and it may be less epileptogenic than the TCAs. Delirium has been reported in bulimic patients taking trazodone. Trazodone may have a role in the control of screaming in the disturbed elderly.(Craig & Burns, 2000) Trazodone does not appear to have a withdrawal syndrome.

L-tryptophan, the amino precursor of the brain amine serotonin, may potentiate the antidepressant properties of some antidepressants such as MAOIs or TCAs (with some risk of a serotonin syndrome if given with these or SSRIs). It is formulated with and without added vitamins (Pacitron, Optimax), the latter being added in the hope of promoting 5-HT synthesis, or to prevent its breakdown by hepatic enzymes. There are conflicting reports about its efficacy. Warm milk contains sufficient L-tryptophan to account for its historical use as a soporific: carbohydrates (cookies) increase L-tryptophan absorption. L-tryptophan has been associated with an eosinophilia-myalgia syndrome with an increase in white blood cells ($> 2,000$ eosinophils/ml), joint pains, swelling of the arms and legs, skin rash/sclerosis³⁶⁶⁷, and pyrexia. The eosinophilia-

³⁶⁶⁴ Removed from market 2006.

³⁶⁶⁵ Chlorpromazine probably causes more haematological problems than does mianserin.

³⁶⁶⁶ Clitoral priapism is very rare.(Pescatori *et al*, 1993)

³⁶⁶⁷ Resembling scleroderma.

myalgia syndrome³⁶⁶⁸ can continue to evolve even after withdrawal of the drug. L-tryptophan is available on a named patient basis only.

Doxepin (Sinequan), a CPY 2D6 inhibitor and the most potent antihistamine in clinical medicine (FDA approved for treatment of anxiety), is sometimes used topically as treatment for pruritus. It is to be withdrawn from the Irish market as of end November 2006 because 'the production site is no longer in operation'. (Pfizer, letter dated January 9, 2006)

Maprotiline (Ludiomil) is a 'tetracyclic' or modified TCA³⁶⁶⁹ that selectively inhibits noradrenaline re-uptake. Its formula resembles that of nortriptyline and its side effect spectrum is very similar to the TCAs. It can cause rashes and is epileptogenic. (Schmidt et al, 1986) It can also be cardiotoxic. (Howland & Thase, 2002)

Flupenthixol (flupentixol: Fluanxol) in a low dose oral preparation may have some antidepressant effect (Young et al, 1976), possibly because of blockade of presynaptic autoreceptors (the same could be said of thioridazine).

Alprazolam (Xanax, Calmax), a BZD, is of benefit in minor neurotic depressions with associated anxiety. It has been used in high doses for panic disorder.

Liothyronine (triiodothyronine or T3) has been used to accelerate the antidepressant action of TCAs. Anginal exacerbation and paroxysmal atrial fibrillation have been reported in elderly patients. (e.g. Cole et al, 1993)

Oestrogens increase plasma TCA levels by inhibiting their metabolism.

Minaprine, an amino-phenylpyridazine, has little anticholinergic, cardiotoxic, sedative, or weight promoting properties. (Wheatley, 1992)

S-adenosylmethionine, a methyl donor, may have antidepressant activity. It can cause nervousness, insomnia, headache and mild GIT upset.

Bupropion (Zyban, Wellbutrin) can cause seizures in higher doses³⁶⁷⁰ and the commonest side effect is excessive stimulation. Psychotic symptoms can occur (Howard & Warnock, 1999) and derive from *dopaminergic* stimulation³⁶⁷¹. If added to L-DOPA there is the potential for hallucinations, confusion, and dyskinesia. Metabolites of bupropion may yield false-positive results for amphetamine in urine as the chemical structure of this unicyclic drug³⁶⁷² resembles that of amphetamine. Bupropion, used in low dosage, may attenuate the sexual dysfunction caused by other medication. Its dopaminergic effects account for its use (in lower doses than for depression: Leonard, 2007) as an aid in smoking cessation. Bupropion is also used to treat ADHD. There does not appear to be a bupropion withdrawal syndrome.

Resistant depression

The occasional depressive does not respond to any of the above drugs. The diagnosis should be reviewed and any missed clue sought, such as social or personality difficulties. The drug may not have been given in optimal dosage or taken at all. Combinations of drugs may be tried. Augmentation strategies may be used. T3 (5-50 mcg) may be superior to T4 in converting TCA non-responders to responders. ECT, sleep deprivation, behaviour or cognitive therapy are other approaches to treatment. Psychosurgery is a very last resort.

Continuation therapy

Mindham et al (1973) evaluated continuation therapy with TCAs in depressives. It was a multi-centre double blind trial conducted throughout Great Britain. The trial was

³⁶⁶⁸ The most likely explanation seems to be that a change in the production process (less powdered carbon) in a Tokyo company led to contamination with strain V of *Bacillus amyloliquefaciens*. A similar syndrome, toxic oil syndrome, followed ingestion of contaminated olive oil.

³⁶⁶⁹ 6-membered central ring stabilised by an ethylene bridge.

³⁶⁷⁰ Particularly in patients with **bulimia nervosa** or a **history of head injury**. The metabolites of bupropion are excreted by the kidney. In patients with end-stage renal disease these metabolites may accumulate and cause seizures.

³⁶⁷¹ There is a structural relationship to amphetamine.

³⁶⁷² A monocyclic phenylbutamine of the aminoketone type.

designed to assess a six-month course of continuation (syn. maintenance) therapy to see if it would prevent a recurrence of symptoms in those patients successfully treated with either imipramine or amitriptyline. Ninety-two patients entered and significantly fewer on active therapy relapsed during the six months: 22% compared with 50% of those on placebo. An interesting finding was that more people complained of dry mouths than could be attributed to the active drugs.

Antipsychotic and anticholinergic drugs

Brian O'Shea

'The spasmodic phenomena of the face and of speech which often appear are extremely peculiar disorders...'(Kraepelin, 1919)

'...in the ideal situation one searches for a gold standard which has virtually no side effects. However, such drugs do not exist.'(Ellenbroek & Cools, 2002)

'We don't wait long enough for a drug to work: time is a drug'.(Stahl, 2003)

'The better someone is doing, the more they have to lose if they stop their medication'.(Kane, 2003)

Antipsychotic drugs³⁶⁷³ ameliorate psychotic symptoms such as hallucinations, thought disorder and delusions, irrespective of underlying cause.(O'Shea, 1998) They are much less efficacious for schizophrenic negative symptoms³⁶⁷⁴. They produce unpleasant feeling states in normal subjects (and 'negative symptoms': Artaloytia ea, 2006) and are therefore of very low abuse potential. Antipsychotic drugs all block postsynaptic dopamine (DA) receptors to a variable extent. Promazine and mepazine have little or no antipsychotic activity. Very high doses of antipsychotic drugs, once commonly employed, should only be resorted to as a last resort.(Hirsch & Barnes, 1994) Use of multiple antipsychotic drugs may increase adverse events and time spent in hospital but with no added clinical benefit.(Centorrino ea, 2004) Koreen ea(1994) gave oral fluphenazine to psychotic patients and found no difference between plasma levels between responders and non-responders and no correlation with measures of psychopathology or extrapyramidal symptoms (EPS). Plasma levels of chlorpromazine³⁶⁷⁵ correlate poorly with therapeutic effect and better with prolactin secretion. However, according to Volavka ea,(1995) plasma levels of haloperidol³⁶⁷⁶ up to c 12 ng/ml may correlate with antipsychotic effect for the first few months (5-20 ng/ml according to other authors), whereas a lower level may improve negative symptoms thereafter. Patients may show large changes in plasma clozapine levels without any change in psychopathology – there is no need to adjust dose if these patients show plasma level variations of +/- 50%. However, larger changes might suggest compliance difficulties.(Kurz ea, 1998) Antipsychotic drugs may give a false-positive pregnancy test.(Edwards, 1995)

Leptin is produced by fat cells and may provide feedback to the brain on the size of adipose tissue. Patients on clozapine or olanzapine may experience a significant increase in weight, BMI and circulating leptin levels, whereas these measures remain stable in subjects on haloperidol or no medication. This may mean that there is reduced feedback of leptin to the CNS, or it could simply mean overeating.(Kraus ea, 1999) Weight gain with, say olanzapine, might be due to its antihistaminic (H1), D2 or 5-HT2C³⁶⁷⁷

³⁶⁷³ Formerly 'neuroleptics' or 'anti-schizophrenic' drugs.

³⁶⁷⁴ E.g. anergia, anhedonia, etc.

³⁶⁷⁵ 3-(2-chloro-10H-phenothiazin-10-yl)-N,N-dimethyl-propan-1-amine. Phenothiazine dyes were developed for commercial use in the 1880s and chlorpromazine is a derivative of such compounds.

³⁶⁷⁶ 4-[4-(4-chlorophenyl)-4-hydroxy-1-piperidyl]-1-(4-fluorophenyl)-butan-1-one.

³⁶⁷⁷ **5-HT2C** knockout mice become obese. The presence of a T allele in the promoter region of the 5-HT2C receptor gene may be associated with lessened propensity for antipsychotic-induced weight gain. Also, the 2548GG genotype at the leptin gene increased

antagonism. Clozapine, in terms of weight gain is the main offender³⁶⁷⁸, followed in descending order by olanzapine, sertindole, risperidone, and ziprasidone. However, haloperidol may be associated with slower (over a year) and equally significant weight gain.(Perez-Iglesias ea, 2008)

Antipsychotic drugs may activate lipid homeostasis genes, at least in vitro (Polymeropoulos ea, 2009), and they may alter the ratio of polyunsaturated to saturated fatty acids and cholesterol content.

Side effect profile in a 90-day Pakistani study of three antipsychotic drugs³⁶⁷⁹

	Body weight Kg (ante/post)	Prolactin ng/dl (ante/post)	Glucose mg/dl (ante/post)
Olanzapine	70.1/72.4*	14/14.9*	123.3/166.6*
Risperidone	69.7/70.7*	16/49.3*	114.9/118
Quetiapine	64.7/65.4*	12.6/13.5*	114.4/115

*P<0.05 for inter-group comparisons

Among conventional (typical) drugs, the situation varies from weight reduction with molindone³⁶⁸⁰ and loxapine to weight gain with thioridazine. Zipursky ea (2005) found significant weight gain in patients treated with olanzapine or haloperidol. A study by Zhang ea (2004) showed significant increases in subcutaneous and intra-abdominal fat (on MRI), a three-fold increase in leptin secretion, and significant increases in levels of circulating lipids and non-fasting glucose in patients treated according to normal local clinical practice (risperidone or chlorpromazine). Weight and blood glucose monitoring of in-patients is the exception rather than the rule.(Boilson & Hamilton, 2003)

Antipsychotic drugs that raise prolactin levels (incl. reserpine: Perkins, 2003, p. 220) should not be used in the presence of a pituitary prolactinoma or breast cancer. No drug of any type to which a patient has shown hypersensitivity should be given to such a patient. The manufacturer's latest data sheet should be consulted when in doubt over dosage schedules or other critical information. In reality, atypical drugs can raise prolactin levels but differ in degree and duration of dose-dependent prolactin elevation (risperidone > olanzapine or clozapine) due to differential binding properties of each drug on pituitary D2 receptors.(Turrone ea, 2002) Abraham ea (2003) found no acceleration of bone mineral density loss due to increased prolactin levels in females on risperidone or olanzapine for one year; perhaps higher prolactin levels over a longer time span might have had an effect. However, Meaney ea (2004) found reduced mineral density in schizophrenic subjects on longterm prolactin-raising antipsychotic drugs and lower testosterone levels in men was associated with reduced bone mineral density; but the study contained no comparison group and the females were past the menopause so that associations with gonadal status could not be measured. Burt and Hendrick (2003, p. 1527) suggest the following approach to managing raised prolactin levels (normal range = 5 – 26 ng/ml): consider reducing the dose of the antipsychotic drug; try dopamine agonist (bromocriptine, 2.5 – 7.5 mg b.i.d. or cabergoline 0.5 mg weekly); or use an oral anovulant. Amenorrhoea usually occurs with prolactin levels over 60 ng/ml. If the level exceeds 100 ng/ml, consider endocrinological referral to outrule a pituitary adenoma.

BMI in schizophrenic patients given antipsychotics.(Reynolds, 2009 – see also Reynolds, ea, 2003) Increases in body fat leads to raised **leptin** levels that then signal the brain to cease food intake. However, antipsychotics, by blocking hypothalamic receptors, interfere with this message from circulating leptin.

³⁶⁷⁸ At least in males, the presence of the -759T variant allele of the **5-HT2C** gene may protect against significant weight gain with clozapine.(Reynolds ea, 2003) There is evidence that weight gain associated with atypical drugs may result to some extent due to predisposition as shown by a study (Gebhardt ea, 2009) looking at clozapine, olanzapine and risperidone where predictors of increased weight were increased parental BMI, patients' premorbid BMI, female sex, younger age and (as a trend) diagnosis of schizophrenia spectrum disorder.

³⁶⁷⁹ Chaudhry ea.(2008) Drug-naïve schizophrenia cases; random assignment; only lorazepam allowed; 40 cases each per drug; means only.

³⁶⁸⁰ Molindone (Moban) is unlikely to significantly increase vulnerability to seizures.

Typical antipsychotic drugs

Chlorpromazine (CPZ³⁶⁸¹) is partially absorbed from GIT, less so in the presence of an antacid. It reaches peak serum levels 2-4 hours after oral ingestion³⁶⁸². IM injections produce 4-10 times higher plasma levels than occurs with the same dose given orally because first-pass metabolism is avoided, the drug avoiding the liver and gaining direct access to the systemic circulation. IV injections of CPZ are best avoided because of the danger of precipitating cardiac arrhythmias. IM injections of CPZ have become much less acceptable since the 1990s because of the potential for cardiovascular adverse effects, including severe postural hypotension. 95% of CPZ is bound to plasma proteins. CPZ is metabolised by gut wall and liver. The 7-hydroxy derivative has therapeutic properties but the sulfoxide is inactive.

Dopamine (DA)

DA inhibits prolactin release

Most antipsychotic drugs inhibit DA causing hyperprolactinaemia +/- galactorrhoea

Bromocriptine is used to treat galactorrhoea

Amenorrhoea is due to negative feedback on the brain by prolactin causing decreased gonadotrophin release

Phenothiazines compete for the same enzymes as do TCAs, and either will prolong the activity of the other³⁶⁸³

Apomorphine is a direct, partial DA agonist that stimulates DA autoreceptors when given in small doses

Peripheral oedema

Occurs in 1-3% of patients on phenothiazines and other psychotropics with prominent antidopaminergic activity

Dopaminergic neurones enhance sodium excretion by direct effect on renal tubule and by modulating renin and aldosterone secretion

Consider antipsychotic drugs in differential diagnosis of idiopathic oedema

After a wave of depolarisation, calcium and sodium move via ion channels into the neurone. This has a series of effects leading to the opening of other channels through which potassium ions move out of the cell. Sulpiride will decrease hyperpolarisation as an acute neuroleptic defect, but with chronic application of a neuroleptic rebound hyperpolarisation occurs. Rebound over activation of such systems roughly parallels clinical improvement after days to weeks, and the net effect is that such neurones (in the rat) become less sensitive to environmental stimulation.³⁶⁸⁴ Blockade of D2 receptors is thought to provide the therapeutic effect of typical antipsychotic drugs³⁶⁸⁵. Blockade of alpha-1 adrenoreceptors may provide the sedative effect.(see table) The tendency of neuroleptics to cause extrapyramidal side effects varies inversely with their muscarinic cholinergic antagonistic potency. The EEG of patients on antipsychotic drugs shows

³⁶⁸¹ Largactil (4560 RP, synthesised from phenothiazine antihistamines in 1950 by Paul Chapentier of Rhône-Poulenc: Turner, 2007) withdrawn 2005; still available from Clonmel Laboratories as Clonazine.

³⁶⁸² Tobacco smoking significantly increases the dose of neuroleptic needed in schizophrenia, but is associated with a significant reduction in levels of Parkinsonism(Goff ea, 1992); reduced and raised serum clozapine levels while smoking and on smoking cessation respectively (smoking cessation may lead to sedation, etc. from clozapine); tobacco induces cytochrome enzymes such as CYP1A2.

³⁶⁸³ Accepting that there will be individual variations, the following are the mean times (in hours) for peak concentration in the blood and biological half-lives (respectively, in brackets) of a sample of oral antipsychotic drugs - chlorpromazine (2-4; 30), fluphenazine (2; 16), flupenthixol (4;35), cis (Z) - clopenthixol (4;20), haloperidol (5;20 - a relative of pethidine; discovered by Paul Janssen), perphenazine (2-4; 9), and pimozide (8;54).

³⁶⁸⁴ This may be in keeping with Broadbent's theories (Broadbent, 1971) on the filter abnormalities in schizophrenia whereby schizophrenics cannot keep irrelevant environmental stimuli out of consciousness and thereby become hallucinated and deluded, eventually withdrawing from society to ward off stimulation.

³⁶⁸⁵ According to PET studies of haloperidol D2 occupancy varies from 38% to 87% and the degree of occupancy predicts clinical improvement, hyperprolactinaemia and EPS. However, some studies suggest that optimal doses of low-potency conventional antipsychotics may not induce more EPS than atypical drugs.(Leucht ea, 2003)

increased synchronisation and voltage and less effect of incoming sensory information on alpha rhythm. Centorrino *et al.* (2002) found the frequency of EEG abnormality to be high with clozapine and olanzapine, moderate with risperidone and typical agents, and low with quetiapine; comorbid hypertension, bipolarity, and older age, but not dose or clinical response, were associated with such abnormalities.

*Some assumed clinical correlates of blockade of receptors by antipsychotic drugs*³⁶⁸⁶

<i>Receptor</i>	<i>Effects</i>
Dopaminergic	EPS (D2 in basal ganglia), NMS, reduced drive, increased prolactin, weight gain
Muscarinic (ACh)	cycloplegia, dry mouth, memory problems, reflex tachycardia, constipation, urinary retention (latter may respond to bethanechol [Urecholine] 15 mg tid)
Histamine (H1)	sedation, drowsiness, potentiation of central depressant drugs, weight gain, postural hypotension
Noradrenergic	tachycardia, inhibition of ejaculation (alpha-1-antagonism, esp. piperidine phenothiazines like thioridazine and mesoridazine), tremor, augmentation of pressor effects of noradrenaline
Alpha-1-adrenergic	dizziness, postural hypotension, reflex tachycardia, impotence
5-HT1A	weight gain
5-HT2	less Parkinsonism and dystonia

Carbamazepine is a potent inhibitor of liver enzymes and lowers the blood levels of haloperidol, which could potentially worsen the symptoms of a schizophrenic. Methyldopa can greatly increase blood levels of haloperidol.

The beneficial effect of active antipsychotic drugs develops over several weeks. Positive schizophrenic symptoms show most drug-related improvement during the third week of treatment; improved social functioning continues to develop for several months if drug treatment is combined with occupational therapy in a milieu appropriate to the patient's abilities.

One action of oxyperthine³⁶⁸⁷ is a reserpine-like depletion of neuronal transmitters.

Post-synaptic D2 receptor agonists, such as bromocriptine, can potentially precipitate a psychosis, even in persons without a prior history.

Secondary negative symptoms, such as mutism and social withdrawal secondary to positive psychotic phenomena³⁶⁸⁸, tend to improve with treatment.³⁶⁸⁹

³⁶⁸⁶ PET studies show antipsychotic drugs block D2 receptors in mesocortical and mesolimbic dopaminergic pathways almost immediately. However, antipsychotic effects require weeks to develop. Also, clozapine has weak affinity for D2 receptors. Also, most antipsychotics have active metabolites with half-lives longer than the parent compounds, so relapse may be delayed for months in some cases after the drug is stopped. The presence of active metabolites and the accumulation of drug in adipose tissue have made it impossible to produce a reliable dose-response curve for neuroleptics.

IV haloperidol has been noted to cause less EPS than oral haloperidol. There is a small risk of *torsades de pointes* ('twisting of the points': described in 1966, a polymorphic arrhythmia [rapid irregular complexes oscillate around baseline] causing syncope and death, associated with prolonged QT, tendency to not benefit from antiarrhythmic drugs, congenital and drug-induced forms; hypokalaemia and hypomagnesaemia may predispose to arrhythmias). For example, 4 cases of *torsades de pointes* were recorded as being due to IV haloperidol among 1,100 consecutive patients in an ICU. (Wilt *et al.*, 1993) Haloperidol is changed to reduced haloperidol in the liver. IV haloperidol enters the CNS before metabolites are produced. This has led to the suggestion that blockade of D2 receptor by haloperidol rather than reduced haloperidol might be responsible for EPS. Phenytoin and heparin precipitate haloperidol, so flush IV tubing with normal saline before giving haloperidol if either of these agents have been used. The Massachusetts General Hospital (Murray, 1991) suggests the following protocol for IV haloperidol in the control of agitation in delirious or demented patients: initially, for mild/moderate/severe agitation give (in mg.) 0.5-2/5-10/10 or more; if still agitated after 20 minutes, double the initial dose; repeat last step until control is achieved. Tachycardia from antipsychotic medication may arise from anticholinergic or postural hypotensive actions.

³⁶⁸⁷ Withdrawn in 1999.

The combination of CPZ and cimetidine may lead to excessive sedation. If the CPZ dose is then reduced and the cimetidine eventually withdrawn the schizophrenic symptoms may get worse, necessitating an increase in the dose of CPZ. (Byrne and O'Shea, 1989). Beta-Blocking drugs increase antipsychotic drug levels.

Oral medication in schizophrenia has certain advantages and disadvantages. Amongst the advantages are a short duration of action and an increased flexibility of dose in the short term. Amongst the disadvantages poor compliance and possible overdose.

The main groups of antipsychotic drugs are shown in the table. Phenothiazines have a three-ring nucleus and members of the family differing in the side chains that are joined to the N atom in the middle ring. The depots available for use, with the exception of fluspiriline (an aqueous suspension), are esters (-COOH) of an active neuroleptic drug plus a long chain fatty acid. The neuroleptic-fatty acid ester is dissolved in an oil vehicle and given by deep IM injection. The ester is released from the oil phase by slow diffusion into the body water phase. Direct or indirect evidence of depot antipsychotic drugs can be found in the body up to 6 months after administration of the drug was stopped. (Wistedt et al, 1981) Local reactions to depots can be reduced in frequency by the use of lower volumes (concentrates), a lower injection frequency, and by ensuring deep intramuscular (rather than subcutaneous) delivery.

Classification of antipsychotic drugs

Phenothiazines: (a) aliphatic, e.g. CPZ (particularly epileptogenic), levopromazine, trifluopromazine
 (b) piperidine, e.g. thioridazine (Melleril, Melzine, Thiozine, etc), mesoridazine, pericyazine
 (c) piperazine, e.g. trifluoperazine (Stelazine), fluphenazine decanoate (e.g. Modectate, formerly Anatensol; Prolixin in USA), prochlorperazine, perphenazine
 Butyrophenones, e.g. haloperidol (Serenace, Haldol – developed by Paul Janssen from pethidine in late 1950s), droperidol³⁶⁹⁰, benperidol, trifluoperidol
 Thioxanthines (synthesised in Denmark by Petersen and co-workers in the late 1950s), e.g. flupenthixol (flupenthixol) decanoate (Depixol), clopenthixol decanoate (Clopixol), chlorprothixene, thiothixene; thioxanthines can be (a) aliphatic or (b) piperazine
 Dihydroindolones, e.g. molindone (Moban), oxypertine
 Diphenylbutylpiperidines, e.g. pimozide (Orap), fluspiriline
 Substituted benzamides, e.g. sulpiride (Dolmatil), amisulpride (Solian), raclopride, remoxipride³⁶⁹¹
 Dibenzothiazepine, e.g. quetiapine (Seroquel)
 Dihydroindolones, e.g. molindone
 Benzisoxazoles, e.g. risperidone (Risperdal), iloperidone (Zomaril)
 Dibenzodiazepines, e.g. clozapine (Clozaril)
 Dibenoxazepines, e.g. loxapine (Loxitane)
 Thienobenzodiazepines, e.g. olanzapine (Zyprexa)
 Benzothiazolylpiperazine, e.g. ziprasidone HCl (Geodon)
 Rauwolfia alkaloids, e.g. reserpine
 Quinolinone, e.g. aripiprazole (Abilify)
 Phenylindol, e.g. sertindole (Serdolect)
 Dibenzothiepine, e.g. zotepine

Depot antipsychotics include:

³⁶⁸⁸ Causing the patient to be preoccupied with delusions and hallucinations.

³⁶⁸⁹ It should be noted that negative symptoms may occur with temporal lobe epilepsy. (Getz et al, 2002)

³⁶⁹⁰ Droperidol (Droleptan) is a systemically administered butyrophenone with a short duration of action and may need to be given repeatedly. It is a potent alpha-adrenergic receptor antagonist that causes less hypotension than CPZ. It has very little affinity for central histamine receptors, which may account for its relatively weak sedative effect. The main uses of droperidol were its use in conjunction with narcotic analgesics in neuroleptanalgesia; as a premedication alone or with a narcotic analgesic; and in the acute management of the agitated manic patient. Because of concerns raised about prolongation of the QT interval, droperidol was withdrawn from the market in 2001. It was also associated with frightening dreams.

³⁶⁹¹ Remoxipride (Roxiam), a substituted benzamide and selective D2-receptor antagonist, was withdrawn in 1994 because of associated aplastic anaemia. Sertindole (Serdolect), an atypical drug, was also removed from the market in 1998, this time because of QT prolongation. (O'Shea, 1998) only to reappear again in 2007.

Flupenthixol (flupentixol: Depixol) 20 mg test dose, 1-4 weekly injections.

Zuclopenthixol (Clopixol) 50 mg test dose, 1-4 weekly injections; zuclopenthixol acetate solution (5%) or Clopixol Acuphase (50-150 mg – suggested max dose 400 mg in 4 injections) is useful for rapid control of psychotic behaviour and lasts 2-3 days after deep IM injection. Longer-lasting depot neuroleptics can and have been started simultaneously with zuclopenthixol acetate.

Haloperidol decanoate (Haldol Decanoas) 25 mg test dose, 4 weekly injections.

Fluphenazine decanoate (Modecate) 12.5-20 mg test dose, 1-4 weekly injections.

Fluphenazine HCL (Moditen Enanthate).

Pipothiazine palmitate (Piportil - withdrawn 2007).

Fluspiriline (Redeptin, a phenylbutyl piperidine) 2 mg test dose, weekly injections (may get local fibrotic nodules).

Olanzapine (Zyprexa IM) see below under atypical drugs.

Olanzapine palmoate (Zypadhera)

Risperidone depot - see below under atypical drugs.

Ziprasidone mesylate IM lasts for 3 days.

Thioridazine (Melleril, Melzine, Thiozine), which is (unlike trifluoperazine and the butyrophenones) strongly anticholinergic, may prolong the QT interval (blockade of delayed rectifier potassium channel {I(Kr)}) leading to prolonged cardiac repolarisation. Use is now restricted to second line treatment of adult cases of schizophrenia under the supervision of a consultant psychiatrist. Contraindications include a history of 'clinically significant' cardiac disorders including arrhythmias, conduction disorders or a history of QTc prolongation (> 450 msec, although > 500 msec seems more realistic and it should be noted that the mean QTc varies in individuals by 76 msec each day). Other conditions/medicines that lead to electrolyte imbalance may increase the risk for serious cardiac arrhythmias. It is 'recommended' that patients have electrolyte estimations and an ECG before and periodically during thioridazine administration. As of December 2000, Novartis limited the use of thioridazine (Melleril) to adult schizophrenia under the supervision of a consultant psychiatrist. Possible mechanisms of sudden death in neuroleptic-treated patients include (a) unrelated, (b) cell membrane sodium pump blockade, (c) NMS, (d) CNS/respiratory depression, (e) hypoxaemia, (f) seizures, and (g) hypotension. (O'Shea, 1998) In the case of thioridazine, mutated genes coding for CYP2D6 isoenzyme (debrisoquine hydroxylase) may lead to metabolite accumulation and potential cardiotoxic effects. (Reilly et al, 2002) Mutations at the HERG (human 'ether-a-go-go') locus causes a congenital long QT syndrome in which potassium channel current is reduced and torsade de pointes occurs frequently, and arrhythmias become more likely following further blockade by drugs. It has also been surmised that the chief reason for cardiac and ejaculatory side effects of thioridazine lies in calcium ion channel blockade – ECG changes produced by thioridazine resemble those caused by verapamil. Mesoridazine (Serentil), a major metabolite of thioridazine, can prolong the QTc interval. Pimozide (Orap), a potent calcium antagonist with a half-life of 53 hours on average, should be avoided in patients with long QT intervals or in patients on drugs that prolong that interval (like TCAs). Regular ECGs, a slow increase in dose, and a low final dose may obviate problems. Also, seizures may occur with high-dose pimozide. This subject is discussed further under the heading 'sudden death' below. The combination of pimozide and fluoxetine can lead to bradycardia and/or delirium. Do not combine pimozide and other calcium channel blocking drugs, such as nifedipine, diltiazem, and verapamil. Drugs that inhibit P450 3A4 enzymes (e.g. erythromycin and nefazodone) increase pimozide levels. Atypical antipsychotic drugs may carry similar risk for sudden death as do the typical (older) drugs. (Ray et al, 2009)

Antipsychotic drugs are **contraindicated** in myasthenia gravis, Addison's disease, narrow angle glaucoma (liase with ophthalmologist), and past or present bone marrow suppression. Special caution is required in cases with renal disease, cardiovascular disorder, Parkinsonism, epilepsy, and serious infection.

Irish Medicines Board (2007) summary of EU review conclusions

Do not use *haloperidol*, *pimozide*, *sertindole*, or *ziprasidone* if there is

- Clinically significant heart disorder (recent MI, uncompensated heart failure, arrhythmias treated with class 1A³⁶⁹² and III anti-arrhythmic drugs)
- QTc prolongation
- History of ventricular arrhythmia or *torsades de pointes*
- Uncorrected hypokalaemia³⁶⁹³
- Patient on another QT interval-prolonging drug

Use these drugs with caution if there is cardiovascular disease or a family history of long QT. (Roden, 2008) Do baseline ECG and consider need for ongoing ECG monitoring. Decrease dose if QT lengthens and discontinue if > 500 ms. Monitor electrolytes and avoid other neuroleptics.

³⁶⁹² Tricyclic antidepressants have class 1A antiarrhythmic properties.

³⁶⁹³ Low magnesium is also a risk factor for prolongation of the QTc interval, as is use of cocaine.

With other antipsychotic drugs exercise caution in cases of cardiovascular disease or family history of long QT, and avoid concomitant use of other neuroleptics.

Drugs such as trifluoperazine and haloperidol are capable of causing stronger EPS than, say, thioridazine³⁶⁹⁴. Antiparkinsonian drugs should be avoided where possible (e.g. lower dose of CPZ) or given only for a brief period. It has been suggested that prolonged use in combination with antipsychotic drugs increase the likelihood of developing tardive dyskinesia (TD). Prochlorperazine (Stemetil) has little or no antipsychotic actions and is mainly used as a sedative or antiemetic. Perphenazine (Fentazin) and pericyazine (Neulactil) are less sedative than CPZ.

CPZ has many non-psychiatric uses, e.g. hiccough³⁶⁹⁵, antiemetic, coolant³⁶⁹⁶, etc. Sulpride (Dolmatil) is a substituted benzamide. In low doses (200-400 mgs BID) the greater affinity of the drug for the presynaptic receptors blocks negative feedback to the presynaptic neurone and the resultant increase in DA in the synaptic cleft may have an alerting effect. With higher doses (400-1,200 mgs BID), both pre- and postsynaptic receptors are blocked, giving a neuroleptic-type effect. Furthermore, postsynaptic D2 receptors (implicated in schizophrenia) are blocked, whereas D1 receptors function normally. The maximum recommended dose is 2,400 mgs per 24 hours. The idea is to use low doses for 'negative' symptoms and higher doses for 'positive' symptoms. Loxapine (Loxapac), a tricyclic dibenzoxazepine like amoxapine with some structural similarity to phenothiazines and carbamazepine, is started at 20-50 mg/day in two doses. It is increased over 7-10 days to 60-100 mg/day, given twice to four times per day. The usual maintenance dose is 20-100 mg/day, and the maximum daily dose is 250 mgs. The elimination half-life is 7 hours. It has the usual range of adverse effects, including TD. According to Buckley and McManus,(1998) loxapine had the highest fatal toxicity index (deaths due to poisoning) of all antipsychotics. Fits³⁶⁹⁷ can occur with overdose of this drug. Loxapine has been shown to be as effective as haloperidol in acute schizophrenia with less potential to cause EPS.

Adverse effects of antipsychotic drugs (O'Shea, 1998)

Skin - allergic reactions, photosensitivity dermatitis³⁶⁹⁸, hair loss³⁶⁹⁹, pigmentary changes³⁷⁰⁰ in skin and cornea, opaque lens

Blood - transient rise or fall in WCC (benign leucopaenia in up to 10% on CPZ: Kane ea, 1992), eosinophilia, agranulocytosis,³⁷⁰¹ and idiopathic venous thromboembolism³⁷⁰²

Liver - transient elevation of enzymes, and cholestatic jaundice; avoid CPZ in presence of liver disease

³⁶⁹⁴ There may be an individual propensity to EPS as there is a tendency for the same patients to develop them on successive exposures to neuroleptic drugs.(Keepers & Casey, 1991)

³⁶⁹⁵ Haloperidol, metoclopramide, carbamazepine, valproic acid, phenytoin, perphenazine and baclofen are other treatments for persistent hiccough.(Howard, 1992)

³⁶⁹⁶ During the early years of heart surgery.

³⁶⁹⁷ These are probably due to potent GABA_A receptor antagonism.

³⁶⁹⁸ Use a strong sunscreen factor or Uvistat.

³⁶⁹⁹ Usually increased shedding, rarely different degrees of alopecia; less common than with TCAs and mood stabilisers.(Warnock, 1991)

³⁷⁰⁰ Pigmentation of the gums may be caused by many substances, e.g. phenothiazines, anti-malaria drugs, lead, mercury, and bismuth.

³⁷⁰¹ 0.32% with CPZ.(Kane ea, 1992) If there is persistent sore throat or fever stop the drug and check WCC. Clozapine may cause a benign fever that responds to paracetamol.

³⁷⁰² This was thought to be more likely in patients on typical agents, especially low potency ones, but atypical agents are not devoid of this risk.(Hägg & Spigset, 2002; Selten & Büller, 2003; Waage & Gedde-Dahl, 2003; Hilli ea, 2008; Srihari & Lee, 2008; Gunasekaran, 2010) Possible mechanisms include venous stasis due to sedation, increased platelet aggregation, anti-cardiolipin action, or antibodies.

Cardiac - wide, flat T waves, increase in QT interval (sudden death is thought to be rare), (haloperidol is relatively safe in this regard), thioridazine may reverse inotropic effect of digitalis (quinidine-like effect)

Metabolic³⁷⁰³/**Endocrine** - weight gain,³⁷⁰⁴ [Clozapine and olanzapine have been reported to cause hyperglycaemia³⁷⁰⁵, diabetes mellitus and diabetic ketoacidosis more often than do other atypicals.³⁷⁰⁶ (Henderson & Ettinger, 2003, p. 107; Henderson ea, 2005)] gynaecomastia, galactorrhoea³⁷⁰⁷, amenorrhoea (high prolactin levels can lower oestrogen levels), and, in the longterm, possible osteoporosis³⁷⁰⁸. According to Goff and Shader (2003, p. 575) inadequate exercise, poor nutrition, cigarette smoking and polydipsia are risk factors for osteopenia in schizophrenic patients. Hummer ea (2005) used dual x-ray absorptiometry to determine bone mineral density and that male schizophrenics, but not females with that diagnosis, had low mineral density in the lumbar region. Minelli ea (2004) suggested that HRT can be used for significant menopausal symptoms. The use of HRT as a first-line prophylactic against osteoporosis in postmenopausal with has come under attack because of associated disorders, such as a slight increase in breast cancer.(Singh, 2003; Irish Medicines Board, 2003) There may also be an increased risk of stroke, particularly ischaemic stroke.(Bath & Gray, 2005) A large, population-based Canadian study (Gill ea, 2007) found that antipsychotic drugs may increase mortality in the elderly demented, typical (conventional) agents carrying a higher risk than atypical drugs³⁷⁰⁹, and the risk developed within one month and lasted for up to 6 months³⁷¹⁰. Regular review of antipsychotic prescriptions are necessary in nursing homes and elsewhere.(Alldred ea, 2007; Anonymous, 2007; Mashta, 2009) The risk for hyperlipidaemia is increased with atypical drugs, e.g. clozapine, quetiapine, risperidone, and olanzapine and with typical drugs (Koro ea, 2002; Meyer, 2003, p. 73; Olfson ea, 2006) Butyrophenones and aripiprazole may be lipid neutral.(Meyer, 2003, p. 68; Olfson ea, 2006)

Dysphoria – can cause this in normals and patients; possibly improved by anticholinergic drugs

Sedation - tolerance to this effect occurs quickly (may give most of the dose at night); neuroleptics enhance respiratory depression from opiates and enhance the analgesic effects of morphine

Temperature - excesses of ambient temperature may lead to cold injury or to severe hyperpyrexia due to hypothalamic dysregulation

Foetus/Neonate - no firm evidence of problems

Eyes - opacities of lens and cornea, retinitis pigmentosa (especially thioridazine; the upper dose of thioridazine should not exceed 800 mg/day³⁷¹¹)

³⁷⁰³ Even community-based people on antipsychotics have an increased prevalence of metabolic syndrome and heightened risk for cardiovascular risk (Mackin ea, 2007) although choice of controls and direction of causality inferences remain problematic.

³⁷⁰⁴ ? Multifactorial aetiology: schizophrenia itself, centripetal obesity from medicines, interaction of H1 and 5HT_{2C} receptor blockade, and insulin resistance secondary to treatment. Adding an H2 blocking agent or sibutramine (Henderson ea, 2005) has been suggested to reduce weight gain in patients on olanzapine. Poyurovsky ea(2003) report that reboxetine may attenuate weight gain in olanzapine-treated schizophrenics. Metformin (inhibits hepatic glucose production) is reported to abrogate weight gain, decreased insulin sensitivity, and abnormal glucose metabolism due to atypical antipsychotics.(Klein ea, 2006; Wu ea, 2008)

³⁷⁰⁵ CPZ causes hyperglycaemia more often than hypoglycaemia.

³⁷⁰⁶ All patients with schizophrenia should be routinely screened for diabetes no matter what medication (or none) they are receiving. Atypical-treated patients may be tested more often for diabetes than those treated with typical drugs.(Taylor ea, 2004) A systematic review and meta-analysis (Smith ea, 2008) found 'tentative' evidence that there is a 'small' increase in risk of diabetes when using second-generation antipsychotics for schizophrenia instead of older drugs, but methodological problems muddy the waters.

³⁷⁰⁷ Most antipsychotic drugs increase prolactin secretion.

³⁷⁰⁸ Associated with high prolactin levels.(O'Keane, 2001; Wieck & Haddad, 2003) Rey-Sánchez ea (2008) found that women with schizophrenia who were receiving antipsychotic drugs had reduced phalangeal bone mass that was associated with reduced levels of 25-hydroxyvitamin D and higher levels of parathormone and increased bone turnover.

³⁷⁰⁹ Kales ea (2007) found risks similar for atypical and typical drugs.

³⁷¹⁰ The editors pointed out that 'sensitivity analyses showed that unmeasured confounders may diminish or erase observed associations'. Without dismissing concerns about pharmacological over-control in nursing homes, such research does not control for the underlying cause of behavioural problems in demented patients.

³⁷¹¹ Beta-blocking drugs could push thioridazine levels up to levels dangerous to the eye.

Confusional States - especially in elderly and if combined with antiparkinsonian drugs

Reduced seizure threshold

Antiadrenergic - inhibition of ejaculation, postural hypotension; patients with postural hypotension should rise slowly, raising the end of the bed may help, and extreme cases may require an IV noradrenaline or metaraminol (**not** adrenaline) infusion³⁷¹²; CPZ combined with the ACE inhibitor captopril can lead to severe hypotension; also, hypotension can follow the combination of a low potency antipsychotic with certain anaesthetic agents, such as halothane, enflurane, and isoflurane; neuroleptics reverse the hypotensive action of guanethidine-like drugs by inhibiting monoamine reuptake

Anticholinergic - especially early on in treatment - dry mouth, blurred vision, mydriasis, constipation, urinary retention, impotence³⁷¹³, tachycardia, confusional states (via central effect), paralytic ileus (once common with use of prolonged deep narcosis)

Abstinence Syndrome - if these drugs are stopped suddenly there may experience nausea, vomiting, insomnia or headaches

Water intoxication – discussed elsewhere

Neuroleptic Malignant Syndrome³⁷¹⁴ (NMS) - high body temperature, generalised muscular rigidity³⁷¹⁵ (lead-pipe, even cog-wheeling), confusion, autonomic symptoms such as excessive sweating and salivation, tachycardia, changing blood pressure levels, tachypnoea, dyspnoea, unstable blood pressure, and incontinence. NMS is a relatively rare³⁷¹⁶, potentially lethal idiosyncratic reaction to therapeutic doses of antipsychotic drugs (typical > atypical), or tetrabenazine.(O'Shea, 1997) The mechanism may relate to antidopaminergic activity in the hypothalamus³⁷¹⁷ and/or basal ganglia, although the balance between serotonin and DA may be important, e.g. clomipramine is only a weak DA receptor antagonist but has been associated with NMS.(Haddow ea, 2004) Many features of the serotonin syndrome are shared with NMS.(Ames & Wirshing, 1993) NMS has been reported to follow stopping levodopa or dopaminergic drugs³⁷¹⁸.(Meltzer & Fatemi, 1998) Most reports of NMS occurring in patients on combined lithium and antipsychotic medication have been associated with dehydration and high serum lithium levels.(APA, 2002, p. 391) The symptoms can arise any time after starting treatment, but usually earlier rather than later. They develop over 1-3 days and tend to subside in about a week, or up to 3 weeks with depot preparations. Re-exposure does not inevitably result in another attack. Triggering of an attack may require the presence of fatigue, dehydration, infection, hyponatraemia, catatonia (it has been suggested that lethal catatonia in unmedicated patients is the same as NMS), or organic brain disease, but this is controversial. Rapid dose escalation may be a factor. Pneumonia may occur³⁷¹⁹. NMS has occurred in cases with Parkinson's disease, when DA agonists were abruptly withdrawn, and in a patient who received metoclopramide³⁷²⁰. DA deficiency in both the basal ganglia and the hypothalamus may underlie NMS. Laboratory investigations merely show non-specific secondary changes, e.g. a neutrophil leucocytosis in the absence of

³⁷¹² Giving adrenaline will lower the blood pressure further because of beta-adrenergic stimulation leading to vasodilatation – the alpha-1-adrenergic properties are blocked so one does not get the usual pressor effect; a similar effect may occur if a low potency antipsychotic is given in the presence of phaeochromocytoma. Asthmatic receiving antipsychotics may require episodic beta-adrenergic medication and should be aware of the potential dangers of receiving adrenaline during acute attacks.

³⁷¹³ Asking about sexual problems before prescribing antipsychotic medication may improve detection of secondary sexual dysfunction following prescription by reducing embarrassment – it may also improve compliance.(Smith ea, 2002)

³⁷¹⁴ Described in 1960 by J Delay, P Pichot and T Lempérière.

³⁷¹⁵ Rigidity may be absent in patients taking atypical drugs.

³⁷¹⁶ Incidence in different reports varies from 0.2-1.0% and the mortality is put at about 20%.

³⁷¹⁷ Injecting antipsychotic drugs into the hypothalamus has produced hyperthermia.

³⁷¹⁸ Never stop high doses of anti-parkinsonian drugs abruptly!

³⁷¹⁹ Somatic illness may predispose to NMS and many such disorders may **mimic NMS**, e.g. malignant hyperthermia (post-anaesthesia), lethal catatonia, serotonin syndrome, tetanus, epileptic status, porphyria, subcortical cerebral lesions, CNS infection, and heat stroke (dry skin, flaccid muscles, low blood pressure). The main differential diagnoses to consider in cases of tetanus are tetany, strychnine poisoning, phenothiazine toxicity, and meningitis.

³⁷²⁰ A DA receptor antagonist, acting on nigrostriatal pathway but not mesolimbic system, and having minimal antipsychotic effect.

infection, elevated liver transaminases, elevated creatinine phosphokinase³⁷²¹ and serum potassium (due to necrosis of voluntary muscle), reduced serum iron, and the EEG may show non-specific slowing. Postmortem studies give normal results.

Risk factors for NMS (after Ahuja & Cole, 2009)

Past personal or family history of NMS

Lewy body dementia, disorder of basal ganglia, catatonia, drug abuse

Dopamine antagonists – anti-emetic, sedative, antipsychotic*

Young, male, activity/tiredness, dehydration/electrolyte imbalance/humid, warm atmosphere

Low serum iron, raised creatinine in psychosis

*Starting with too high a dose or too fast, IM/IV, depot, suddenly stopping antipsychotic drug

The differential diagnosis includes rhabdomyolysis from other causes, severe dystonic reactions, malignant hyperthermia (CO₂ levels are typically raised in this disorder and are normal in NMS), catatonia, CNS infections³⁷²² or lesions, heat stroke, allergic drug reactions, toxic encephalopathy, hyperthyroidism, pheochromocytoma, serotonin (5-HT) syndrome, tetany and Parkinson's disease. Complications include metabolic acidosis, dehydration, shock, coagulopathy, acute myoglobinuria and renal failure, respiratory failure and pneumonia, and cerebellar damage. Management includes stopping the offending drug, cooling the body, treating any infection or organ failure, replacing body fluids, and, if prompt improvement doesn't occur, considering ECT. (Troller & Sachdev, 1999; Ozer et al, 2005) The following drugs may be used on their own or together, although there is a report that contrasts to most others suggesting that they can prolong the disorder (Rosebush et al, 1991): Bromocriptine (Parlodel), 60 mgs per day - acts centrally as a DA agonist. Dantrolene (Dantrium, 10 mgs/Kg/day) acts peripherally to reduce skeletal muscle tone. It may cause liver toxicity (Marangell et al, 2003, p. 1092) and should be avoided in patients with poor hepatic function. Kellam (1987) suggested the following treatment for NMS: try dantrolene with either amantadine or bromocriptine or both - if no response, give IV lorazepam (especially if catatonic symptoms are marked) - if DA agonists have cured the rigidity and pyrexia but psychotic symptoms persist, one might consider ECT.³⁷²³ Some authors caution delaying ECT until the syndrome has subsided. Other suggested drug therapies have included L-DOPA and amantadine.³⁷²⁴ There may be a relationship between NMS and malignant hyperthermia, although this is strongly disputed. (Sackeim, 2003, p. 535) The latter trait is inherited as an autosomal dominant³⁷²⁵ and is an abnormal muscle reaction to anaesthetics. Also, White (1992) points out that the occurrence of NMS and catatonia as separate episodes in the same patient suggests that they may be different aspects of the same diathesis. A clustering of cases in South Wales during the early 1990s added to the aetiological debate. (Huckle et al, 1993) Temperature and blood pressure should be routinely monitored in disturbed patients requiring rapid sedation and the co-prescription of short-acting BZDs alongside antipsychotic drugs may help to avoid cumulative dosing.

³⁷²¹ This has poor diagnostic reliability because it is also raised after IM injection, injury, use of restraints, oral neuroleptics, acute dystonia, acute psychosis, acute myocardial infarction, various muscle diseases, rhabdomyolysis secondary to drug abuse, etc. Urinary myoglobin is increased in NMS, PCP/cocaine/LSD users, and with restraints.

³⁷²² An NMS-like state can be caused by meningoencephalitis of almost any aetiology, 'so that the presence of a neuroleptic is merely coincidental'. (Friedman & Fernandez, 2004, p. 174)

³⁷²³ Consider using non-depolarising muscle relaxant, e.g. atracurium or mivacurium. The effect of ECT varies from effective to ineffective to precipitation of cardiac arrhythmias. In 55 published cases of NMS who were given ECT (Troller & Sachdev, 1999) 40 responded of which 25 achieved remission and 11 had a partial response.

³⁷²⁴ As stated above, a similar syndrome to NMS follows withdrawal of DA agonists, such as L-DOPA, amantadine or bromocriptine, in patients with Parkinson's disease.

³⁷²⁵ Diagnosed by caffeine- or halothane-induced muscle contractures on muscle biopsy; incidence of 1 in 12,000 children and 1 in 40,000 adults; gene localised to 19q12-13.2; similar condition found in swine.

The 'hyperthermic malignant syndrome', which resembles NMS, may follow surgery in patients with Parkinson's disease who have had to stop L-DOPA³⁷²⁶. This can be treated with IV or SC apomorphine (DA agonist). In fact, Colosimo *et al* (1994) suggest using apomorphine to replace L-DOPA in Parkinson's disease patients undergoing GIT surgery.

CNS

Antipsychotic drugs, from the point of view of this discussion, may be seen as acting at three important sites within the central nervous system (CNS): DA receptors in limbic system - hence antipsychotic effect; hypothalamo-pituitary - hence raised prolactin; and extrapyramidal system - the main clinical effects are:

Bradyphrenia – sluggish thinking – may respond to anticholinergic drugs.

Akinesia is a very common and usually extremely early adverse effect of antipsychotic medication. There is less than normal spontaneity of movement or facial expression, there is *no hypertonia*, and the patient feels tired, indifferent, sad, or 'like a zombie'. It must be differentiated from the apathy of depression or schizophrenia. Treatment involves dose reduction or use of anticholinergic drugs.

Acute dystonia³⁷²⁷ – Aetiological theories involve presynaptic DA autoreceptor blockade or increased striatal anticholinergic activity. Sustained contraction of muscles of neck, mouth, tongue, or occasionally other muscle groups that is subjectively distressing and often painful.³⁷²⁸ Examples are oculogyric crisis³⁷²⁹, blepharospasm, glossopharyngeal dystonia³⁷³⁰, torticollis, lordosis, scoliosis, opisthotonus, and twisting of mouth or rotation of neck.³⁷³¹ Bizarre movements are sometimes mistaken for 'hysteria' or malingering. Acute first-episode psychotic patients are more likely to develop acute dystonia if they are relatively young and have negative symptoms. The young³⁷³² male (well muscled) is the classic victim but the association with male sex is questionable. Other drugs that have been reported to cause acute dystonia include metoclopramide, prochlorperazine, SSRIs, cocaine,³⁷³³ (Catalano *et al*, 1997) antihistamines in OTC cold and cough cures in children (Owens, 2000), and, arguably, tetrabenazine, mefenamic acid, oxetidine, flunarizine, and cinnarizine³⁷³³. Flecainide, a substituted benzamide and class Ic antiarrhythmic, has been reported to 'possibly' cause oro-facial dyskinesia in one case. (Miller & Jankovic, 1992) Even though most cases subside spontaneously within hours, early intervention is required for these intense experiences. Treatment is with parenteral anticholinergic (e.g. procyclidine [Kemadrin] 5-10 mg IV) followed by oral agent such as biperiden (Akineton). Benzodiazepines (e.g. lorazepam 1 mg IM or IV) are second-line interventions. Reducing the dose of antipsychotic drug may lead to a transient worsening of dystonic movement, but about 50% of the movements will improve or disappear eventually. (Barrett, 1993)

Tardive dystonia might possibly be due to a neuroleptic-induced frontal lobe syndrome. It may be impossible to differentiate from TD but anticholinergic drugs may help some cases with tardive dystonia. Median of 5 years exposure to antipsychotic drugs but can occur as early as 3 weeks. Face and neck are main areas affected. (APA Task Force on Tardive Dyskinesia, 1992) Similar movements to primary torsion dystonia. Blepharospasm may be the presenting sign. Anticholinergic drugs, tetrabenazine, reserpine, clozapine, or stopping the offending drug are all possible management strategies. Most cases are males who have a relatively short exposure to antipsychotics. Partial response to therapy is often the situation. Clozapine has been suggested for

³⁷²⁶ L-DOPA is poorly water soluble, so can't be given parentally.

³⁷²⁷ Described in 1695 as post-encephalitic ocular spasm by J P Albrecht.

³⁷²⁸ The reaction occurs early, is more marked with haloperidol than with CPZ and is very rare with clozapine. (Owens, 2000)

³⁷²⁹ This can occur late in treatment. Psychosis may worsen during a crisis. (e.g. Thornton & McKenna, 1994)

³⁷³⁰ Dysarthria, dysphagia, breathing problems, cyanosis.

³⁷³¹ Children can develop opisthotonos, scoliosis, lordosis, or writhing movements.

³⁷³² The incidence of dystonia declines by 4%/year and is very rare after 40 years of age. (Arana *et al*, 1988)

³⁷³³ The latter two drugs, vestibular sedatives, are piperazine derivatives.

refractory, persistent, life-threatening cases (e.g. laryngeal dystonia). Cunningham Owens (2004, p. 269) believes that it “should always be considered”. Botulinum toxin can be used for circumscribed tardive dystonic syndromes, such as laryngeal dystonia, but injections need to be repeated every 3-6 months. Thalamotomy, pallidotomy, and deep brain stimulation of the globus pallidus are surgical approaches to managing refractory cases.

Dystonic storm³⁷³⁴ is a severe exacerbation of dystonic spasm that can lead to myoglobinuria and renal failure. It usually persists for days, requires management in an ICU, and may occur for no obvious reason or is precipitated by intercurrent illness, including infection.

Tardive dysmetria is a controversial term (Sachdev, 2004, p. 152) for chronic disturbance of attention, concentration and executive cognitive activity that accompanies tardive movement disorder.

Dopamine supersensitivity psychosis (tardive psychosis), (DSP) variously defined as the emergence of agitation, confusion, and affective instability after longterm neuroleptic therapy is stopped (Chouinard & Sultan, 1990) or whilst on chronic neuroleptic treatment (Kay & Tasman, 2006, p. 393). Typical schizophrenic thought disorder is said to be absent. Suggested treatment for DSP is with anticonvulsant drugs. The existence of DSP is controversial. Distinguishing between an exacerbation of the underlying psychosis and DSP would be difficult, although a patient given longterm neuroleptic drugs for, say, Tourette disorder, might pose less of a diagnostic problem.

Tardive dysbehaviour disorder, the occurrence of increased activity, aggression, screaming, insomnia and so on after stopping long-term antipsychotic drug treatment (Gualtieri et al., 1984) is another controversial disorder.

Acute akathisia³⁷³⁵: The mechanism may be one of DA receptor blockade in the frontal cortex innervated by the mesocortical DA pathway, although pathogenesis is uncertain.

Akathisia

May be responsible for non-compliance with medication, violence or even suicide

Occurs in both medicated and unmedicated Parkinsonism

Occurs in about 20% (12.5-45%) of patients on antipsychotic drugs

Clozapine less likely to cause akathisia

Other drugs reported to cause acute akathisia: lithium, calcium antagonists, carbamazepine, ethosuximide, methysergide, reserpine, tetrabenazine, SSRI antidepressants, TCAs, amoxapine, and buspirone

Other serotonin reuptake inhibitors (SRIs) such as ritanserin and cyproheptadine may have similar potential

Minimal evidence that low dose mianserin (a 5-HT₂ antagonist) may alleviate akathisia, but it has also been blamed for akathisia!

Low serum iron might be a risk factor?

The affected person complains of restlessness or inner tension. There may be subjective and objective components, but the absence of the subjective element (pseudoakathisia) does not negate the diagnosis (Sachdev, 2004, p. 152) although objective-only cases are more likely in chronic and tardive forms of akathisia. Severe cases are unable to sit still for even a brief moment. Lying down offers some relief, unlike what happens in restless legs syndrome. However, the supine case may still show legs crossing and uncrossing, shifting of the position of the trunk, and various other movements. Anticholinergic drugs or BZDs may give some benefit but fat-soluble beta-blocking drugs like propranolol (Inderal) are suggested as the ideal treatment. Newer treatment options include low-dose

³⁷³⁴ *Status dystonicus*.

³⁷³⁵ Motor restlessness (Gk, ‘not to sit’) - the term was coined by the Czech neuropsychiatrist Ladislav Haskovec (1866-1944) in 1901. Akathisia was first reported as a complication of antipsychotic medication by Hans Steck (1954) a psychiatrist at C  ry-Lausanne.

mirtazapine (15 mg once daily), mianserin, and cyproheptadine.(Poyurovsky, 2010)
Clonidine and amantadine might be tried if other options fail.

Withdrawal akathisia develops days to weeks after stopping or reducing the dose of an antipsychotic drug. However, akathisia following removal of a drug that suppresses akathisia does not fit this definition.

Tardive³⁷³⁶ **akathisia** does not always respond to anticholinergic drugs or to reducing the dose of antipsychotic drugs. Usually of 'pseudoakathisia' form, i.e. there is no subjective component of restlessness. These terms are often used in different (and confusing) ways, e.g. tardive is sometimes used synonymously with withdrawal akathisia, i.e. appearing when longterm antipsychotic drug therapy is stopped; it is also used to mean persistence of the symptoms despite stopping the offending medication. Also, pain or burning in the oral or genital regions has been included in this category.(Ford et al, 1994) Like the acute syndrome, tardive akathisia is usually relieved by lying down. Tetrabenazine or reserpine may improve some cases of tardive akathisia.

Pseudoakathisia is an unfortunate term that may mean tardive dyskinesia of the lower limbs or that there is no subjective sensation of restlessness.

Hemiaakathisia (affects one half of body) and **monoakathisia** (one limb involved) are curiosities. Although reported in relation to drug therapy, they should lead one to consider a physical cause.

Secondary akathisia may be due to Parkinson's disease, cerebral trauma, damage to the lenticular nucleus or subthalamic nucleus, or encephalitis lethargica.(Sachdev, 2004, p. 133)

(‘Pseudo’) Parkinsonism consists of mask-like facies, dribbling, bradykinesia, lack of associated movements like arm swinging whilst walking, rigidity, pill-rolling tremor, cogwheel rigidity³⁷³⁷. Whilst forward flexion of the spine is typical, some cases may stand stiff and upright³⁷³⁸ whilst others may even bend backwards. Extrapyramidal rigidity can be lead-pipe (persistent resistance to passive movement) or cogwheel (succession of resistances). Treat with anticholinergic drugs or lower dose of offending drug. Tolerance often develops to drug-induced Parkinsonism. Older women are the classic victims. Wilson and Primrose (1986) suggested that drug-induced Parkinsonism might increase the chances of later developing Parkinson's disease. There is some evidence for this.(Chaudhuri & Nott, 2004) In a graph with arms showing clinical response against dose of antipsychotic drug there is a point where DA and Ach are widely separated, the point of maximum Parkinsonism. Above and below that point these two activities come closer together so that Parkinsonism becomes less at lower and higher doses. This accounts for the well-known clinical phenomenon of an increase in Parkinsonism as the dose of neuroleptic is reduced! EPS are made worse by anxiety and lessened by sleep.

Numerous drugs have been reported as causing Parkinsonism, e.g. antipsychotic drugs, vestibular sedatives (cinnarizine and flunarizine), and reserpine, disulfiram, manganese, and valproate (after at least 12 months treatment). Whilst most cases are reversible, some may represent unmasking of idiopathic Parkinson's disease.(Chaudhuri & Nott, 2004) Amiodarone may cause tremor.(Hotton & Clough, 2004)

Tardive dyskinesia³⁷³⁹ (TD) is a term that may encompass all persistent abnormal involuntary movements presumed to may be due to chronic neuroleptic use, or it may apply to the classic form of TD, so-called tardive stereotypy. It is hypothesised to be due to supersensitive DA receptors but there is much we do not understand about its

³⁷³⁶ Late-onset.

³⁷³⁷ Get patients to hold pen and stare at it as he squeezes it, now test other arm by moving joints passively as his concentration is diverted elsewhere.

³⁷³⁸ Poker spine.

³⁷³⁹ Fr *tardif*, late. The first modern description may have been that of Matthias Schönecker in 1957 (of Essen-Brobeck) and the term 'tardive dyskinesia' was proposed by Arild Faurbye (1907-1983) of St Hans Psychiatric Hospital Roskilde (Denmark) and co-workers in 1964.(see Mattay & Casey, 2003, p. 558) *The movements of TD decrease during voluntary action and therefore patients can usually manage to feed themselves.*

pathogenesis.(Manschreck ea, 2003, p. 207) Whilst GABA underactivity has been suggested as being a factor in the genesis of TD, treatment aimed at correcting this³⁷⁴⁰ has produced inconsistent results. It can develop months (Dulcan, 1996) to years after starting neuroleptics (or amoxapine, prochlorperazine, metoclopramide, or SSRIs).(O'Shea, 1997; Gerber & Lynd, 1998) Sandler (1996) reported TD in association with fluoxetine treatment. Mattay and Casey (2003, p. 560) hold that while lithium and TCAs may worsen TD they probably do not cause it. Indeed, there is some suggestion that lithium therapy may reduce the likelihood of TD when give to patients with affective disorders.(Mattay & Casey, 2003, p. 564) TD may not a single entity and about 90% are mild.(APA, 2002, p. 374) Store-depleting antipsychotic drugs like reserpine and tetrabenazine, while causing other EPS, do not cause TD. Patients with affective disorders who are given neuroleptics (disputably, depressed patients may be at greater risk than schizophrenic patients – Yassa ea, 1992; Larkin & Gervin, 1998 – but not all studies agree: Twamley ea, 2003, p. 790) and patients with non-psychotic disorders given antipsychotic drugs can develop TD. In patients of 55 years or older with bipolar affective disorder, the ones with involuntary movements were not distinguished from those without them by past or current exposure to antipsychotic drugs, anticholinergics, or carbamazepine, but they had poorer cognitive function, had fewer major depressive episodes, and had received briefer exposure to lithium.(Waddington and Youssef, 1988) The association between involuntary movements and cognitive dysfunction parallel that found in schizophrenia by the same authors. However, there is a complex inter-association between TD, cognitive impairment, certain negative symptoms and formal thought disorder.(Davis ea, 1992) The most common form is the facio-bucco-labio-lingual- masticatory syndrome. TD is characterised by writhing movements. It is more common with age³⁷⁴¹, anticholinergic drug given in addition³⁷⁴², possibly female sex, depot neuroleptics³⁷⁴³, and perhaps early Parkinsonism. Risk factors found at Yale (Anonymous, 1993) for TD were increased age, being black, being on higher doses of antipsychotic drugs³⁷⁴⁴, and being right-handed or ambidextrous. The first 5 years of treatment with neuroleptics was the period of greatest risk for TD³⁷⁴⁵, but the risk continued to increase with continued exposure.

Problems with much of the TD research are that more antipsychotic drug for longer periods may have been a result of greater illness severity which might itself have been associated with greater risk for TD and the lack of suitable matched unmedicated controls.

Whilst studies have suggested that vulnerability to TD may vary by race (e.g. African Americans), confounding may have occurred due to assignment of ethnicity in a multiracial society, and other factors such as medication choice and dosage, tobacco, alcohol³⁷⁴⁶, diet, and genes must all be taken into account.(Swartz ea, 1997) There have been reports of increased levels of IGA and IGM in schizophrenics with TD and more common and longer drug-free periods in the more severe forms of TD. Suddenly stopping the offending drug may even make matters worse³⁷⁴⁷. TD is made worse by anxiety.

³⁷⁴⁰ Valproate, BZDs, baclofen, and progabide.

³⁷⁴¹ Fenton(2000) suggests that 40% of schizophrenic patients aged at least 60 years have spontaneous dyskinesia.

³⁷⁴² Controversial - TD may improve if they are withdrawn.

³⁷⁴³ Possibly this may be because of greater compliance or more severe illness. However, a meta-analysis has shown no excess of NMS, TD or EPS with depot over oral neuroleptics.(Guinta, 1997)

³⁷⁴⁴ Does this reflect illness severity?

³⁷⁴⁵ 32% of patients affected by then.

³⁷⁴⁶ Cocaine or a long history of alcohol abuse may itself increase risk for TD.(De Leon & Jankovic, 2004)

³⁷⁴⁷ Stopping an antipsychotic may lead to gradual decline in TD, although TD may worsen initially (*withdrawal-emergent dyskinesia*, to distinguish it from treatment-emergent dyskinesia). *Withdrawal-emergent* dyskinesia may either resolve over some weeks or may not resolve, the latter presumably representing cases that were latent or simply suppressed by D2 blockade. Withdrawal-emergent dyskinesia may follow a change from a typical to an atypical antipsychotic.

Motor disorders may have more to do with mental illness that is modified by drugs (*perhaps brought forward in time*) than any direct effect of the drugs. (Owens *et al.*, 1982; McCreadie *et al.*, 1996; Fenton, 2000; Halliday *et al.*, 2002) Modestin *et al.* (2008) followed up inpatients on typical antipsychotics and/or Clozapine from 1995 to 2003/4. Their findings are shown in the box.

Evolution of neuroleptics-induced extrapyramidal syndrome in inpatients on long-term antipsychotic drugs (Modestin *et al.*, 2008)

N assessed 1995 = 200

N assessed 2003/4 = 83 (63 had died)

% with akathisia in 1995 and 2003/4 = 14 and 14 respectively

% with TD in 1995 and 2003/4 = 24 and 13 respectively

Only association with evolution of TD = illness duration

No significant association between changes in TD ratings and and long-term treatment with typical, clozapine or other atypical antipsychotic drugs

Considerable fluctuations intra-individually in extrapyramidal signs even while overall prevalence remained the same

Current atypical and clozapine associated with increase in and reduction in akathisia respectively

Tendency for increased Parkinsonism to be associated with current treatment with typical drugs

Research on Indian schizophrenic patients suggests that TD is due to schizophrenia *per se*. (McCreadie *et al.*, 1996) Certainly, TD was described long before modern drugs became available (Kraepelin, 1919; Farran-Ridge, 1926) and it occurs even today in unmedicated psychosis. Adolescents with schizotypal disorder were found to have an excess of movement disorder that progressed with time and that correlated with prodromal psychotic symptoms. (Mittal *et al.*, 2008) Pappa and Dazzan (2009) performed a systematic review of spontaneous abnormal movements in antipsychotic-naïve first-episode psychosis subjects (13 relevant studies found) and found spontaneous dyskinesia and parkinsonism median rates of 9% and 17% respectively; presence of spontaneous abnormal movements may be associated with negative symptoms and cognitive dysfunction; and the authors suggest that spontaneous abnormal movements are intrinsic to schizophrenia. McCreadie *et al.* (2002) using MRI, looked at chronic unmedicated Indian schizophrenic patients and normal controls. The left lentiform nucleus was 11% larger in dyskinetic patients *v* controls, and the right lateral ventricle-hemisphere ratio was 33% larger in patients without dyskinesia *v* controls. As controls age the volume of caudate and lentiform nuclei shrink, a pattern not seen in the patients. The authors suggested that dyskinetic patients have striatal pathology, whereas cortical atrophy is more pronounced in non-dyskinetic cases. A generally accepted figure is that new cases of TD occur at a rate of 2.5% of patients/year on longterm treatment, and 10% of elderly patients develop TD within one year. The limbs, especially the extremities, may be the sites of rudimentary isolated choreiform movements. Early signs of TD include lingual myokymia³⁷⁴⁸ (worm-like tongue movements), tic-like movements of the lips and face, and rapid blinking. The 'bon-bon' sign is when the tongue goes beyond the teeth it makes movements akin to sucking a sweet (bulging of cheek). 'Fly-catcher' sign involves jerky protrusions of the tongue at the corners of the mouth. Severe cases are unable to hold their tongue out for 30 seconds. 'Bridling movements' are irregular retractions of the angles of the mouth. The eyebrows may be raised.

Other manifestations (e.g. Marsalek, 2000)

³⁷⁴⁸ **Myokymia** or 'live flesh' is also the name for a familial innocuous orbicularis oculi (or other muscle) twitch. The term is also used to refer to rare sinuous, wavy or fine lower facial movements due to lesions of the brainstem.

Chewing and grinding of jaws
 Blepharospasm
 Blepharoclonus
 Grimacing (reminiscent of Huntington's disease)
 'Piano-playing' movements of fingers (as in Sydenham's chorea)
 Hand clenching
 Dorsiflexion of great toe
 Shoulder hugging
 Hip flexion
 'Copulatory' movements (pelvic thrusting)
 'Axial hyperkinesia' (involvement of postural muscles)
 Involvement of the respiratory or deglutition muscles (may emit bizarre animal grunts)
 Aerophagy with belching
 Mouth ulcers
 Tardive oculogyrus (conjugate ocular deviation)
 Weight changes

The patient is usually less disturbed than the onlooker. Complications of TD, some of which are very rare, include dental problems, ulceration of lips/tongue, dysphagia, tempomandibular joint degeneration, aspiration pneumonia, dysphonia, hypertrophic lingual and truncal musculature, raised creatine kinase levels³⁷⁴⁹, myoglobinuria. Dean and Thuras (2009) examined the death certificates of American patients who had been repeatedly assessed for TD during life. TD was significantly associated with an increase in mortality, more so if they had been taking conventional (versus atypical) antipsychotics and particularly if they were older.

Differential diagnosis of neuroleptic-induced TD

Other drug effects³⁷⁵⁰
 Schizophrenic mannerisms and stereotypies
 Dental problems³⁷⁵¹
 Senile dyskinesias such as Meige's
 Anoxia
 Hepatic failure
 Renal failure
 Huntington's disease
 Wilson's disease
 Hyperthyroidism
 Hypoparathyroidism
 Post-encephalitic states
 Chorea gravidarum
 Sydenham's chorea
 SLE
 Torsion dystonia
 Tumours

Schizophrenia, especially if accompanied by a 'defect state' with cognitive deficit and negative symptoms, may militate against awareness of TD. Patients with TD may show an excessive release of developmental (primitive/neonatal) reflexes, e.g. grasp, snout,

³⁷⁴⁹ A raised **creatine kinase** level may be due to NMS, hyperthermia (e.g. malignant catatonia or serotonin syndrome), muscular dystrophies, rhabdomyolysis (restraints, rigidity/dystonia, ischaemia, agitation, isotonic exercise, psychosis, IM injections), damaged myocardium (MB fraction). (Ahuja & Cole, 2009)

³⁷⁵⁰ Antihistamines, antimalarials, phenytoin, heavy metals, L-DOPA, and sympathomimetics.

³⁷⁵¹ E.g. ill-fitting dentures/edentulousness.

corneo-mandibular, and glabellar reflexes, suggesting perhaps anomalies in brain development rather than cerebral deterioration from a once normal level of functioning. One may stop the antiparkinsonian medication³⁷⁵², reduce the dose of the antipsychotic drug or stop it altogether, or try sulpiride, tetrabenazine³⁷⁵³ or an atypical agent like clozapine (with or without clonazepam). TD has returned following cessation of clozapine. Ondansetron, a 5-HT₃ receptor antagonist, has been reported in an open-label study to improve AIMS scores in patients with TD.(Sirota *et al*, 2000) Other drugs that have been said to cause TD-like movement disorders are L-dopa (a hyperkinetic syndrome³⁷⁵⁴), amphetamine (dyskinesia), phenytoin, antihistamines, TCAs, and the contraceptive pill. Certain 'typical' antipsychotics cause less movement disorder, e.g. thioridazine and sulpiride,(Livingston, 1994) although cases of TD have been described in patients on sulpiride.(Cullen & Daly, 1996) Interestingly, Shiloh *et al* (1997) and Agelink *et al*(2004) advocate adding sulpiride (circa 600 mg/day) to clozapine in partially responsive schizophrenia³⁷⁵⁵. Waddington and Youssef (1985) found TD in 41% of chronic schizophrenics. The prevalence increased with age and was independent of the length of time on antipsychotic drugs and of the average daily dose over this period. They found no significant difference in prevalence between the sexes. Waddington *et al* (1985) reported that schizophrenics with TD were more intellectually impaired, had more negative symptoms, and were older than those without TD. Prolonged neuroleptic treatment of young rats is associated with late-onset orofacial movement; however, such movements occur spontaneously in untreated old rats. Structural brain changes consequent to ageing and disease processes may be associated with the emergence of orofacial dyskinesia, even in the absence of exposure to antipsychotic drugs. Vitamin E (a membrane-soluble antioxidant) enjoyed a brief period of promise as an anti-TD agent because of the theory that antipsychotic drugs increase catecholamine metabolism (increasing free radical production) and enhance trace metals, both mechanisms producing TD via cytotoxicity.(Adler *et al*, 1999) There are claims that melatonin may improve AIMS scores, possibly by an antioxidant effect and attenuation of both striatal DA activity and release of DA from the hypothalamus.(Shamir *et al*, 2001) Controversially, many practitioners simply increase the dose of neuroleptic in order to mask TD. This practice may be necessary in life-threatening cases. Phenylketonurics may *possibly* be at increased risk for TD.(Mattay & Casey, 2003, p. 563) It is suggested that TD may be associated with reduced clearance of ingested phenylalanine, a large neutral amino acid, and there is some evidence that giving branched chain amino acids (e.g. valine, leucine, isoleucine: Tarvil) reduces the symptoms of TD.(Richardson *et al*, 1999, 2003) It has been remarked that many drug treatments for TD do better in open trials than in methodologically rigorous research.(APA, 2002, p. 375) Deep brain stimulation and bilateral posteroventral pallidotomy have produced useful results in extreme cases of TD.(Mattay and Casey, 2003, p. 567) In conclusion, TD can be a side effect of medication or 'a motor symptom of mental disorder in its own right'.(Sims *et al*, 2000) **Pisa syndrome**³⁷⁵⁶: tonic flexion of the trunk to one side, accompanied by its slight rotation, in the absence of other concomitant dystonic symptoms. The condition is exacerbated by walking. It is arguably a dystonia³⁷⁵⁷ or variant of TD. May improve when antipsychotic drugs are withdrawn but anticholinergic drugs are unhelpful. **Tardive Tourette's disorder** (tardive tourettism) – has emerged during neuroleptic therapy. There are multiple tics and vocalisations, even echolalia and coprolalia, sometimes with TD-like movements.

Tardive myoclonus – uncommonly myoclonus is the predominant feature of TD.

³⁷⁵² Improvement, if it occurs, may take months.

³⁷⁵³ 12.5 mg bid to start, titrating to max of 50 mg tid in weekly intervals.

³⁷⁵⁴ Adding a dopamine agonist to L-DOPA reduces the risk of dyskinesia but increases cost and potential side effects.(LeWitt, 2008)

³⁷⁵⁵ Other selective D₂ antagonists such as pimozide and amisulpride have also been suggested.(Travis, 2002)

³⁷⁵⁶ Described by Ekblom in 1972 (one of his 3 eponymous syndromes).

³⁷⁵⁷ Affects one side of trunk – if bilateral it would cause arching.

Tardive tremor – variant of TD with absence of other features of Parkinsonism; may respond to tetrabenazine.(Stacy & Jankovic, 1992)

Rabbit syndrome - this perioral tremor may not be part of TD. It may indeed represent a variant of drug-induced Parkinsonism.(Chaudhuri & Nott, 2004, p. 66) There is a fine, rapid movement of the lips (3-6 Hz) that mimics the chewing movements of a rabbit. It occurs late during antipsychotic drug therapy. Rabbit syndrome may occur in 4% of such patients who are not receiving concomitant anticholinergic drugs. An anticholinergic drug may be helpful. One case responded to olanzapine.(Durst ea, 2000)

Blepharospasm-omandibular dystonia syndrome³⁷⁵⁸ (BODS, Meige's) BODS must be distinguished from hysteria and TD. Different components of the syndrome can occur together or in isolation. It may be precipitated by antipsychotic drugs, including risperidone.

BODS

Usually occurs in mid-life

Women are affected more often than are men

Dystonic contractions of jaw and facial muscles (often including platysma)

Difficulties in mastication, speaking and swallowing

May bite tongue or mouth

Jaw may dislocate (sometimes)

Blepharospasm may cause functional blindness

Neuroleptic-induced catatonia might respond to amantadine 100 mg bid given for several weeks and stopping the offending drug may be followed by gradual recovery

Recent research on tardive dyskinesia (TD)

1982. Richardson and Craig point out that the observed coexistence of neuroleptic-induced Parkinsonism and TD argues against any generalised hyperdopaminergic state since the increase in dopamine should improve the Parkinsonism!

1983. Early acute drug-induced EPS increases risk for TD.

1984. Expect a 50% reduction in dyskinetic movement in most patients by 18 months after stopping antipsychotic drugs.

1985. Postmortem study showed no difference in D1 or D2 receptor binding in schizophrenics with and without movement disorders, a finding interpreted as being against DA supersensitivity in TD.

*Transient withdrawal dyskinesia and TD reported in 8 to 51% of antipsychotic drug-treated children and adolescents.*³⁷⁵⁹

1987. Unlike adults, dyskinesias have been reported within months of starting neuroleptics in younger patients.

1988. Increasing age is associated with increasing prevalence of dyskinesia.

1989. Risk of non-compliance after informing American patients of risk of TD may be exaggerated.

1991. 16 year follow up of females with 'non-organic brain syndromes' from a mental hospital: prevalence of TD rose from 18.4% to 46.5% - associated with neuroleptic dose and enlarged cerebral ventricles

Retrospectively, of those on neuroleptics 58% had chronic-persistent TD and the rest had intermittent pattern; chronic-persistent pattern associated with increased age and presence of non-orofacial dyskinesia at baseline

1992. APA Task Force estimate incidence of TD as 5% per year of exposure to neuroleptics among young adults and 30% after 12 months of exposure among elderly patients.

³⁷⁵⁸ Described by a French neurologist, Henri Meige; or Breughel's syndrome - the latter after the painter of 'infernal monsters', Breughel or Breughel the Elder, Dutch artist, d. 1569: actually described by Marsden in 1976. Moore(2001) states that Breughel's syndrome differs from Meige's syndrome by the absence of blepharospasm and the presence of oromandibular dystonic yawning-like movements. Authors differ!

³⁷⁵⁹ Stopping/reducing the dose of a conventional/typical antipsychotic or switching to an atypical antipsychotic (but stopping clozapine has led to withdrawal dyskinesia and dystonia: Ahmed ea, 1998) can sometimes cause a withdrawal dyskinesia (or unmask a dyskinesia suppressed by the typical agent) that usually resolves in about six weeks,(Munetz ea, 1989) although this author has treated a persistent case of respiratory dyskinesia in an elderly male by reintroduction of the typical antipsychotic followed by very slow withdrawal.(O'Shea, 2001) Withdrawal dyskinesia is typically seen in children. Treatment of withdrawal dyskinesia or dystonia may include re-starting the drug followed by a slow taper.

1993. In chronic schizophrenic patients, both oro-facial and trunk and limb dyskinesia are associated with negative symptoms, but only oro-facial dyskinesia showed a significant increase in prevalence with increasing age; patients with negative symptoms tend to develop oro-facial dyskinesia at an earlier age. Diabetes mellitus may be a risk factor for TD.

1994. Young Nigerian schizophrenics who never had neuroleptics did not have TD and TD in younger schizophrenics was related to longer duration on these drugs.

10-year follow-up in Hungary: overall prevalence of TD (30%) varied little; some cases experienced remission whilst others developed TD during the study; outcome not significantly related to neuroleptic treatment or age; TD remains stable; and authors suggest maintaining neuroleptic treatment if it is keeping psychosis under control.

Rate of dyskinesia in mentally retarded women is negatively recorded with IQ.

Three cases of valproate-induced dyskinesia reported in association with significant learning difficulties.

1995. Early brain damage, poor frontal lobe function, and craniofacial dysmorphogenesis have been reported as possible risk factors by various authors.

In a study of outpatients aged over 45 years an increased of TD was associated with higher amounts of neuroleptics (esp. high potency), alcohol abuse/dependence, and subtle movement disorder at the start of the study.

1996. In first episode schizophrenia there was a cumulative incidence of presumptive TD of 6.3% after 1 year of follow up, 11.5% at 2 years, 13.7% at 3 years, and 17.5% at 4 years. The cumulative incidence of persistent TD was 4.8%, 7.2% and 15.6% at years 1, 2 and 4. Poor response to treatment and, to a lesser extent, antipsychotic drug dose, correlated with development of TD.

Schizophrenic patients who developed TD had larger left caudate nucleus on CT than those who did not develop this movement disorder.

Few British psychiatrists inform patients of risk of TD, often citing non-compliance as a reason.

Assessed dyskinesia in 4 groups of *elderly* Indians (normals, relatives of schizophrenics, never-medicated schizophrenics, and medicated schizophrenics): prevalence of dyskinesia similar in never-medicated and medicated patients (c 40%) and was significantly higher than in the other 2 groups (15%). Never-medicated schizophrenics had classic TD.

1997. A lack of the cytochrome P450 enzyme CYP 2D6 may contribute to the risk of neuroleptic drug-induced movement disorders, including TD; 5% of Caucasians have this deficiency (poor metabolisers); however, it does not make patients prone to acute dystonia.

In older patients, higher doses of neuroleptic, greater cumulative total neuroleptic dose, and greater severity of negative symptoms predicted severe TD – because of the lack of comparison with patients not on such drugs, spontaneous dyskinesia cannot be ruled out.

Nearly 15% of schizophrenic patients treated in the pre-neuroleptic era developed documented oro-facial movement disorders that were indistinguishable from TD. Being neuroleptic-naïve and schizophrenic carried a higher risk for movement disorder than having another diagnosis and being neuroleptic-naïve. Spontaneous dyskinesia, Parkinsonism, and neurological soft signs appear to represent neuromotor components of schizophrenia.

Association between Ser9Gly polymorphism in D3 receptor gene and TD.

Association between Taq 1 polymorphism in D2 receptor gene and TD (after chronic neuroleptic treatment).

Free radicals: lower blood or red cell superoxide dismutase (SOD) activity found in Parkinson's disease and Wilson's disease and in schizophrenic patients with TD: cause and effect unclear.

Never-treated schizophrenics in Morocco more commonly exhibit abnormal involuntary movements than do treated cases.

1998. 'Schizophrenia spectrum personality' (schizoid, paranoid, and schizotypal) v normals. No TD in latter. Spontaneous dyskinesia found in 12% of spectrum subjects, especially in schizotypals (24%).

Risk of developing TD is related to the number of interruptions in neuroleptic treatment (evidence against idea of 'targeted' or intermittent therapy).

Patients > 55 years of age getting neuroleptics for the first time: cumulative TD rates were 25%, 34%, and 53% after 1, 2 and 3 years of treatment (much higher than for young people, despite lower doses); risk increased with past ECT, higher mean daily and cumulative antipsychotic drug doses, and early EPS; and no difference between diagnostic groups in TD rates.

It is pointed out that EPS are reported in 17-29% of neuroleptic-naïve schizophrenics, raising the question of the role of antipsychotics in the aetiology of TD.

1999. The presence of a serine allele on D3 receptor might be a risk factor for TD.

Patients on olanzapine for over 200 days get TD but significantly less often than if on haloperidol for similar length of time.

Gabapentin improved TD in patients with mood disorders.(Hardoy et al, 1999)

Olanzapine may suppress respiratory dyskinesia.

2000. Increased incidence of TD (23% to 41%) in Nithsdale (Scotland) between 1981-96 might be due to greater use of antipsychotic drugs or intermittent compliance (increase in tremor by the same percentage as for TD).

Functional polymorphism in promotor region of CYP1A2 associated with TD.

2001. First episode and chronic schizophrenic patients (plus healthy controls) on typical agents; first episode cases put on risperidone and rescanned after a year (MRI); found no abnormalities; movement disorders seen in both groups of patients, suggesting effects of both illness and treatment.

Computerised neurocognitive tasks suggest orofacial TD and evident negative symptoms are relatively independent markers of compromise of cerebral systems mediating spatial working memory: fronto-striatal-thalamic systems, especially those involving DLPFC, may be involved.

Positive association between 5-HT 2C receptor gene and TD.

Positive association between 5-HT 2A receptor gene and TD.

Negative association between 5-HT 2A receptor gene and TD.

2003. Indian study finds that dyskinesia (but not Parkinsonism) is more common in never-treated siblings of schizophrenics who have the (corresponding) movement disorder.(McCreadie ea, 2003)

2004. Systematic review of 11 longterm studies suggest that risk for TD is less with second-generation antipsychotics compared to older agents, although doses of haloperidol in comparator studies were relatively high.

2006. Association of TD and EPS significant but do not robustly identify people at high risk for TD.

Abnormal Involuntary Movement Scale (AIMS)

1. Observe gait on way into room.
2. Have patient remove gum or ill-fitting dentures.
3. Check if patient aware of any movements.
4. Patient sits on firm armless chair, hands on knees, legs slightly apart, feet flat on floor – now and throughout examination observe entire body.
5. Patient sits with hands unsupported and dangling over knees.
6. Patient to open mouth twice – observe for tongue movements.
7. Patient to protrude tongue twice.
8. Patient taps thumb against each finger for 15 seconds with each hand – observe face and legs.
9. Patient stands with arms extended forward.

Rate each item on a 0-4 scale for highest severity observed. Movements that occur only on activation merit 1 point less than spontaneous movements.

0 = no movement, 1 = minimal (may be extreme normal), 2 = mild, 3 = moderate, and 4 = severe.

Facial + oral movements	1. Muscles of facial expression	0-4
	2. Lips & perioral area	0-4
	3. Jaw	0-4
	4. Tongue	0-4
Extremity movements	5. Upper	0-4
	6. Lower	0-4
Trunk movements	7. Neck/shoulders/hips	0-4
Global judgements	8. Severity of abnormal movements	0-4
	9. Incapacitation from abnormal movements	0-4
	10. Awareness* of abnormal movements	0-4**

*Patient's awareness. **0 = unaware, 4 = severe distress.

'Atypical' antipsychotic drugs (Kupfer & Sartorius, 2002)

Tandon (2004) defined atypical antipsychotic drugs as those that produced the same reduction in positive symptoms as did typicals but with less EPS (Lencer ea, 2004); they also cause less dysphoria, less TD, less negative symptoms, and better cognition³⁷⁶⁰.

However, not all research agrees that changing from typical to atypical antipsychotic drugs improves quality of life (Jones ea, 2006), reduces discontinuation rates (Kuhn ea, 2008), is associated with less EPS (Miller ea, 2008) or is associated with increased effectiveness (Kuhn ea, 2008), and there is an argument that the concept of atypicality is unwarranted (Lieberman ea, 2005; Owens, 2008; Rosenheck, 2008; Leucht ea, 2009c) and that the atypical group is a heterogenous one (Leucht ea, 2009a). Neither is there agreement that atypical drugs are necessarily better than haloperidol in terms of cognitive improvement.(Davidson ea, 2009)

³⁷⁶⁰ Cognitive deficits predict functional outcomes.(Velligan, 2004)

It is thought that combined 5-HT₂ and D₂ receptor antagonism³⁷⁶¹ selectively enhances prefrontal DA activity, leading to correction of regional imbalance between cortical and midbrain dopaminergic systems. Actions on serotonergic systems may underlie improved profiles among atypical agents³⁷⁶², such as improvement in negative symptoms, although whether these drugs tackle primary or secondary negativity (e.g. Parkinsonism) is still debated. (Owens, 1998; Fleischhacker, 1999; Kopelowicz et al, 2000; Kane et al, 2001; Tandon et al, 2008) Kelsey et al (2007, p. 368) suggest that atypical agents cause less DA-blockade-associated side effects because (1) 5-HT₂ blockade attenuates effects of nigrostriatal DA blockade, (2) preference for D₄ blockade over D₂ blockade decreases degree of nigrostriatal/tuberoinfundibular DA blockade, and (3), at therapeutic doses, they occupy less (65-75%) of D₂ receptors than do typical antipsychotics. Alternatively, atypicals block D₂ receptors for relatively brief periods as with clozapine or (in the case of aripiprazole) act as partial agonists at D₂ receptors. PET work (Kegeles et al, 2010) seriously questions the mesolimbic selectivity of atypical antipsychotic drugs. There is no reason why atypicals *per se*³⁷⁶³ should not be used to treat mania, despite occasional reports that they cause mania³⁷⁶⁴. (Allen, 1998; Fahy & Fahy, 2000; Murphy, 2003; Hirschfeld et al, 2004) Concomitant use of a mood-stabiliser may or may not be necessary in such cases. One study suggested that risperidone plus a mood stabiliser was more efficacious than a mood stabiliser alone, and as efficacious as haloperidol plus a mood stabiliser for rapid control of mania. (Sachs et al, 2002) Tohen et al (2003) found olanzapine to be equal to haloperidol in terms of efficacy in treating bipolar mania; predictably, the former drug caused weight gain and the latter drug was associated with EPS.

Clozapine aside, the clinician would do well to choose an antipsychotic drug on the basis of its pharmacological and side-effect profile rather than whether it belongs to the novel/atypical/second generation or is an old/typical/first generation compound. (Bonham & Abbott, 2008; Crossley et al, 2010) The 'atypical' antipsychotic drugs are expensive. (Thomas & Lewis, 1998) While a meta-analysis of randomised controlled trials (RCTs) found clozapine better than conventional antipsychotic drugs for both treatment-resistant and non-resistant schizophrenia trials were mostly of short duration. (Wahlbeck et al, 1999) Moncrieff (2003) examined ten trials involving clozapine and found that recent large-scale studies did not find a strong clinical superiority for clozapine; shorter duration of study, pharmaceutical company backing, and higher baseline symptom score consistently predicted greater advantage for clozapine. Geddes et al (2000) conclude that when the dose of typical drugs is controlled for they are as efficacious and as tolerable as the atypical antipsychotics.³⁷⁶⁵ Chakos et al (2001) concluded that clozapine was more effective than typical drugs, but probably not by a robust margin, and the evidence, they found, was inconclusive for other new agents. In contrast, Azorin et al (2001) found clozapine superior to risperidone in previously poor treatment responders; both drugs were well tolerated, although clozapine caused less EPS. Volavka et al (2002) found clozapine, olanzapine and risperidone to cause statistically significant improvements on the PANSS relative to haloperidol, but results were clinically modest and the atypicals caused weight gain. Clozapine was best at reducing negative

³⁷⁶¹ When ritanserin, a specific central 5-HT₂ antagonist, was combined with a D₂ antagonist the result was a reduction in negative symptoms of schizophrenia and less EPS than would have been predicted from a D₂ blocking agent given alone. (O'Shea, 1998) Fananserin, a mixed D₄-5HT_{2A} antagonist, is not an antipsychotic. (Truffinet et al, 1999)

³⁷⁶² However, typical antipsychotic drugs like chlorpromazine also block 5-HT_{2A} receptors! (Trichard et al, 1998)

³⁷⁶³ Olanzapine, clozapine, sertindole, quetiapine, amisulpride, and ziprasidone. Sulpiride, remoxipride, and loxapine could be included in this list on the basis of low EPS potential. Whether amisulpride should be included depends on the definition. Mortimer (2002) stated that the most powerful predictor of 'atypicality' is fast dissociation of the drug from D₂ receptors: as measured by the K_{off}, clozapine and quetiapine have the fastest dissociation. A more satisfactory term is 'novel' antipsychotics, but this would omit clozapine. A scientific definition of an atypical antipsychotic drug is that (unlike typical drugs) it *doesn't cause catalepsy in rats*. In real-life clinical practice, there is only one sure way of knowing who will respond to a particular drug, and that means trying it. Some patients for example respond to risperidone and not to clozapine and *vice versa*. (Bondolfi et al, 1998)

³⁷⁶⁴ Vieta et al (2004) found that risperidone exacerbated mania in 4.2% of cases of mania.

³⁷⁶⁵ Interestingly, the authors included clozapine in the typical group!

symptom scores. Davis *et al.* (2003) in a meta-analytic study, found that clozapine, amisulpride, risperidone and olanzapine³⁷⁶⁶ were more efficacious than first-generation antipsychotics. Unlike Geddes *et al.* (2000) Davis *et al.* (2003) did not find that the dose of haloperidol or other first-generation antipsychotics affected these results, and the latter authors found no difference in efficacy between amisulpride, risperidone and olanzapine. Sechter *et al.* (2003) found a similar efficacy between amisulpride and risperidone in chronic schizophrenia; both drugs had a similar incidence of EPS, but amisulpride had less endocrine and sexual adverse effects and caused less weight gain. McCue *et al.* (2006) found haloperidol, olanzapine, and risperidone superior to aripiprazole, quetiapine, and ziprasidone in the treatment of acute schizophrenia. Robinson *et al.* (2006) used olanzapine or risperidone for first-episode schizophrenia: clinical outcomes were equal and olanzapine caused less motor side effects but caused more weight gain. Leucht *et al.* (2009b) analysed 78 studies of schizophrenia patients and found olanzapine superior to aripiprazole, quetiapine, risperidone, and ziprasidone; risperidone was better than quetiapine and ziprasidone; clozapine was superior to zotepine and (if dose was > 400 mg/day) risperidone; such differences as there were derived from reduction in positive but not negative symptoms. The authors stated that results 'were rather robust' in relation to the influence of pharmaceutical industry sponsorship, the quality of research, doses, and duration of trials! Komossa *et al.* (2009) reviewed RCTs and concluded that aripiprazole was somewhat less effective than olanzapine although aripiprazole had less sedative and metabolic side-effects than olanzapine; risperidone and aripiprazole may be equally efficacious but aripiprazole was less likely to cause dystonia, increased cholesterol and prolactin, and had less effect on QTc.

Despite some methodological deficiencies, research indicates that atypical antipsychotic drugs help to prevent relapse in schizophrenia.(Leucht *et al.*, 2003)

Sertindole and clozapine, and probably quetiapine, do not increase prolactin levels, at least not in any clinically significant manner.(cf. Turrone *et al.*, 2002)

The risk for dysglycaemia is doubled in community-based treated schizophrenic patients compared to the general population, and recognition and treatment of diabetes and pre-diabetes is low in this group.(Voruganti *et al.*, 2007) As pointed out by Leonard *et al.* (2002) the role of clozapine³⁷⁶⁷ is unclear because high rates of diabetes were reported in schizophrenia before the advent of any antipsychotic drugs (Mukherjee *et al.*, 1996) and atypical antipsychotics (Dixon *et al.*, 2000), obesity is common in schizophrenia (Taylor & McAskill, 2000), and the prevalence of obesity generally may be increasing.(Murphy, 2001) Also, impaired fasting glucose tolerance has been reported in drug-naïve, first-episode schizophrenics.(Ryan *et al.*, 2003) Also, beta-cell function and insulin sensitivity have been found to be inversely correlated with acute psychotic stress.(Shiloah *et al.*, 2003) Nevertheless, BMI results do tend to implicate clozapine.(Leonard *et al.*, 2002) Hedenmalm *et al.* (2002) reported increased risk of glucose tolerance in patients on clozapine, olanzapine, or risperidone. In a prospective randomised study, Lindenmayer *et al.* (2003) found that clozapine, olanzapine, and haloperidol were associated with increased plasma glucose values, and the two atypicals were associated with increased plasma cholesterol levels. Elevated serum triglyceride levels has been recorded in patients taking phenothiazines, clozapine, olanzapine, and quetiapine.(Farmer, 2003) Use of atypical antipsychotic drugs in children and adolescents may lead to obesity and abnormal metabolic parameters, with olanzapine (worst) and aripiprazole (best among the drugs studied) being at opposites extremes.(Correll *et al.*, 2009)

What are the issues involved in the employment of atypical drugs to control behavioural and psychiatric symptoms in people with dementia? This issue is discussed below with regard to individual drugs. Some general issues are covered here. The *en masse* withdrawal of these drugs that followed warnings of increased (about threefold from

³⁷⁶⁶ But not aripiprazole, quetiapine, remoxepride, sertindole, ziprasidone, or zotepine. Zotepine was 'marginally different' from first-generation agents.

³⁷⁶⁷ Or other neuroleptics *per se* for that matter.

1.1% to 3.3%) risk for cerebrovascular incidents has been condemned as being hasty. Individual patient circumstances and the side effect profile of alternatives should come first, i.e. a risk-benefit analysis should have been performed (see Haw ea, 2009). Herrmann ea (2004) and Gill ea (2005) found no excess of cerebrovascular incidents in elderly people given atypicals compared to those given typical antipsychotics, but Gill ea (2007) did find early increase in mortality (typical > atypical antipsychotics). Mehta ea (2010) conducted a retrospective study of community-dwelling older adults and found that second generation antipsychotic agents were associated with an increased risk of cerebrovascular incidents compared to first generation drugs and that long-term use of either of these classes of drug were associated with an increased risk of such adverse events. Douglas and Smeeth (2008) looked at a UK general practice database and found that use of any antipsychotic drug was associated with a rate ratio for stroke of 1.73 for typicals and 2.23 for atypicals; in patients receiving any antipsychotic drug the rate ratios were 3.50 for dementia patients and 1.41 for non-dementia patients. There is more research evidence for the effectiveness of atypical drugs in managing behavioural and psychiatric symptoms in people with dementia than for the typical drugs. Patients should only be retained on these drugs (after due consultation) if they have responded to them, if the behavioural problem is persistent or if severe adverse consequences are likely to follow their discontinuation, or if no suitable alternatives exist. It is good practice, however, to keep such prescribing under review (say, every 3 months) and to document why a decision is made. Also, if adverse effects become burdensome (as often happens), the clinician may need to withdraw the medication or modify the dosing regimen.(Schneider ea, 2006)

Atypical antipsychotic drugs (O'Shea, 1998)

Clozapine³⁷⁶⁸ (Clozaril, Denzapine: a dibenzazepine): Despite nine Finnish deaths from clozapine-induced agranulocytosis during the 1970s, interest in clozapine was resurrected by Kane ea (1988) who found that after 6 weeks 30% of treatment-resistant schizophrenic patients responded to clozapine³⁷⁶⁹, only 4% to a typical agent. Clozapine is indicated for nonresponse to or intolerance to other antipsychotics and for treatment of unresponsive psychosis in Parkinson's disease.

Clozapine is said to improve both positive and negative symptoms of schizophrenia, although some results suggest that such negative symptoms may actually represent withdrawal responses to positive symptoms, and not all results agree that negative symptoms are helped.(Buchanan ea, 1998; Breier ea, 1999) It is indicated for schizophrenic psychosis refractory to adequate trials of (2 to 3) other drugs or where side effects prohibit the use of other drugs. It is thought to improve 30-50% of patients in the former category and 70-76% in the latter group. Not every patient will respond to clozapine.(King & Mills, 1993) Early onset of illness and female sex may be indicators of poor response.(Lieberman ea, 1994) There is a greatly reduced³⁷⁷⁰ risk of TD and it may actually improve established TD.

Possible reasons for lack of neurological adverse effects of clozapine

Potent anticholinergic action

Preferential binding: limbic > striatum

³⁷⁶⁸ 5-H dibenzo [be, e]-1, 4-diazepine; synthesised in 1958; found effective for schizophrenia in 1962; originally developed by Hünziker and co-workers. Granulocytopenia due to clozapine was reported in 1975. Ashkenazi Jews and Finns may be at special risk of agranulocytosis from clozapine. Clozapine-induced agranulocytosis usually reverses in 2-3 weeks after stopping the offending drug. Also, it should be noted that Walker ea (1997), using the US Clozapine National Registry, found that stopping clozapine was associated with a higher mortality rate than was staying on the drug; this was mainly due to clozapine's effect of reducing suicide risk.

³⁷⁶⁹ Reasons for clozapine's efficacy in resistant cases may relate to its complex receptor profile or to the fact that it is less dependent than are other neuroleptics on P-glycoprotein, a drug efflux transporter, in order to traverse the blood-brain barrier.(Loscher & Potschka, 2005)

³⁷⁷⁰ Clozapine carries the lowest risk of all antipsychotics for TD, but the absence of risk is not absolute.(Dave, 1994)

Fluoxetine may increase clozapine levels. ECT is usually safe with clozapine (prolonged seizure is rare). Clozapine may reduce hostility and suicidality, but not all reports agree. It may be useful for L-DOPA-induced dyskinesia and for psychosis in Parkinson's disease, in which clozapine is well tolerated³⁷⁷². Polydipsia may be diminished by clozapine therapy. Among the other reported indications for clozapine are treatment-refractory mania, psychotic depression, and schizoaffective disorder. High doses may suppress chorea in Huntington's disease. A more controversial suggestion is its use for intractable borderline personality disorder.

The starting dose is 12.5mg once/twice daily, increasing slowly to 300 mg within 2-3 weeks, and the usual effective dose is 200-450 mg/day. Optimum (best response/least adverse effects) trough (blood drawn at end of dosing interval) plasma clozapine levels are 0.35-0.6 mg/L.(Flanagan, 2007) Fluvoxamine should be avoided as it increases clozapine levels or the clozapine level might need halving if the combination is employed. Deaths have followed cessation of smoking because of increased clozapine levels³⁷⁷³.

Clozapine pharmacokinetics in children and adolescents differs from those in adults: levels of the active metabolite norclozapine are up to 25% less than those of clozapine in adults, whereas younger patients have higher norclozapine than Clozapine levels. Adverse effects vary with norclozapine levels, therapeutic effects varying with levels of Clozapine.(James & McClellan, 2008, p. 824)

Clozapine is considered to have relatively weak antidopaminergic actions³⁷⁷⁴ but to strongly block 5-HT2 receptors³⁷⁷⁵, to have high affinity for D4³⁷⁷⁶, 5-HT6 and 5-HT7 receptors, to have strong actions at alpha-1 (postsynaptic) and alpha-2 receptors. 5-HT antagonism may be relevant to clozapine's efficacy against positive symptoms³⁷⁷⁷,(Jones ea, 1998) although one small SPECT study failed to find any relationship between 5-HT2A receptor blockade by either clozapine or risperidone and global outcome in schizophrenia.(Travis ea, 1998) Interestingly, monotherapy with a HT2A receptor blocking drug (e.g. M-100907) does not seem to be effective in schizophrenia.(Miyamoto ea, 2003, p. 452) When the potent alpha-2 antagonist idazoxan is added to fluphenazine it may improve the therapeutic activity of the latter drug, which suggests that one cannot rule out alpha-2 antagonism as a possible antipsychotic mechanism for clozapine. SPECT has shown future clozapine responders to have a relatively high perfusion of the thalamus, left basal ganglia and right prefrontal regions whilst on prior neuroleptic treatment, subcortical perfusion decreasing when a good response was achieved to clozapine. Prepulse inhibition is reduced in schizophrenia.³⁷⁷⁸ Clozapine appears to normalise prepulse inhibition to a greater degree than do conventional antipsychotics in schizophrenia. Clozapine may be more efficacious than typical antipsychotic drugs in

³⁷⁷¹ It binds loosely to D2 receptors.

³⁷⁷² Use low doses: start with 12.5 mg/day and increase slowly in Parkinson's disease, the maximum dose being 100 mg/day, although the usual effective dose is usually 25-37.5 mg/day.

³⁷⁷³ Nicotine patches do not affect clozapine levels. Starting to smoke leads to a fall in clozapine levels, as when patients leave smoke-free inpatient units. The effect from nicotine and cannabis cigarettes on clozapine levels may be due to hydrocarbons.(Flanagan, 2007)

³⁷⁷⁴ Low D2 occupancy in basal ganglia may explain low EPS; D2 and D3 blockade in temporal cortex is similar to typical drugs;(Pilowsky ea, 1997) but PET data suggests low D2 occupancy in both striatum and extrastriatal regions.(Talvik ea, 2001)

³⁷⁷⁵ Homozygosity of C102 allele in coding region of 5-HT2A gene on chromosome 13q was at first considered more common in non-responders but further work found no relation between allelic variation in this gene and response to clozapine.

³⁷⁷⁶ Whether this explains its antipsychotic action is doubtful because the distribution of alleles for the D4 gene does not distinguish responders from non-responders.(see Shaikh ea, 1993) High dose chlorpromazine also blocks 5-HT2A receptors.(Trichard ea, 1998)

³⁷⁷⁷ Blunted prolactin response to d-fenfluramine at 20 months correlated with reduction in positive symptoms.

³⁷⁷⁸ Prepulse inhibition means a reduction in response to a strong startle stimulus if this is preceded by [30-50 msec] a prestimulus or prepulse that is too weak to cause a measurable startle response itself; prepulse inhibition is regulated by forebrain cortico-striato-pallido-thalamic-mediated plasticity (gating) of the startle response. The results of a study (Perry ea, 2002) suggested that prepulse inhibition is abnormal in acute psychotic schizophrenia independent of medication status.

reducing comorbid substance abuse in schizophrenia: 50% of schizophrenics abuse substances at some time (e.g. cocaine), often as self-treatment.(Buckley, 1998) The plasma half-life of clozapine is 6-26 hours (mean = 12 hours)³⁷⁷⁹. It is subject to first-pass metabolism. The absolute bioavailability is 50-60%. 95% is bound to plasma protein. Inactive metabolites are excreted in urine (50%) and faeces (30%). It may compete with warfarin for protein binding sites. Clozapine does not induce catalepsy or block stereotypies induced by DA agonists, or, after chronic treatment, produce DA receptor supersensitivity. Clozapine can cause neutropaenia and agranulocytosis³⁷⁸⁰, especially during the first 6 months of therapy³⁷⁸¹, in the elderly, and in females. Asians may be at increased risk of agranulocytosis. Granulocyte colony-stimulating factor may normalise clozapine-induced neutropaenia. Clozapine's anticholinergic effects may potentially compromise cognitive function in some patients (Goldberg *et al*, 1993) although it is suggested also that clozapine ameliorates cognitive dysfunction, especially attentional and verbal fluidity problems, in schizophrenia.

Treatment is initiated and monitored in co-operation with the manufacturers (Clozaril Patient Monitoring Service - CPMS).³⁷⁸² Monitoring is less in some countries than others.(e.g. Tharyan, 1998) Clozapine should not be given if there is a history of agranulocytosis and it should not be combined with other drugs capable of inducing agranulocytosis³⁷⁸³, e.g. carbamazepine, propylthiouracil, captopril, or sulphonamides (with the exception of previous chemotherapy). The use of depot antipsychotic drugs is discouraged. The cumulative incidence of agranulocytosis during one year of exposure is 0.8%. Fatal agranulocytosis occurs in 0.01% of patients monitored by the CPMS and in 0.3% of those not monitored. According to Atkin *et al*,(1996) after 4.5 years (n = 6,316 patients in UK and Ireland) 2.9% of patients developed neutropaenia and, again, 0.8% had developed agranulocytosis. The first 6-18 weeks of treatment contained the peak incidence of both disorders. Fatal agranulocytosis occurred in 0.03% of patients, the incidence of agranulocytosis showing a decrease to that noted with some phenothiazines. Figures from the CPMS in February 2003 showed an incidence of agranulocytosis per 1000,000 person-weeks of observation of 32.0, 2.3 and 1.8 for weeks 0-18, 19-52 and 53 onwards respectively. Rosenheck *et al* (1997) reported that 3 out of 205 patients on clozapine developed agranulocytosis, all showing full recovery. Mild/moderate neutropaenia (500-1500 neutrophils/cu mm) rapidly reverses on cessation of clozapine. Severe neutropaenia (less than 500 neutrophils/cu mm), mild asymptomatic eosinophilia, chronic leucocytosis (sometimes with low-grade pyrexia), and severe lymphopaenia (with/without fever and diarrhoea) may also occur. Clozapine should be stopped immediately if the WCC (WBC) is below 3000/cu mm or the absolute neutrophil count (ANC) is below 1500/cu mm. If the WCC is 3000-3500 or the ANC is 1500-2000 the clozapine is continued with twice weekly blood sampling until the counts stabilise or increase. Values of at least 3500 and 2000 for WCC and ANC respectively indicate that clozapine therapy can continue. Clozaril should be discontinued if the eosinophil count rises over 3000/cu mm, and only restarted after it falls below 1000. The same applies if the platelet count falls below 50000/cu mm.

In the UK and Ireland, a WCC (white cell count) with differential count is done weekly for 18 weeks, two-weekly for weeks 18-52, and thereafter every 4 weeks. Monitoring should continue for at least 4 weeks after stopping clozapine. In the US, weekly WBC (white blood cell count) and ANC (absolute neutrophil count) are required for the first 6

³⁷⁷⁹ The main metabolite is norclozapine, which appears to be active and to have a longer half-life than clozapine. The clozapine/norclozapine ratio is important. Norclozapine levels are less prone to fluctuation and give a better idea of compliance.

³⁷⁸⁰ Agranulocytosis in 1% of cases.

³⁷⁸¹ A number of experts question the need for continued white cell monitoring beyond that point.

³⁷⁸² The clozapine generic preparation **denzapine** (Merz Pharma) became available in 2010. A web-based Denzapine Monitoring System (DMS) allows secure access to patients' blood monitoring and dispensing history and support from trained staff including an on-call haematologist.

³⁷⁸³ Ghaznavi *et al* (2008) argue that causes of neutropaenia other than clozapine should be sought and that consideration should be given to tapering the (assumed) offending drug first before stopping clozapine.

months (and for 4 weeks after stopping clozapine), every 2 weeks from 6-12 months, and every 4 weeks thereafter.

Re-challenge with clozapine following significant leucopaenia or neutropaenia is contraindicated. However, it has been done. Dunk ea (2006) re-challenged 56 patients. 20 experienced further blood dyscrasia of whom 20 experienced a more severe dyscrasia and in 12 it was of longer duration. In 17 of the 20 experiencing dyscrasia haematological problems occurred more quickly than had on first exposure to the drug. The authors concluded that re-challenge may be justified in some cases. Of course, potential benefits would have to be greater than the risks of re-challenge and wide consultation would be mandatory.

Some side effects of clozapine³⁷⁸⁴

Sedation³⁷⁸⁵

Ptyalism (especially nocturnal),³⁷⁸⁶ dry mouth, nausea, vomiting, weight increase (with risk of diabetes)³⁷⁸⁷

Increases in liver enzymes, cholestasis, hypertriglyceridaemia, obesity, hypertension (e.g. Feeney ea, 2007)

Dizziness

Constipation³⁷⁸⁸

Tachycardia,³⁷⁸⁹ cardiac arrhythmias, prolongation of the QT interval,(Cohen ea, 2001) heart block, pericarditis, myocarditis,³⁷⁹⁰ thromboembolism (*keep the patient mobile*) (O'Lunaigh & Scully, 2006)

Postural hypotension (see below), hypertension

Respiratory depression

Transient pyrexia³⁷⁹¹

Skin rashes

Tremor, akathisia, rigidity, seizures³⁷⁹²

Stuttering (Hallahan ea, 2007)³⁷⁹³

Urinary incontinence

Clozapine should not be given to people with (rare) inherited problems of galactose intolerance. Uncontrolled epilepsy is a contraindication to clozapine therapy, as are severe liver dysfunction or paralytic ileus. Orthostatic hypotension, excess sedation or confusion should prompt a limitation/deferment of dose increases; for very severe cases of postural hypotension, moclobemide and Bovril have been used (Goldberg, 1997) but do not use adrenaline because clozapine's (and other antipsychotics with similar actions) anti-adrenergic effect may lead to a reverse effect from adrenaline with a further fall in blood pressure.

The risk of myocarditis³⁷⁹⁴ is greatest in the first 6-8 weeks of treatment. If the diagnosis is confirmed, re-challenge with clozapine is contraindicated.

³⁷⁸⁴ Different protocols suggest monitoring different things and at different frequencies, e.g. serum troponin during the first 8 weeks and lipids and fasting blood glucose 6-monthly or more frequently.

³⁷⁸⁵ Often for first 4 weeks; made worse by alcohol; may respond to modafinil.

³⁷⁸⁶ Drooling/sialorrhoea/hypersalivation: this is unexpected considering clozapine's anticholinergic activity but may relate to impaired oesophageal motility. Anticholinergic drugs, hyoscine, propantheline, pirenzepine, amisulpride or clonidine are suggested remedies.

³⁷⁸⁷ 36.8% developed diabetes in one five-year follow-up. Lund ea (2001) found no greater risk of diabetes or hyperlipidaemia than with conventional agents, but Newcomer ea (2002) have shown that clozapine is associated with hyperglycaemia.

³⁷⁸⁸ High fibre diet or bulk-forming laxatives may be required.

³⁷⁸⁹ If very severe consider low dose β -blocker.

³⁷⁹⁰ Rare (0.015-0.188%); may be fatal, with eosinophilic infiltration and myocytolysis.(Coulter ea, 2001)

³⁷⁹¹ This usually occurs during the first few weeks of treatment and lasts a few days.

³⁷⁹² Lipid and seizure disorders can occur in clozapine-treated children and adolescents.(Shaw ea, 2006)

³⁷⁹³ Cases have responded to dose reduction and, if related to seizures, sodium valproate.

³⁷⁹⁴ The risk of myocarditis from clozapine is at least 0.015-0.188%, although it has been suggested that up to 66% may have some non-specific findings consistent with this diagnosis.(Merrill ea, 2006) Suspect myocarditis or cardiomyopathy if there is persistent

Pseudophaeochromocytoma³⁷⁹⁵ has been described in a number of cases receiving clozapine therapy. Management includes stopping clozapine. (Prasad & Kennedy, 2003) Seizures are especially common in high dose regimes: one estimate is that 1-2% experience seizures at doses up to 300 mg/day and 5% at 600-900 mg/day and another estimate is that 10% of patients after 3.8 years of clozapine treatment had experienced seizures. Phenytoin can decrease clozapine levels and compromise bone marrow status. The prescriber should use valproate³⁷⁹⁶ or phenobarbitone for seizures when necessary. Clozapine should be withheld for 24 hours after a seizure and restarted at a lower dose. Clozapine may potentiate the effects of alcohol, BZDs³⁷⁹⁷ and other central depressants, MAOIs and hypotensive drugs. Combination with BZDs, not uncommon in practice, may cause excess sedation, loss of consciousness, respiratory distress, and lability of blood pressure; the advice is to titrate doses slowly. (Chong & Remington, 2000; Travis, 2002) Rebound psychosis (and cholinergic rebound) may follow withdrawal of clozapine: do not interrupt clozapine on admission to a general ward; if it is stopped for over 4 days it should be reintroduced at a low dose and titrated up to the original dose. Prolactin levels remain normal. Pregnancy and breastfeeding are contraindications to clozapine. Contraceptive measures may be needed (if menses return). Careful monitoring is essential in the presence of liver disease. NMS may be more likely if lithium is co-prescribed with clozapine. Do not give clozapine with depot antipsychotics³⁷⁹⁸. Outrule an immunocompromised state before starting clozapine, e.g. TB or HIV. Great care is required in those patients with prostatic enlargement, narrow angle glaucoma or paralytic ileus. Clozapine may exacerbate obsessions and compulsions³⁷⁹⁹.

Overdose³⁸⁰⁰

Mortality c. 12%

Death chiefly from cardiac failure or aspiration pneumonia

MacGillivray *et al* (2003) conducted a retrospective study of 201 people who commenced clozapine therapy between 1990 and 1997. Of these, 45% had discontinued clozapine before 3 years. The latter were more likely to have been relatively elderly at the start of therapy with this drug. Despite the number of potentially serious complications, clozapine may reduce the net mortality rate, possibly by reducing the suicide rate. (Walker *et al*, 1997)

Risperidone³⁸⁰¹ (Risperdal; Quicklet orodispersible tablets in 1 mg and 2 mg strengths; liquid = 1 mg/ml; Risperger, Rispal) is a benzisoxazole derivative with a half-life of four hours. (Edwards, 1994) The metabolite 9-hydroxyrisperidone is active and has a half-life of 22 hours (see paliperidone). The combined active moiety has a half-life of 24 hours. Risperidone is a potent 5-HT₂ and D₂ antagonist (PET suggests equal D₂ occupancy as for low dose typical and risperidone has a low dissociation constant for D₂ receptors, i.e. it sticks tenaciously to the receptor) that is devoid of central anti-Ach activity. EPS is only important at higher doses. (e.g. Marder *et al*, 2003) A single dose of risperidone reduces glucose metabolism in the ventral striatum, thalamus and frontal cortex, and the

tachycardia at rest, palpitations, arrhythmias, chest pain, other signs of heart failure, or symptoms suggestive of myocardial infarction. Such patients should stop taking clozapine and see a cardiologist.

³⁷⁹⁵ Hypertension, tachycardia and elevated 24-hour urinary catecholamines.

³⁷⁹⁶ Which can increase clozapine levels.

³⁷⁹⁷ Probably safe in most cases once stable clozapine dosage is achieved.

³⁷⁹⁸ Increased risk of neutropaenia.

³⁷⁹⁹ This may be a result of antagonism at 5-HT₂ receptors or it may be associated with sequence variations in the glutamate transporter gene SLC1A1. (Kwon *et al*, 2009) SSRIs are usually effective.

³⁸⁰⁰ Overdose leads to a drowsy, lethargic, areflexic or hyperreflexic, confused, hallucinated, agitated, delirious state. There may be coma. Extrapyramidal signs, seizures, hypersalivation, big pupils, cycloplegia, labile temperature, hypotension, tachycardia, cardiac arrhythmia, and dyspnoea may be found. Management involves gastric lavage with or without activated charcoal if the time since ingestion is less than six hours. Avoid adrenaline. Treat symptoms and monitor organ function and electrolyte levels and acid-base balance. Delayed reactions should be considered during the first week.

³⁸⁰¹ Like haloperidol, risperidone was synthesised by Paul Janssen.

degree of reduced metabolism in the left hippocampus may predict amelioration of positive symptoms. It lacks disturbing levels of sedation. Working memory may be improved in risperidone-treated schizophrenic patients compared to those patients receiving haloperidol or, according to Bilder *et al.* (2002) even clozapine. There is evidence from a double-blind multicentre prospective trial that risperidone is superior to haloperidol in reducing the risk of relapse in clinically stable outpatient schizophrenic and schizoaffective patients. (Csernansky *et al.*, 2002) Risperidone has α -1 and α -2 adrenergic and histamine receptor blocking actions. Metabolism is via hydroxylation and N-dealkylation. Peak plasma concentration is reached in 1-2 hours. 88% is plasma protein bound, as is 77% of its metabolite. Steady state serum levels are reached within 5 days. Prolactin levels are increased. It has been suggested that raising the prolactin level (as a measure of DA blockade) up to about 20 may allow maximum antipsychotic effect with minimum EPS. (Williams, 1999) Initial hyperprolactinaemia in children tends to decrease over time. (James & McClellan, 2008, p. 824) Concentrations of risperidone in breast milk are similar to those in serum but placental transfer is limited. Risperidone is excreted in faeces and urine. The starting dose is 0.5-1 mg bid, the lower dose being appropriate in the elderly or in people with renal or hepatic disease. Doses over 5 mgs bid probably give no increase in efficacy, and the optimal dose may be c 6 mg/day.³⁸⁰² EPS becomes more likely as dose increases. The liquid form contains 1 mg/ml.

Potential side effects

Anxiety, headache, somnolence (or insomnia), fatigue, dizziness, poor concentration
Constipation, indigestion, nausea, abdominal pain
Diplopia
Erectile and ejaculatory dysfunction, orgasmic difficulties
Rhinitis
Skin rash
EPS (incl. dystonia)
Orthostatic hypotension with reflex tachycardia
Galactorrhoea, amenorrhoea
Weight gain (Sernyak *et al.* [2002] report a risk of diabetes in younger patients – cf. olanzapine next)
Water intoxication (hyponatraemia)
Seizures
Nose bleeds, +/- thrombocytopaenia (Harrison-Woolrych & Clark, 2004)
Overdose: sedation, tachycardia, hypotension and EPS

Olfson *et al.* (2006) but not Koro *et al.* (2002) reported an increased risk for hyperlipidaemia in patients on risperidone. TD may be less likely than with typical drugs³⁸⁰³ and NMS appears to be very rare. (Kane, 1994) However, TD has been described in patients on risperidone. Transient hypertension could follow abrupt withdrawal of risperidone, possibly due to withdrawal of its α -1 blocking effect. Randomised trials in elderly demented patients suggest a threefold increase in cerebrovascular adverse events (3.3% v 1.2% in risperidone- and placebo-treated cases respectively). Patients should be monitored for any evidence of such events and consideration should be given to stopping the drug if necessary. This risk may be higher for patients with a past history of CVA/TIA, hypertension or cardiovascular disease. Of note is the finding of a systematic review of risperidone and olanzapine in demented patients (Lee *et al.*, 2004) that found adverse events to be common, i.e. EPS, somnolence, and gait abnormality. The trials

³⁸⁰² 4-8 mg dose range: bell-shaped dose-response curve. Perhaps the optimal D2/5-HT_{2A} blocking ratio occurs in the 6-8 mg/day range. 4 mg/day has also been recommended as the ideal dose because it is associated with 70-80% D₂ occupancy.

³⁸⁰³ There is some evidence that it may actually improve severe TD. (Chouinard *et al.*, 1993)

looked at were too short to pick up impaired glucose metabolism or hyperlipidaemia. CVA/TIA was not reported, possibly for the same reason.

Risperidone depot (Risperdal Consta – 25 mg, 37.5 mg, 50 mg) consists of risperidone microspheres (Medisorb) that gradually release medication. A SmartSite Vial Access Device offers needle-free access to the vial of microspheres, thus eliminating the original need for 3 needles. It is recommended that the drug be administered orally for three weeks *until therapeutic levels of the long-acting drug are achieved*, after which attempts are made to withdraw oral risperidone. However, oral supplementation may take longer in practice³⁸⁰⁴. (Paton & Okocha, 2004) The injection is then given every 2 weeks. (Imperio, 2001) The initial dose is 25 mg IM (*gluteal or deltoid*) two-weekly. 37.5 mg might be considered if the patient has been stable on over 4 mg per day. An increase in the initial dose of 12.5 mg can be considered after 4 weeks elapse (in fact 4 weeks interval is suggested between all dose increases). The maximum dose is 50 mg every 2 weeks. One naturalistic study of 50 patients found an attrition rate of 42% at six months. (Paton & Okocha, 2004) A randomised, controlled, open-label study (Keks ea, 2007) found depot risperidone and oral olanzapine to be equally efficacious. According to Turner ea (2004) a stable patient's conventional depot antipsychotic drug can be changed directly to Risperdal Consta without an intervening period on oral risperidone³⁸⁰⁵.

Paliperidone (Invega extended-release tablets³⁸⁰⁶) is the active metabolite of risperidone (9-hydroxyrisperidone). There is no need for dose titration³⁸⁰⁷. There is minimal hepatic metabolism of the drug. The drug occupies central D2³⁸⁰⁸ and 5-HT2A receptors³⁸⁰⁹. It may have an early onset of action. It is suggested that one-third of its effects on negative symptoms is attributable to a direct drug effect. It improves personal and social functioning and may have a relatively early therapeutic effect. (Canuso ea, 2009) Paliperidone, which appears to have a good 6-week metabolic profile, (Meyer ea, 2006) may increase prolactin levels³⁸¹⁰ and may cause akathisia and EPS (9 mg or above). There is a modest increase in QTc. NMS has been reported. Orthostatic hypotension and syncope may occur. Weight increase appears not to be a major issue. (Owen, 2007) Paliperidone should be avoided in demented psychotic patients. Caution is advised if there is a history of seizures.

Paliperidone palmitate long-acting injection is undergoing trials.

Olanzapine (Zyprexa oral tablets: 2.5, 5, 7.5, 10 and 15 mg), a thienobenzodiazepine and derivative of the clozapine molecule, is well tolerated relative to other antipsychotics. (Lieberman ea, 2005). It shows affinity for 5-HT2, D1, D2 and muscarinic receptors.³⁸¹¹ It seems less likely than typicals to cause EPS or TD³⁸¹² and much less likely to cause haematological problems than clozapine. It improves depression in schizophrenia more than does haloperidol³⁸¹³, although it was equally efficacious (but

³⁸⁰⁴ Some authorities give oral risperidone until the patient has received the third Consta injection. They also give oral risperidone for 3 or 4 weeks after an increase in Consta dosage. However, Risperdal Consta has been given to patients with schizophrenia or schizoaffective disorder (diagnosed within previous 3 years, symptomatically stable, on same dose of an antipsychotic for at least 1 month, open and non-comparative study) and was well accepted. (Parellada ea, 2005)

³⁸⁰⁵ One possible approach is to give a Risperdal Quicklet on day one and the depot next day if there is no adverse reaction.

³⁸⁰⁶ Uses osmotic-release oral system (OROS) to deliver drug in an extended-release formulation over 24 hours in order to minimise peak-trough fluctuations (once-daily dosing). According to Pani (2008) risperidone or even haloperidol would be improved by using the OROS system, i.e. there would be smoother plasma levels with less likelihood of the drug being in the higher, EPS-inducing range.

³⁸⁰⁷ The usual dose is 6 mg mane.

³⁸⁰⁸ Mean striatal D2 occupancy of 75-78% for a dose of 6 mg: <65% would be sub-therapeutic and >80% would increase risk for EPS.

³⁸⁰⁹ It should be noted that antagonism of 5-HT2A receptors in the striatum is thought to lead to release of dopamine.

³⁸¹⁰ Pani (2008) states that prolactin elevation induced by paliperidone is similar to that caused by risperidone.

³⁸¹¹ PET work suggests that near saturation of 5-HT2 receptors at only 5 mg/day and that D2 occupancy increases with increasing dose; the D2 occupancy is higher than that for clozapine but similar to that of risperidone. PET suggests equal D2 occupancy with olanzapine and risperidone as for low dose typicals.

³⁸¹² 7% got TD on olanzapine and 16.2% got TD on haloperidol after a median of just over 200 days in one study; a review suggested that there is no greater risk of TD than in never-medicated psychosis, i.e. '1% per year'.

³⁸¹³ Or does it cause it less often?

with less adverse effects) with chlorpromazine for treatment-resistant schizophrenia in one study.(Conley ea, 1998) Patients with Parkinson's disease show limited tolerability for olanzapine. Cognitive function may be improved in olanzapine-treated schizophrenic patients, but probably by little more when compared with low doses of haloperidol or with other atypicals.(Keefe ea, 2004; Keefe ea, 2007)

Side effects

Common³⁸¹⁴

Somnolence

Weight gain (with risk of diabetes: Newcomer ea [2002], Koro ea [2002]; caloric intake is increased on olanzapine and schizophrenic patients take little exercise with or without this drug: Gothelf ea [2002]; adding fluoxetine does not help: Poyurovsky ea, [2002]; topiramate [Topamax], 50 mg/day is worth trying [Vieta ea, 2004])

Less common

Dizziness, peripheral oedema, postural hypotension, transient anticholinergic effects³⁸¹⁵, and raised liver transaminases³⁸¹⁶

Koro ea (2002) reported an increased risk for hyperlipidaemia

Rare

Photosensitivity

Elevated CPK

Asymptomatic blood changes

At least one case of priapism

Pancreatitis has been rarely reported, but alcohol probably played a role in those cases

ALT (SGPT) is raised in 2% of treated patients

Falanagan (2007) suggests that the therapeutic plasma level for olanzapine in a 10-16 hour post-dose sample is 23 µg/L. Smoking and carbamazepine induce activity in cytochrome P450 1A2 enzyme, increasing olanzapine metabolism. Clearance of olanzapine is 33% lower in non-smokers than in smokers. Carbamazepine increases olanzapine clearance by 44%. Prolactin increase can occur, but is often transient and asymptomatic. The starting dose is 2.5-10 mg, lower doses being used in the elderly or those with liver or kidney impairment. The usual dose range is 5-20 mg/day.

*Zyprexa VeloTabs*³⁸¹⁷ dissolve in the mouth and are a useful strategy in non-compliant acute cases.

Olanzapine (*Zyprexa IM*: 10 mg Powder for Solution for Injection) is a 'rapid acting intramuscular' preparation for use in the acutely agitated psychotic patient.(Jones, 2001) 10 mg of this is roughly equivalent to 7.5 mg haloperidol in reducing agitation, measured 2 hours after administration. Peak concentration is reached in < 1 hour. The effects last about a day. 2.1 ml of sterile water from a vial or ampoule is injected into a freeze-dried vial containing 11 mg Zyprexa IM. The vial is rotated to dissolve and mix the contents. The required volume is withdrawn to obtain the correct dosage³⁸¹⁸. It should only be given intramuscularly, never IV or SC. It can be given on a maximum of 3 consecutive days. The starting dose is 10 mg (elderly or in people with hepatic or renal impairment = 2.5-5 mg). A second injection of 5-10 mg can be given 2 hours later if necessary. The maximum daily dose is 20 mg (combined oral plus IM). No more than 3 injections should be administered over a 24-hour period. These instructions should be strictly adhered to.

Adverse effects of Zyprexa IM

Somnolence

³⁸¹⁴ It is essential that all known data are released if the frequency of adverse results are to be calculated accurately.(Dyer, 2007)

³⁸¹⁵ E.g. constipation and dry mouth – however, sialorrhoea has also been reported.

³⁸¹⁶ Usually transient and asymptomatic.

³⁸¹⁷ 5, 10, 15 and 20 mg.

³⁸¹⁸ 10 mg = 2 ml, 7.5 mg = 1.5 ml, 5 mg = 1.0 ml.

Dizziness Asthenia Hypotension Postural hypotension Tremor Acute dystonia
--

No significant changes occur in mean QTc duration. Vital signs must be recorded for 2-4 hours after administration. Eight fatalities were reported as of August 31, 2004 (cardiorespiratory arrest, hypotension, and bradycardia). (Lilly, communication of October 1, 2004)

Zyprexa IM should be avoided in patients with unstable medical disorders. **Co-prescription of parenteral benzodiazepines should be avoided if at all possible** (if they are essential they should be given at least one hour after Zyprexa IM).

Olanzapine is 'contraindicated' in elderly patients with dementia-related psychosis and/or behavioural disturbance because of evidence for an association with an increased mortality rate and a greater likelihood of stroke. (Irish Medicines Board, 2004) This is discussed further above.

A true depot preparation of olanzapine, olanzapine palmoate suspension (Zypadhera³⁸¹⁹) (Jones, 2001) and is available. It is given every 2-4 weeks. A rough approximation of dose is got from dividing the dose³⁸²⁰ of injection by the number of days between injections which gives the oral dose/day in mgs. Injection is by deep gluteal injection, making sure a blood vessel has not been entered. Peak plasma levels are reached in 3 days. Weight increase is similar to oral olanzapine. About 1.4% of patients developed a 'post-injection syndrome' (variable in severity, manifestations, and time to occurrence) due to an excessive concentration of olanzapine in blood: sedation, delirium, EPS, dizziness, dysarthria, aggressiveness, raised blood pressure, and seizures. All patients recovered and 70% continued to get the injection. The fact that it may not arise until after a number of injections are administered suggests that faulty injection technique must play some part in its aetiology. (Kane ea, 2010) Treatment is symptomatic. Benzodiazepines may compound sedation when given, for example, for agitation. The patient should not drive or operate machinery on the day of the injection and should be observed for 3 hours after receiving the depot.

Quetiapine fumarate³⁸²¹ (Seroquel) has a greater affinity for 5-HT₂ than D₂ receptors. Both clozapine and quetiapine are loosely bound to the D₂ receptor (compared with typical drugs like haloperidol) and are rapidly displaced by endogenous DA. It causes EPS at the placebo level and does not cause any 'sustained' hyperprolactinaemia (but see Chaudhry ea, 2008) or significant haematological problems. The half-life is 7 hours and 83% is bound to plasma protein. The starting dose is 50 mg/day, half that in the elderly. Seroquel is given twice daily. The optimum dose is probably > 250 mg/day. The starting dose is 50 mg/day and the maximum dose is 800 mg/day³⁸²². *Seroquel XR* (prolonged release: Kahn ea, 2007) is given once daily with 300 mg on day one and 600 mg on day two. The dose range is 400-800 mg/day. However, there may be little difference in outcome 300-400 mg/day and 750-800 mg/day in terms of response rate, change in positive symptoms, and discontinuation due to ineffectiveness or adverse effects. (Painuly, 2010)

³⁸¹⁹ ZypAdhera ®.

³⁸²⁰ Doses in mgs: oral olanzapine 10, 15, and 20/day = ZypAdhera starting dose 210/2 weeks (or 405/4 weeks), 300/2 weeks, and 300/2 weeks respectively = maintenance dose after 2 months of ZypAdhera treatment 150/2 weeks (or 300/4 weeks), 210/2 weeks (or 405/4 weeks), and 300/2 weeks respectively; depending on clinical situation dose may be adjusted within range 150-300/2 weeks or 300-405/4 weeks.

³⁸²¹ A dibenzothiazepine and a derivative of clozapine.

³⁸²² There is a 300 mg tablet.

Caution is required in the presence of hepatic impairment³⁸²³, cardiovascular disease, hypotensive states, a history of seizures, drugs prolonging the QTc interval, and co-administration of hepatic enzyme inducers or inhibitors. Smoking does not affect quetiapine levels.

Side effects

Somnolence
Dizziness
Postural hypotension
Tachycardia
Syncope
Dry mouth
Indigestion
Constipation
Weight gain³⁸²⁴
Asthenia
Rhinitis
Seizures (uncommon)
NMS (rare)
Transient leucopaenia and eosinophilia
Increased transaminases and gamma-GT levels (asymptomatic and transient)

The possibility of changes in the lens of the eye occurring with longterm use has been raised but there is little evidence to support this.³⁸²⁵ Quetiapine may be useful in Parkinson's disease with psychosis and in Lewy body dementia,(Goldstein, 2000; Hellewell, 2002) but Ballard ea (2005) found that neither quetiapine or rivastigmine were effective in treating agitation in Alzheimer patients³⁸²⁶ and, relative to placebo, quetiapine was associated with significantly greater cognitive decline.

Sertindole (Serdolect)

This atypical drug was withdrawn in 1998 due to QT prolongation.(O'Shea, 1998) It became available again in 2007 as a once-daily treatment for schizophrenia intolerant to at least one other antipsychotic drug³⁸²⁷. It is said to be limbic selective and to selectively inhibit mesolimbic DA neurones and to have balanced inhibitory actions on central D2, 5-HT2 and alpha1 adrenergic receptors. It may be particularly useful for negative (as well as positive) symptoms.(Azorin ea, 2006) Contraindications include hypokalaemia, hypomagnesaemia, history of significant cardiovascular disease, CCF, cardiac hypertrophy/arrhythmia/rate less than 50/minute, personal/family history of congenital long QT syndrome, QTc over 450 msec in males or 470 msec in females, severe liver impairment, pregnancy, and lactation. Placebo level EPS is claimed. Weight gain over 12 months is about 3 Kg. Sedation is not a problem.

Some adverse effects of sertindole

Nasal inflammation/congestion
Reduced volume of ejaculate
Dizziness, postural hypotension
Peripheral oedema
Dyspnoea
Paraesthesiae

³⁸²³ Metabolised by P450 3A4.

³⁸²⁴ With risk of diabetes.(Sernyak ea, 2002)

³⁸²⁵ Some countries requiring six-monthly slit-lamp examinations.(Gunasekara & Spencer, 1998)

³⁸²⁶ Not surprising for rivastigmine since it itself can cause agitation.

³⁸²⁷ Start with 4 mg once daily increasing every 4-5 days. Dose range = 12-20 mg (max. 24 mg). Go slower in elderly and keep upper dose lower.

Prolonged QTc (be careful not to combine with drugs that do same)
 Urine positive for red and white cells

Amisulpride (Solian), a substituted benzamide, is highly selective for D2 and D3 receptors³⁸²⁸ and has a higher affinity for limbic than striatal DA sites. Protein binding is low at 16% and drug interactions are unlikely. It is claimed that low doses (50-300 mg/day), which may be selective for presynaptic DA autoreceptors, will alleviate negative symptoms of schizophrenia.³⁸²⁹ (Leucht & Peretti, 2002) Higher doses, like standard antipsychotic drugs, also block postsynaptic DA receptors (400-1200 mg/day in divided doses, max 1,200 mg/day). Some workers wonder if amisulpride is more suited to the treatment of mild to moderate cases of schizophrenia than for severe cases, although others report it to be as effective as olanzapine for acute psychotic exacerbations of schizophrenia, and with significantly less effects on body weight. (Martin ea, 2002; Mortimer ea, 2004) There is a low propensity to induce EPS, (Leucht ea, 2002) at least at modest dosage.

Side effects

Insomnia, anxiety, agitation, somnolence
 Gastrointestinal upset, weight increase (less than with risperidone)
 EPS including TD
 Hyperprolactinaemia with galactorrhoea³⁸³⁰
 Hypotension, bradycardia
 Rare: allergies, seizures, and NMS
 Elderly: hypotension and sedation

The dose should be halved if the creatinine clearance³⁸³¹ is 30-60 ml/min and reduced to a third if it is less than this. Ordinary doses are recommended in the presence of hepatic insufficiency.

Ziprasidone³⁸³² (Geodon) has a high affinity (antagonist) for D2 receptors and an even higher affinity for 5-HT_{2A} receptors. Also interacts with 5-HT_{2C}, 5-HT_{1D} and 5-HT_{1A} receptors³⁸³³. There is moderate affinity for neuronal 5-HT and noradrenaline transporters and for H₁ and α -1 receptors. Ziprasidone inhibits neuronal reuptake of noradrenaline and serotonin. It has negligible affinity for M₁ receptors. Higher doses (e.g. 160 mg/day), as with olanzapine and risperidone, can cause EPS. Somnolence is a relatively common adverse effect. It can prolong the QT interval.³⁸³⁴ If the prolactin level rises it tends to normalise over time. Upper respiratory symptoms and rhinitis may occur.

Contraindications

Hypersensitivity³⁸³⁵

³⁸²⁸ More selective than sulpiride.

³⁸²⁹ But Speller ea(1997) found that low-dose amisulpride was similar to low-dose haloperidol in terms of negative symptom alleviation.

³⁸³⁰ Mortimer (2002) states that amisulpride has little effect on endocrine function.

³⁸³¹ 24-hour collection of urine and a serum creatinine level are required. **Creatine clearance** (a GFR surrogate) = $U \times V/P$ = urine creatinine concentration (U) x rate of urine flow in ml/min (V) ÷ plasma creatinine concentration (P). Normal = 90-140 ml/min (males) and 80-125 ml/min (females). Creatine clearance is an assessment of glomerular filtration rate. The Cockcroft-Gault formula states that creatine clearance = $(140 - \text{age}) \times \text{weight in kg} \times 1.23$ (or 0.85 for females) and divide your answer by creatinine in $\mu\text{mol/L}$.

³⁸³² Development of ziprasidone was slowed by prolongation of the QT interval (risk of tachyarrhythmias) but it became available in the US in 2001 and in Ireland in the following year. Oral (40 mg BID with food, max 80 mg BID, and suggested maintenance at perhaps 20 mg BID; reduce dose for hepatic, but not renal, insufficiency) and IM (as mesylate; to control agitated schizophrenic patient; 10-40 mg/day; can give 10 mg every 2 hours; some cases need 20 mg to start; avoid in elderly because of limited experience; lasts three days) forms are available.

³⁸³³ Affinity at least as strong as for D2 receptor.

³⁸³⁴ Leucht and Peretti (2002) suggest that olanzapine and haloperidol have little effect on the QTc, quetiapine a little more, the risperidone, followed by ziprasidone, with the greatest effect from thioridazine.

³⁸³⁵ As are all drugs.

Known QT prolongation
 Congenital QT syndrome
 Recent MI
 Uncompensated heart failure
 Arrhythmias
 Treatment with certain drugs³⁸³⁶

Schatzberg ea (2005, p. 197) do not routinely do follow-up ECGs on their ziprasidone-treated patients; however, they suggest a baseline and repeat ECG in people with a known history of arrhythmias. Breier ea (2005) found that olanzapine was superior to ziprasidone in terms of reducing psychopathology in schizophrenia, but that ziprasidone caused fewer problems with weight and lipids.³⁸³⁷

Zotepine³⁸³⁸ (e.g. Zoleptil) is structurally related to clozapine. It strongly inhibits noradrenaline reuptake and causes fewer EPS than haloperidol.

Adverse effects

Sedation
 Weight gain
 Increase in liver enzymes (transient)
 Uricosuric activity
 Seizures

Aripiprazole³⁸³⁹ (Abilify): This new antipsychotic quinolinone/dihydrocarbostyryl appears to show high affinity partial agonism at presynaptic D2 receptors but antagonism at postsynaptic D2 receptors³⁸⁴⁰. It is said to be a dopamine system stabiliser (DSS) that strikes a balance between too much and too little DA: its partial agonist action in the brain causes activation where dopaminergic tone is low and inhibition where it is too high. PET studies suggest that 60-80% striatal D2 receptor occupancy accounts for antipsychotic activity among DA receptor antagonists, the incidence of EPS increasing as occupancy surpasses 80%. Aripiprazole occupies up to 95% of striatal D2 receptors, but EPS levels are no higher than with placebo, probably a result of weak partial agonism at D2-like DA receptors.(Gründer ea, 2003) This novel partial dopamine agonist action augments the 5-HT1A and 5-HT2 effects of aripiprazole³⁸⁴¹. It is said to reduce negative and cognitive symptoms when given once daily³⁸⁴². Motor side effects are said to be absent. Hyperprolactinaemia is less pronounced than for risperidone.(El-Sayeh ea, 2006) In fact, adding aripiprazole to a haloperidol regimen may normalise prolactin levels and lead to a return of menstruation.(Shim ea, 2007) There is little effect on the QTc.(Potkin ea, 2003; El-Sayeh ea, 2006)

Side effects

Headache

³⁸³⁶ E.g. class IA and III antiarrhythmics, thioridazine, pimozide, cisapride, etc.

³⁸³⁷ According to Simpson ea (2004) ziprasidone may even lead to weight loss and a decrease in triglycerides. In one meta-analysis (Allison ea, 1999) the following weight gain in pounds was put on over 10 weeks with clozapine or olanzapine – 10, risperidone or quetiapine – 5, and ziprasidone – 1.

³⁸³⁸ Zotepine is available in a number of countries. Daily doses are 50-75 mg (starting), 150-300 mg (maintenance), and 300 mg (maximum).

³⁸³⁹ A partial DA and 5-HT agonist. Tablets: 5, 10, 15, 20 and 30 mgs. Orodispersible tablets come as 10 and 15 mgs. Dehydro-aripiprazole, its major metabolite, has similar D2 affinities as has the parent drug and represents 40% of the parent drug exposure in plasma. Bifeprunox (rejected by FDA in 2007) has similar actions to aripiprazole on DA receptors.

³⁸⁴⁰ Aripiprazole has in fact a high affinity for D2/D3 receptors and dissociated very slowly from these receptors leaving them almost saturated for up to a week following the last dose.(Gründer ea, 2008)

³⁸⁴¹ Suggesting a possible tendency to cause akathisia.

³⁸⁴² Start at 15 mg/day, can then increase to a maximum of 30 mg/day after 2 weeks if necessary. Orodispersible tablets, 10 mg and 15 mg available.

Agitation³⁸⁴³
 Dizziness
 Somnolence/insomnia
 Nervousness

Only a small percentage of treated cases put on significant weight. The evidence suggests that aripiprazole has no clinically relevant effect on total cholesterol, triglycerides, HDL and LDL. Plasma levels are increased by ketaconazole (inhibits CYP 3A4), quinidine (inhibits CYP 2D6), and carbamazepine (induces CYP 3A4). Orthostatic hypotension may occur due to alpha-1 antagonism. Use in pregnancy depends on the results of a risk-benefit analysis. Because of lack of data, women taking this drug should not breast feed. It is **not** approved for the treatment of dementia-related psychosis and/or behavioural disturbances because of the danger of cerebrovascular adverse events.

An injectable form of aripiprazole will be available in Ireland soon. (Andrezina ea, 2006)

Iloperidone³⁸⁴⁴ (Zomaril): This new atypical agent, which has yet to be launched (including a depot preparation), is a benzisoxazole derivative and therefore related to risperidone. Iloperidone is described as a broad spectrum DA/5-HT/noradrenaline receptor antagonist with low EPS/weight gain/sedation potential and no detected increase in prolactin. There may be a small dose-dependent effect on QTc.

Sudden death

Postmortem examination is usually negative. Reilly ea (2000) found abnormal QT³⁸⁴⁵ dispersion (and T wave abnormalities) to relate more to lithium therapy than to antipsychotic drugs, whereas antipsychotics, especially thioridazine and droperidol, were associated more with QTc prolongation! Thioridazine more than other antipsychotic drugs, and low potency (like thioridazine) more than high potency (such as haloperidol) have been associated with reports of sudden, unexplained death. (e.g. Mehtonen ea, 1991; Reilly ea, 2002) Reported incidence-rate ratios for sudden cardiac death among users of high-dose antipsychotics (compared to non-users) have varied from 1.72 (haloperidol) to 5.05 (for thioridazine). (Schneeweiss & Avorn, 2009) Drugs such as thioridazine and pimozide (acts as a calcium channel blocker) should be avoided in those patients with a prolonged QT interval or a history of cardiac arrhythmia. In doses > 10 mg/day pimozide causes marked prolongation of the QT interval, and in doses > 20 mg/day it is associated with an increased risk of developing seizures. Glassman and Bigger (2001) reviewed the evidence for sudden death and *torsade de pointes* and found documented reports incriminating pimozide, sertindole, droperidol and haloperidol, with the highest risk associated with thioridazine. There was no evidence implicating risperidone, olanzapine, or quetiapine. Ziprasidone does prolong the QT interval but there was no documented evidence of sudden death or *torsade de pointes* to date.

Dangers of high doses of antipsychotic drugs

Sudden death (hypotension due to peripheral noradrenergic receptor antagonism, and cardiac arrhythmias due to actions at sodium and calcium channels)
Severe EPS (espc. Parkinsonism and akathisia)

³⁸⁴³ Agitation was the commonest reason for discontinuing aripiprazole in a retrospective study of 85 patients. (Shajahan, 2008)

³⁸⁴⁴ According to Miyamoto ea, (2002, p. 778) and compared with clozapine, iloperidone has relatively high affinity for D₁, 5-HT_{2C}, 5-HT₆, 5-HT₇, α₂, and H₁ receptors, and relatively low affinity for D₂, D₃, D₄, 5-HT_{1A}, 5-HT_{2A}, and α₁ receptors.

³⁸⁴⁵ The QT interval is measured from the beginning of the QRS complex to the point where the T wave meets the isoelectric line, the normal being < 420 msec, and > 500 msec increasing the chances of developing torsades de pointes. The QTc is the QT interval (time taken for cardiac electrical system to repolarise) corrected for heart rate. Opinion varies as to which is the most relevant measurement: the QTc prolongation or QTc dispersion, the latter representing the difference between the longest and the shortest QTc interval on the 12-lead ECG.

NMS (possibly related more to rate of dose escalation rather than dose size *per se*)
 Paradoxical deterioration in behaviour
Confusion (high doses of drugs with atropinic effects, e.g. thioridazine)

Regular ECGs have been recommended for patients on high doses of antipsychotic drugs. This may be more readily achievable in some centres than in others.

Schizophrenic patients on antipsychotic drugs who undertake exercise find it harder to lose body heat than do controls, and this is not explicable on the basis of a difficulty with sweating.

There is some evidence that blood levels of haloperidol between 5-30 ng/ml may be therapeutic but that higher levels may be associated with a poorer clinical response. It is important to remember that sudden death in psychiatric patients may be nothing to do with treatment. (Janicak *et al*, 1997; Hennessy *et al*, 2002)

Ray *et al* (2009) looked at risk of sudden death in current Medicaid users of antipsychotic drugs in Tennessee and found that both typical and atypical drugs had a similar dose-related increased risk for this outcome. Adjusted incidence-rate ratios for typical and atypical drugs were 1.99 and 2.26 respectively.

Sudden death in psychiatric patients

Suicide

Natural causes (e.g. cardiovascular disease)

Accidents

Treatment, especially higher doses

Lifestyle factors are important here. (Ruschena *et al*, 1998; Albert *et al*, 2000) Special consideration should be given to patients with known cardiovascular disease. (Ray *et al*, 2001) Some practitioners were sceptical about the decision of the British Committee on the Safety of Medicines in 2000 to restrict the use of thioridazine believing it safer than aspirin, too cheap to be profitable, and only rarely toxic; they also pointed to the not inconsiderable distress caused to patients who have had to stop taking it after many years. (e.g. Bisset, 2002) Others pointed to the need for caution in reducing or withdrawing thioridazine in special populations, e.g. adverse effects such as re-emergence of psychosis and behavioural problems in the intellectually disabled. (Matthews & Weston, 2003) In fact, the main problem with thioridazine was probably excessive dosage, i.e. 600 mg or more per day. (Hennessy *et al*, 2002)

Tetrabenazine (Nitoman)

This drug is mentioned here for convenience. Tetrabenazine is used to treat abnormal movement disorders like Huntington's disease and TD. It depletes neuronal stores of biogenic amines, including DA. Its actions resemble but are less pronounced than those of reserpine. The starting dose is 25 mg/day, increasing to 25 mg tid, the maximum dose being 200 mg/day. It can cause drowsiness, indigestion, hypotension, and Parkinsonism at high doses. If the patient becomes depressed a MARI can be added. MAOIs should be avoided because a confusional state may ensue.

Some anticholinergic-antiparkinsonian drugs

This section deals briefly with aspects of these drugs of special relevance to psychiatry. (O'Shea, 1998) It is not always possible to avoid giving anticholinergic drugs, e.g. a dystonic reaction could be dangerous in a patient in spinal traction. Interestingly, one Missouri-based study found poor compliance with these drugs! (Goad & Ezell, 1990) The available anticholinergic drugs³⁸⁴⁶ are biperiden (Akineton and Akineton Retard, PO)

³⁸⁴⁶ Orphenadrine, which could cause fits and cardiac arrhythmias, was removed from the market. (Buckley & McManus, 1998) Benzhexol (trihexyphenidyl) disappeared from *MIMS Ireland* in 2002 and benztropine (benzatropine) in 2003.

and procyclidine (Kemadrin, PO or IV; the initial recommended IV dose for Kemadrin [10 mg/2 ml] is 2.5 mg).

Side effects of anticholinergic drugs

Blurred vision
Constipation
Dry mouth (oral hygiene is essential)
Reduced sweating (hot/dry skin, risk of heat stroke)
Delayed or retrograde ejaculation
Memory problems
Delirium
Mydriasis
Exacerbation of asthma or narrow-angle glaucoma
Pyrexia
Photophobia
Sinus tachycardia
Urinary retention
Delayed gastric emptying³⁸⁴⁷

Anticholinergic drugs do have street value as drugs of abuse because of their euphoriant effect. They can be lethal in overdose and can impair learning in young people. (Owens, 2000)

Diphenhydramine (Benadryl; 25-50 mg thrice daily) an H1-blocker, has also been used as a treatment for drug-induced Parkinsonism. It is not a first line treatment. One advantage may be its relative lack of anticholinergic effects (less chance of delirium).

Amantadine³⁸⁴⁸ (Symmetrel - removed from Irish market in 2008.), 100 mg bid to start, potentiates DA release in the basal ganglia and potentiates amphetamine.

³⁸⁴⁷ Reduced absorption of drugs like L-DOPA and antipsychotic drugs because of gut motility changes and possibly because of increased hepatic metabolism of antipsychotic drugs – therefore anticholinergic drugs reduce plasma antipsychotic drug levels and antipsychotic action is diminished.

³⁸⁴⁸ The adamantane amantadine, a synthetic symmetrical amine and relation of memantine, is active against influenza A but not B. **Side effects of amantadine:** nausea (gastric irritation), dizziness (orthostatic hypotension), insomnia, poor concentration (although memory, especially visual memory, may be less affected than with anticholinergic drugs – may be suitable for elderly patients), irritability, depression, anxiety, ataxia, seizures, ankle oedema, livedo reticularis, visual hallucinations (rare). Owens (2000) is sceptical about the longevity of action of amantadine and suggests that it can cause dyskinesia in the longterm. Overdose can lead to toxic psychosis and cardiopulmonary arrest.

Tranquillising and Beta-blocking Drugs, and Emergencies

Brian O'Shea

'And you will give yourself peace if you perform each act as if it were your last'. Marcus Aurelius (121-80).

Tranquillisers

Benzodiazepines (BZDs)

It is interesting to note, as pointed out by Ling et al (2003, p. 907), that people do not usually find the subjective effects of sedative-hypnotic drugs to have appeal, unless they are 'predisposed to addiction'. Most BZDs are variations on the basic 1,4 benzodiazepine structure, a 7-membered ring of carbon and nitrogen atoms. These drugs bind to postsynaptic sites at GABAergic synapses (see box). The latter are especially plentiful in the limbic system, cerebral cortex, cerebellum and spinal cord. BZDs potentiate GABA's inhibitory effect by increasing neuronal permeability to chloride ions, thus making the cell more difficult to excite. Chlordiazepoxide (Librium) and diazepam (Valium – a 2-ketobenzodiazepine) were the first members of this class to be introduced.³⁸⁴⁹ They are very effective, probably as much as were the barbiturates and the propanediols (e.g. meprobamate). Many experts (e.g. Williams and McBride, 1998) counsel practitioners against withholding BZDs from patients with psychiatric illness or withdrawing them from non-problematic longterm users³⁸⁵⁰. Their main indication is for severe anxiety states regardless of aetiology. Diazepam is one of the most widely used, and probably overused, drugs on this planet³⁸⁵¹. There may be a too ready tendency to commence patients on BZDs in general and psychiatric hospitals and units, and such prescriptions may not be reviewed and reasons for prescribing them may not be recorded³⁸⁵² (e.g. Hallahan et al, 2008; Finnerty, 2009) and many such patients remain on these drugs after discharge (Surendrakumar et al, 1992; Anonymous, 1992). They are relatively safe in overdose. Tolerance to the sedative effects of BZDs often develops but this is disputed for the anxiolytic effects (e.g. Lader, 2000).

Benzodiazepines

(a) Receptors and tolerance

BZDs, barbiturates and barbiturate-like substances all have their primary effects on the GABA_A receptor complex, which contains a chloride ion channel, a binding site for GABA, and a BZD binding site (alpha-1 to -5 subunits). There is an influx of chloride ions when GABA binds to its receptor. BZDs, barbiturates and barbiturate-like substances increase the affinity of the receptor for GABA, the result being hyperpolarisation (i.e. inhibitory). During longterm BZD intake GABA causes less chloride influx (perhaps the basis of tolerance), i.e. the receptor is down-regulated.)

³⁸⁴⁹ Their active metabolites are desmethyldiazepam (half-life = 30-200 hours) and desmethyldiazepam (half-life = 28-100 hours) respectively.

³⁸⁵⁰ The short-acting, high-potency BZDs like alprazolam often need a very gradual taper, even stretching to months (e.g. in patients taking alprazolam for more than 2-3 months the dose may be reduced by about 10%/week – if the patient was on 4 mg/day reduce dose by 0.5 mg/week over a period of 8 weeks). Alternatively, alprazolam can be switched to clonazepam which may then be tapered over weeks (0.5 mg clonazepam = 1 mg alprazolam).

³⁸⁵¹ Diazepam was probably the subject of the Rolling Stones' 'Mother's Little Helper'.

³⁸⁵² Similar considerations apply to non-BZD hypnotics (Finnerty, 2009).

BZDs also act at adenosine receptors and at mitochondrial outer membrane. In the later case they may be involved in cholesterol transportation into the mitochondrion and the genesis of neurosteroids.

(b) Classification of benzodiazepines (according to substitution on diazepine ring)

2-keto – chlordiazepoxide, diazepam, flurazepam, chlorazepate, prazepam, halezepam

3-hydroxy – oxazepam, lorazepam, temazepam

Triazolo – alprazolam, triazolam, estazolam

Imidazo – midazolam

2-thione - quazepam

BZDs seem to affect the limbic system (the centre of emotion) by increasing the effects of GABA, the chief inhibitory neurotransmitter in the brain. They have more effect on the reticular and limbic systems and less effect on the cortex than does the barbiturates.

In 1977, specific high-affinity binding sites for BZDs were reported in the brain. Such sites are believed to be the primary site of action of BZDs and are found on the same protein as GABA receptors. The search for endogenous ligands³⁸⁵³ is still ongoing. Many chemicals from different classes act on the receptors. The receptor can increase or decrease anxiety levels; i.e. it modulates anxiety levels. Agonists or inverse agonists, decreasing and increasing anxiety respectively, act on this receptor. The elimination half-life of diazepam increases from 20 hours in a young adult to 90 hours at 80 years of age. BZDs, being weakly basic, are well absorbed from the duodenum and they undergo first-pass metabolism. BZDs are firstly metabolised by N-dealkylation or aliphatic hydroxylation. This is followed by conjugation via glucuronyl transferases to water-soluble glucuronides that can be excreted in the urine. Omeprazole delays the elimination of diazepam, phenytoin and warfarin.

BZDs are highly lipid soluble. They are highly protein-bound in plasma and widely distributed to the tissues. Some metabolites are active, such as those of temazepam, oxazepam (less sedative in overdose than temazepam), diazepam and chlordiazepoxide. BZDs cause minimal induction of hepatic microsomal enzymes, which means much less drug interactions than was the case with barbiturates. The rate of metabolism and the nature of metabolites determine duration of action. Heavy smoking may reduce the efficacy of BZDs. BZDs rapidly cross the blood-brain barrier.

There is little to choose between members of the BZD group.³⁸⁵⁴ Diazepam has muscle relaxant and anticonvulsant effects. All 1,4 BZDs are sedative, anticonvulsant and muscle relaxing. Some of the newer 1,5 BZDs, like clobazam (Frisium), are less sedative but still have anxiolytic and anticonvulsant properties. BZD-induced enhancement of GABA function reduced excitability of glutamatergic neurotransmission, accounting for the anticonvulsant action. Clorazepate³⁸⁵⁵ (Tranxene) is a prodrug for N-desmethyldiazepam (nordiazepam), a slowly eliminated metabolite.

A hypnotic is simply a tranquilliser taken whilst going to bed. Flurazepam (marketed as a hypnotic) may be given by day and diazepam (sold as a tranquilliser) by night.

Half-lives (hours) of some BZDs

Diazepam, 20-90

Chlordiazepoxide, 5-30

Nitrazepam, 18-36

Temazepam 4-10

Lorazepam, 5-10

Oxazepam, 5-10

³⁸⁵³ Substances naturally found in the brain, which act in the same way as the exogenous substance under consideration.

³⁸⁵⁴ Examples of BZDs are diazepam (Valium, Diazepam, Atensine), chlordiazepoxide nitrazepam, flurazepam (Dalmane), temazepam (Normison, Tenox, Euhypnos - this and flunitrazepam (Rohypnol; street names include forget-me pill, Mexican Valium, R2, roofies, roofinol, rope, and rophies) have been controlled drugs in Ireland since 1993; addicts had injected liquid capsule contents – intra-arterial temazepam can cause tissue necrosis and rhabdomyolysis), triazolam (banned in UK in 1991 because of concerns over [anterograde] amnesia-induction [of use before minor surgery], rebound anxiety, aggression, excitation, psychosis, and fatality in overdose), lormetazepam, lorazepam, prazepam, medazepam, potassium chlorazepate, alprazolam, and loprazolam.

³⁸⁵⁵ Chlorazepate (Tranxene), withdrawn 2006.

Triazolam, 2-4

Triazolam, midazolam and brotizolam are short-acting BZDs with half-lives of about 6 hours. Lormetazepam, lorazepam and temazepam are medium-acting with half-lives of 6-12 hours. Long-acting BZDs (half-life > 12 hours) include nitrazepam, flurazepam and flunitrazepam.

Benzodiazepines (by half-life)

<i>Long</i>	<i>Intermediate</i>	<i>Short</i>
Chlordiazepoxide	Alprazolam	Brotizolam
Chlorazepate	Bromazepam	Midazolam
Clobazam	Flunitrazepam	Triazolam
Diazepam	Lorazepam	
Flurazepam*	Lormetazepam	
Ketazolam	Nitrazepam	
Medazepam	Oxazepam	
Przepam	Temazepam	

*The long half-lives of flurazepam and quazepam are a result of their metabolite desalkylflurazepam.

Two forms of diazepam are worth noting: Diazemuls (5-10 mgs – 5 mg/ml) which is given IV or by infusion, and Stesolid (5-10 mgs) which is given rectally. Where available, IV or IM midazolam (Hypnovel amps 10 mg/2 ml) is given in preference to diazepam because of faster absorption and less local pain.(see TREC Collaborative Group, 2003) If diazepam is put into a bag for IV infusion it will crystallise in a dextrose solution but dissolve in normal saline; venous thrombosis and phlebitis may occur at the infusion site.

BZD abstinence syndrome

Hyperacusis
Photophobia
Paraesthesiae
Hypersomnia
Hypersensitivity to touch and pain
GIT disturbances
Headaches
Muscle spasms
Seizures
Vertigo
Sleep disturbance

Certain symptoms suggest true withdrawals rather than an exacerbation or return of the original anxiety: nausea, anorexia, objective depression, depersonalisation or derealisation, hyperacuity of sensory perception (smell, sight, taste, and touch), and abnormal perception or sensation of movement. BZD abuse is not associated frequently with escalating doses. Someone can be deemed to be dependent on BZDs while continuing to consume them in therapeutic doses. Significant withdrawal effects may be more common in patients on BZDs for years and in those with a personality disorder, predominantly of the dependent type. Therapeutic withdrawal may need to be extended to several months in such cases. However, abstinence symptoms may occur after as little as a few weeks taking BZDs and in such cases the dose should be reduced by about an eighth

every fortnight. Some people are helped to withdraw if started on an antidepressant drug some weeks before commencing withdrawal of the BZD.

Typical BZD abuser (relative to opiate abuser) (O'Connor & Stafford-Johnson, 1990)

Older

Female³⁸⁵⁶

Have abused BZDs for many years

Relatively well educated

No legal history

History of being employed or homemaker

Good support from family and spouse

Have abused alcohol prior to abusing tranquillisers

Risk factors for BZD dependence (Livingston, 1994)

Longterm use

High doses

High potency (e.g. lorazepam and alprazolam)

Dependence on alcohol or other substances

Personality disorder

Non-prescription BZD use

Risk factors associated with (Atkinson, 1997)

(a) The drug

Longer treatment duration

Higher dosage

Shorter half-life

High milligram potency

(b) The patient

Past or concurrent alcohol or sedative drug dependence

Chronic insomnia (rather than anxiety) as target of drug therapy

Coexisting chronic painful illness

Personality disorder

Long-term users of daytime BZDs in a general practice (Salinsky and Doré, 1987)

Used age and sex matched controls.

Crown-Crisp index showed revealed a chronic neurotic disposition

Most were women in late middle age or older

79% felt that the treatment was helpful

BZD use seemed to declining rapidly

Authors felt doctors express concern about overuse/misuse of minor tranquillisers

Long term users of BZDs in USA (Salzman, 1990)

Older, medically ill patients

Panic disorder patients

Chronically dysphoric patients

Chronic sleep-disordered patients

Chronically psychotic patients where BZDs were used adjunctively with antipsychotic drugs

A number of authors have suggested that BZD abuse is strongly associated with abuse of other drugs, including alcohol. Intravenous BZD abuse in Britain became a problem from the mid-1980s and the main drugs used were temazepam³⁸⁵⁷, flurazepam, diazepam, triazolam and nitrazepam.

³⁸⁵⁶ Women may be prescribed BZDs more often than are men. (van der Waals et al, 1993)

³⁸⁵⁷ Despite the capsular content being changed from liquid to semisolid gel in 1989. Intra-arterial lorazepam may cause gangrene, muscle necrosis and myoglobinuria.

The risk of a serious road traffic accident is five times greater for BZD users than for non-users.³⁸⁵⁸

Common side effects of BZDs

Taste in mouth

Hangover

Ataxia

Confusion in elderly

Rebound insomnia on withdrawal (withdraw slowly)

Chronic therapeutic dosage with BZDs in elderly may cause

Poor recall

Forgetfulness

Impaired concentration

(Simulating a, usually mild, dementia)

Paradoxical/disinhibitory reactions

Irritability, aggressiveness

Occur in a few patients³⁸⁵⁹

Good practice dictates prescribing on a PRN (*pro re nata*, as required) basis or for a week or two at a time. Seizures may be more likely after withdrawal of short-acting BZDs. They can occur as early as 24 hours after stopping the drug. The prescriber should gradually stop them and consider substituting long-acting BZDs during the withdrawal period.

About two-fifths of regular users of BZDs develop pharmacological dependence and have withdrawal symptoms when the dosage of their drug is reduced or when treatment is stopped. (Tyrer, 1988). Withdrawal symptoms occur within 2-3 days of stopping short-acting BZDs and within 7 days of stopping their longer-acting relatives. They last for one to two weeks. (Owens, 2004, p. 300) Carbamazepine (Tegretol) may reduce the effects of withdrawing benzodiazepines. (O'Shea, 1989) especially if dosage reduction is rapid, although the effect is not marked. Propranolol, a beta-blocking drug, has slight ameliorative effects. A shift from long- to short-acting BZDs may alleviate subsequent abstinence effects. If necessary, BZD dependent patients who are detoxified from these drugs might be helped to stay off them if prescribed trazodone 10 mg tid. (Ansseau & De Roeck, 1993) Lader (1994) recommends a 4-week detoxification period (some people need a much slower detoxification). Shapiro et al (1995) suggest shifting to zopiclone. Voshaar et al (2006) found no benefit for psychotherapy in terms of abstinence rates. Frequent, high doses of alprazolam have been used in the management of panic disorder. It must be withdrawn extremely slowly.³⁸⁶⁰ Perhaps its main use should be in the acute detoxification of alcoholics. Its role as an adjunct in the treatment of depression is probably not unlike that of other benzodiazepines. (O'Shea, 1989)

Pregabalin (Lyrica)

This non-BZD relative of GABA is indicated in adults (only) for anxiety disorders, particularly GAD, (Rickels et al, 2005) peripheral neuropathic pain, and as adjunctive therapy for partial seizures, and perhaps fibromyalgia as well. It appears to be effective and safe in elderly GAD patients. (Montgomery et al, 2008) It binds to a subunit of the

³⁸⁵⁸ The risk is increased with age, taking alcohol, dose, and long half-life drugs.

³⁸⁵⁹ According to Paton (2002) those at highest risk are patients with impulse control problems, neurological disorders, intellectual disabilities, and < 18 years or > 65 years of age.

³⁸⁶⁰ The Van der Kroef reaction (Van der Kroef, 1979) is the collective term used to describe a withdrawal syndrome associated with the abrupt discontinuation of triazolam (Halcion). It consists of depersonalisation, derealisation, paranoid ideation, suicidal thoughts, nightmares, and anxiety. It has also been described in association with alprazolam (Xanax) discontinuation. (Browne & Havge, 1986).

1159

calcium channel³⁸⁶¹ and has other downstream effects. The starting dose is 150mg/day (75 mg bid). The usual dose range is 150-600mg/day³⁸⁶². The medication should be tapered gradually when it is being discontinued. Dosage adjustment is required for renal (and haemodialysis), but not hepatic, impairment. Avoid pregabalin in people with galactose intolerance, the Lapp lactase deficiency or glucose-galactose malabsorption and caution should be observed concerning driving/using machinery. Weight gain in diabetics may require regime change. Pregabalin causes excess sedation if combined with oxycodone and may potentiate the effects of alcohol and benzodiazepines.

Pregabalin

Withdrawal symptoms

Insomnia, nervousness, depression

Headache

Nausea, diarrhoea

Flu-like symptoms

Pain

Sweating

Dizziness

Side effects

Somnolence*

Dizziness*

Euphoria, confusion, irritability, feeling drunk, poor attention, impaired memory, fatigue

Ataxia/abnormal coordination, tremor, dysarthria, paraesthesia

Blurred vision, diplopia, vertigo

Decreased libido, erectile dysfunction

Dry mouth, constipation, vomiting, and flatulence

Peripheral oedema

Weight increase

*Most common

It may worsen cognitive and motor effects of oxycodone and increase the effects of alcohol and BZDs. Pregnancy is a contraindication unless a risk-benefit analysis favours its use; women of childbearing years should be protected against pregnancy; and breast-feeding is not recommended.

Flumazenil (Anexate)

Flumazenil, a BZD receptor antagonist and 1,4-imidazobenzodiazepine resembling midazolam, reverses the sedation produced by BZDs (and 'Z' drugs) and may have some role in helping patients withdraw from these drugs. It seems as if BZD dependence is associated with an allosteric change in the benzodiazepine receptor³⁸⁶³. Flumazenil may reset the receptors for normal function. It has minimal effects on the normal CNS and can be given IV, IM or orally. It lasts for 15-140 minutes after a single IV injection (elimination half-life = 50 minutes). When flumazenil is used after brief procedures using BZD premedication or anaesthesia one may need to repeat the injections or to give it as an infusion. This is because most BZDs are longer acting than flumazenil. Flumazenil has an elimination half-life of one hour and the liver mostly inactivates it. Re-sedation may follow 1-2 hours after giving flumazenil. The initial adult dose is 200 micrograms, with

³⁸⁶¹ An auxiliary subunit (alpha2-delta protein) of voltage-gated calcium channels in CNS, causing a potent displacement of [³H]-gabapentin.

³⁸⁶² The dose may be increased from 75 mg bid to 150 mg bid after 3-7 days and then, if required, the dose may be increased after an additional 7 days.

³⁸⁶³ This augments the action of inverse agonists.

further 100 microgram increments at 60-second intervals until sedation is reversed, up to a maximum of 2 mg.

Day anaesthetic cases will still not be able to drive home or to travel unescorted, in case of late-onset re-sedation. In a BZD overdose flumazenil is unlikely to improve the outcome but it may clarify the diagnosis. In cases of *mixed TCA-BZD overdose* flumazenil may cause arrhythmias and seizures, the latter being TCA effects controlled by the BZDs. Flumazenil should not be given to *ventilated patients who have raised intracranial pressure following head injury* as the drug will raise the intracranial pressure even further and reduce cerebral perfusion pressure.

Side effects of flumazenil

Nausea, vomiting
Dizziness, headache
Flushing
Agitation, anxiety, confusion
Seizures (especially in epileptics)
Transient tachycardia and hypertension

The 'Z' drugs (zopiclone, zolpidem, zaleplon)

Conclusions drawn from NICE on these drugs suggest that the methodology of studies carried out were defective for a number of reasons³⁸⁶⁴. No consistent difference was found between these drugs and BZDs for effectiveness or safety, and the Z drugs are several times more costly than BZDs. (Holbrook, 2004) This caveat should be kept in mind when reading about each of these drugs. Ecause there is a risk of inducing dependence, they should be employed cautiously for short-term treatment of insomnia.

Zopiclone³⁸⁶⁵ (Zimovane, Zopitan, Zorclone)

This non-BZD cyclopyrrolone derivative is a mildly sedative drug marketed as a hypnotic. The elimination half-life is only 3-8 hours. Zopiclone facilitates GABA by acting on BZD receptors at a site close to, rather than identical to BZDs, i.e. the omega site. Even though zopiclone is not a BZD, its actions are blocked by flumazenil. The suggested dose is 7.5 mgs nocte (range, 3.75-15 mgs). The tablet can be broken in half (3.75 mg) for elderly patients. The patient may experience a bitter or metallic taste in the mouth. Withdrawal can cause rebound insomnia and also to craving and anxiety. (Jones & Sullivan, 1998) Zopiclone may increase TCA metabolism. Carbamazepine increases plasma zopiclone levels. Care should be taken when driving. (Barbone ea, 1998) According to Shapiro ea, (1995) zopiclone may facilitate withdrawal from BZDs. Bannan ea (2005) highlighted the misuse of patients attending a Dublin methadone maintenance programme, detected by finding its breakdown product³⁸⁶⁶ in urine. Moloney ea (2007) reported two cases of depression whose agitation ceased when zopiclone was stopped.

Zolpidem (Stilnoct, Nytamel, Zolnod)

Zolpidem has a higher affinity for BZ1 than for BZ2 receptors. This hypnotic³⁸⁶⁷ should be avoided in the presence of obstructive sleep apnoea³⁸⁶⁸, myasthenia gravis, severe hepatic insufficiency, acute pulmonary insufficiency, or respiratory depression.

Potential side effects

Malaise
Drowsiness
Dizziness

³⁸⁶⁴ E.g. selective reporting of positive findings, short duration, suboptimal comparators, and use of surrogate markers such as sleep variables.

³⁸⁶⁵ The hypnotic agent eszopiclone (Lunesta in the USA) is an enantiomer of zopiclone.

³⁸⁶⁶ 2-amino-5-chloropyridine.

³⁸⁶⁷ An imidazopyridine; half-life = 2-4 hrs; mainly metabolised by conjugation; no active metabolites; reversed by flumazenil.

³⁸⁶⁸ Although others see it as harmless. (Neylan ea, 2003, p. 978)

Diarrhoea
 Headache
 Memory problems
 Nightmares, somnambulism, night eating disorder
 Nausea, vomiting
 Dysphoria
 Vertigo
 Compulsive behaviours, e.g. repetitive shopping or cleaning (Madden *et al.*, 2009)
 Visual hallucinations, confusion, depression (Wang *et al.*, 2001)
 Falls leading to fractures (Adverse Drug Reactions Advisory Committee, 2002)
 Possible increased daytime anxiety if drug stopped suddenly
 Laboratory animals self-administer zolpidem (possible dependence)

Zolpidem lacks muscle relaxant effects and is said to have minimal effect on sleep architecture (total REM and REM latency usually unmodified). Zolpidem is much less likely to be associated with rebound of REM or insomnia than are the BZDs. It is secreted in breast milk. The dose should be reduced in cases with hepatic or renal impairment. The action of the drug may last longer in the elderly and it may be foreshortened in children. The average dose is 10 mg for adults and 5 mgs for the elderly, taken just before sleep. The combination of zolpidem with an SSRI may potentially cause delirium. (Coleman & Ota, 2004)

Zaleplon (Sonata)

This pyrazolopyrimidine hypnotic³⁸⁶⁹ binds selectively to BZD type I receptors, has an extremely short elimination half-life of about 60 minutes, and is metabolised in the liver. Inactive metabolites are excreted in urine (17%) and faeces (17%). The dose should be halved in the presence of hepatic insufficiency but no dose adjustment is required for renal insufficiency. Sleep architecture is unaffected. It may be useful for jet lag. Contraindications include severe liver insufficiency, hypersensitivity, sleep apnoea, myasthenia gravis, severe respiratory insufficiency, and people less than 18 years of age (for whom data is lacking). Its short half-life makes it useful for sleep onset problems. Food delays the onset of maximum plasma concentration by two hours (normally reached in 1 hour). Cimetidine³⁸⁷⁰, ketoconazole, and erythromycin increase Zaleplon's plasma level. Rifampicin reduces its plasma volume. Carbamazepine and phenobarbitone may also reduce the efficacy of zaleplon. Alcohol should be avoided. Zaleplon appears in breast milk. Patients on zaleplon should be advised that driving skills might be adversely affected (do not use within 5 hours of driving). Rebound insomnia and abstinence symptoms are said to be minimal.

Potential side effects

Somnolence
 Mild headache
 Asthenia
 Dizziness
 Anterograde amnesia
 Unmasking of depression
 Paradoxical reactions

Indiplon

This new pyrazolopyrimidine (like zaleplon but more potent) starts to act in less than 60 minutes and has a half-life of about one-and-a-half hours. It can be used in immediate or extended release forms.

³⁸⁶⁹ 10 mg nocte, except for 5 mg at night in the elderly – can be repeated during the night on waking.

³⁸⁷⁰ By 85%.

1162

Buspirone (Buspar)

Buspar was withdrawn by Bristol-Myers Squibb in late 2009 'for operational reasons'. Buspirone, an azaspirodecanedione and a 5-HT-1A partial agonist (in brainstem raphe nuclei) and a weak dopamine antagonist, takes 1-2 weeks to produce full therapeutic effect. Buspirone, a failed antipsychotic, is indicated for the short-term (!) management of anxiety. Buspirone is a partial DA agonist.³⁸⁷¹ There may also be some DA antagonism because there have been single cases of acute myoclonus and akathisia, and oral dyskinesia. The starting dose is 5 mgs B.I.D. to T.I.D. This can be increased every 2-3 days. The usual therapeutic dose is 45 mgs/24 hours. It does not prevent BZD withdrawal symptoms³⁸⁷². Some studies have found that patients with experience of BZDs do not respond to buspirone and others have found the opposite. (Hollander & Simeon, 2000, p. 569) 5-HT-1A partial agonists (buspirone, gepirone, and ipsapirone) are ineffective for panic disorder and may make the symptoms worse. (Deakin et al, 2001) Buspirone should not be combined with MAOIs.

Side-effects (usually mild)

Dizziness

Headache

Nervousness

Lightheadedness

Palpitations

Chest pain

Drowsiness

Confusion

Dry mouth

Tiredness

Sweating

Tachycardia

Raised prolactin levels and exacerbation/precipitation of EPS (Owens, 2004, p. 300)

According to Harrison-Read et al, (2004, p. 466) buspirone may have limited application because of delayed action and 'dysphoric' effects. It lacks the hypnotic, anticonvulsant and muscle relaxant properties of the BZDs and there is no cross-tolerance with alcohol and no physical dependence when it is given over the long-term to animals.

Melatonin (Circadin)

This contains prolonged-release melatonin 2mg tablets for 'short-term' (3 weeks) treatment of 'primary' insomnia in people aged at least 55 years or more. It is taken 1-2 hours before retiring and after food. Anonymous (2009) believes that the evidence for efficacy of this product is limited. Caution is advised in the presence of renal insufficiency and it is to be avoided in the presence of pregnancy/lactation, liver impairment, or autoimmune disease. It may impair driving or the handling of machinery. Patients with problems relating to galactose or those taking fluvoxamine should not take this tablet. Adverse effects include headache, sore throat, back pain, and asthenia.

*Ramelteon*³⁸⁷³

This MT1 and MT2 melatonin receptor selective agonist and hypnotic may lack abuse potential and have safe motor and cognitive profiles. (Johnson et al, 2006) It has been associated with raised prolactin and decreased testosterone levels.

Tasimelteon

³⁸⁷¹ It is possible that 1-(2-primidiny) piperazine, one of its metabolites, may contribute to its long-term pharmacological effects.

³⁸⁷² Therefore, BZDs should either be withdrawn slowly before contemplating the use of buspirone or they should be tapered slowly after the patient is taking buspirone for, say, a month.

³⁸⁷³ Rozerem in the US.

1163

This MT1 and MT2 melatonin receptor selective agonist and hypnotic improves sleep latency and maintenance. (Rajaratnam et al, 2009)

Ropinirole (ReQuip)

This is a non-ergoline DA agonist. It may rarely cause sudden onset of sleep during daily activities. Patients should not drive.

Carisoprodol (Soma)

This centrally acting muscle relaxant has become a drug of abuse in the US. It is metabolised to meprobamate. Preparations may contain various analgesics including opioids. It can lead to stimulation or depression of the CNS. Tachycardia, hypotension, agitation, nystagmus, coma, seizures, and death from aspiration have been reported. Poisoning from salicylates or paracetamol (contained in the same preparation) should be considered. Flumazenil should not be used.

Orexin antagonists

Orexins are released during waking hours and orexin antagonists may have some use in treating insomnia.

Kava³⁸⁷⁴ (Piper methysticum³⁸⁷⁵)

Derived from a Polynesian root, its mild anti-anxiety effects may be due to kavapyrones³⁸⁷⁶ that are central muscle relaxants. These chemicals are involved in GABA receptor binding and inhibition of reuptake of N-Ad. Gastrointestinal upset, headache and dizziness are the main side effects. Poisoning may lead to hair loss, breathing and vision problems, yellow skin³⁸⁷⁷, and severe liver damage.³⁸⁷⁸ Parkinsonism may also be a side-effect of kava. (Lees et al, 2009)

Beta-adrenergic receptor-blocking drugs (β -blockers)

The main psychiatric uses of this group of drugs are stage fright, akathisia, and the long term management of violence in patients with brain disease³⁸⁷⁹. Use of high doses in schizophrenia is no longer popular.

Contraindications

Obstructive airways disease

Severe ventricular dysfunction

Relative contraindications³⁸⁸⁰

Diabetes mellitus

Peripheral vascular disease (incl. Raynaud's disease)

Bradycardia

Heart block³⁸⁸¹

Insomnia and vivid dreams may occur during treatment with beta-blockers, especially propranolol (because it is more lipophilic and therefore crosses the blood-brain barrier readily). Initial hopes of using beta-blockers to prevent PTSD proved to be disappointing. There have been reports of propranolol-induced delirium. It is also associated with nightmares, depression and drowsiness. Propranolol uncommonly causes depression, other beta-blockers less so. By way of contrast, atenolol, (e.g. Adalat, Atecor) which is

³⁸⁷⁴ Banned in France and carries a warning from the FDA in the US.

³⁸⁷⁵ 'Intoxicating pepper'.

³⁸⁷⁶ These are related to myristicin found in nutmeg.

³⁸⁷⁷ The skin may be pellagra-like: dry and flaky skin, red eyes, and discoloured hair.

³⁸⁷⁸ There may be an eosinophilia. Liver transplantation has been required in a number of cases.

³⁸⁷⁹ Doses in organic brain disorders might be metoprolol (e.g. Betaloc) 200-300 mg/day or propranolol slowly increased to 1 g/day.

³⁸⁸⁰ Beta-blockers are often used for stable heart failure but may exacerbate acute cardiac failure.

³⁸⁸¹ Some authorities list heart block as a full contraindication.

water-soluble and is largely excreted unchanged by the kidneys, rarely causes central side effects.

Beta-Blockers may cause

Lassitude

Depression³⁸⁸²

Poor concentration

Nightmares and other sleep disturbances

EEG changes

Hallucinations and psychosis

Impaired short-term memory

Cold hands

Beta-Blocker drug toxicity

Mild – bradycardia

Severe – coma, hypotension, convulsions +/- delirium, hallucinosis, cardiac arrest

Management – IV glucagon (or, less reliably, IV atropine)

Beta-blockers affect brain function, though less severely than would low-dose BZD.

They seem unlikely to affect driving skills. People doing skilled work involving memory and vigilance or careful thought are most vulnerable. Drugs like cimetidine and the SSRIs decrease metabolism of beta-blockers with the potential for severe bradycardia.

Beta-blockers should be withdrawn slowly to avoid cardiac rebound phenomena.

Beta-blocker abstinence syndrome

Arrhythmias

Exacerbation of angina

Myocardial infarction

Violence & psychiatric emergencies

'Alcohol, without question, is the greatest contributor to violence.' (Hughes, 2000)

'.....much of the violence in society is related to factors such as economics, drug dealing, and other criminal activities not within the usual realm of psychiatric expertise....' (Tardiff, 2003)

'Environmental precipitants are as important as underlying psychiatric or medical diagnoses when determining a patient's level of dangerousness.' (Sanders, 2004, p. 505)

Dangerousness is hard to predict and attempts are at best 'an inexact science'. (Dolan & Doyle, 2000; RCPsych, 2008) Nevertheless the risk of a patient harming themselves or others should be part of psychiatric assessment. It is not something which should be confined to forensic psychiatric work. Various measures³⁸⁸³ are employed in assessing risk.

³⁸⁸² Debatably so. (Long & Kathol, 1993)

³⁸⁸³ The *Glasgow Risk Screen* (NHS Greater Glasgow, 2005: *Report of the Audit of the Use of the Glasgow Risk Screen.*) is an attempt at transparent, systematic and multidisciplinary clinical risk assessment. It comprises categorical identification of a number of historical, precipitating and protective factors organised under self-harm, violence, neglect and other risks.

The *Historical, Clinical and Risk Management – 20* (HCR-20: Webster et al, 1997) consists of non-weighted items that require clinical judgment in determining level of risk (low, medium, high): historical (past violence, young when first violent, unstable relationships, employment difficulties, drug use problems, major psychiatric disorder (MPD), psychopathy, early maladjustment, personality disorder, prior supervision failure), clinical (poor insight, negative attitudes, active symptoms of MPD, impulsive, non-response to treatment), and risk management (plans not likely to succeed, destabilising forces, low personal supports, non-adherence with remediation attempts, stress). In other words: a composite of 20 risk factors for violence: 10 stable past risk factors, 5 current/changeable clinical items, and 5 situational items.

*Some questions to be asked during risk assessment*³⁸⁸⁴

What is the risk of suicide, self-neglect, and being exploited?

What is the risk of homicide?

Are there vulnerable people at risk, e.g. children, spouse, employer, doctor, etc?

From a medico-legal standpoint ones notes must allow the reader to understand what information was gathered and considered and the reasoning process guiding decision-making.(McNiel ea, 2008)

Murders increased by 22% in England and Wales during World War II (Davies, 2006, p. 382)
 US Supreme Court rejected APA position on difficulties involved in predicting dangerousness in *Barefoot v Estelle* 463 US 880 (1983)
 Patients with Capgras delusions may kill (de Pauw & Szulecka, 1988)
 About 1.6 million people worldwide died as a result of violence in 2000, about half attributable to suicide, almost one in three to homicide, and approximately a fifth to armed conflicts (Ghodse, 2006)
 Past dangerousness is the most important predictor of present dangerousness (Maden ea, 2004)
 Major predictor of aggression after head injury is pre-injury antisocial behaviour
 Drug and alcohol abuse³⁸⁸⁵, a frightened psychotic, and mania or antisocial personality disorder, are other common associations (Putkonen ea, 2003; Monshouwer ea, 2006)
 Commonest victims of violence are young men who often go out in the evenings
 If domestic violence is included, then women may be the commonest victims
 Incidence of battered wives is unknown but over 90% of victims of domestic violence are women.
 Reported cases of domestic violence in UK: lifetime prevalence is 25% of women and annual prevalence is one in nine women (Mezey & Robbins, 2000)
 Most women will either not disclose source of their injuries to doctor, or will only hint at it
 Not all studies agree that domestic violence is one way, e.g. according to a British Home Office survey,(Home Office, 1998) 4.2% of women and the same percentage of men reported being assaulted physically by a current or former partner in the past year
 Mentally ill are more likely to be violent toward persons who have close personal contact with them than to strangers (Das ea, 2002)
 Psychotic subjects are often the victims of violence, especially in the presence of severe mental symptoms, homelessness, substance misuse, previous violent behaviour, or comorbid personality disorder (Walsh ea, 2003)
 Berzins ea (2003) found harassment of mentally ill living in the community (41%) to be twice as common as harassment of general population (15%)
 Pressure into unwanted, and often unprotected, sex is not uncommon in histories of psychiatric patients (Wainberg ea, 2003, p. 117)
 Inner city people with severe mental illness requiring admission often have recent histories of aggressive behaviour and of being victims of assault, and men (47%) more than women (17%) will have had at least one conviction for violent crime (Hodgins ea, 2007)
 Either sex with severe mental illness who develop conduct disorder by mid-adolescence are at risk of being aggressive and violent.(Hodgins ea, 2008)
 Actuarial instruments³⁸⁸⁶ can be used to predict violent recidivism in mentally disordered offenders, although they may over-predict reconvictions.(Snowden ea, 2007)
 Schizophrenic patients feel safer outside cities and their being attacked is associated with their abusing alcohol and drugs and having been arrested in the past.(Schomerus ea, 2008)
 1.43 million deaths occur worldwide annually from violent acts, mostly individual acts.(Siever, 2008)
 10-year-old who eat confectionery every day are at increased risk for being convicted for violence at age 34 years, probably because sweets were used to control their behaviours, thus preventing their learning to defer gratification.(Moore ea, 2009)
 Excessive partner alcohol abuse and violence in India increased risk for common mental disorders 2 to 3 times; to some extent women's condoning of violence has a part to play here and should be addressed.(Nayak ea, 2010)
 Inter-partner violence is more common in those with a history of child sexual abuse.(Friesen ea, 2010)

³⁸⁸⁴ See, e.g. Royal College of Physicians and RCPsych (2003) and RCPsych.(2008) The latter (RCPsych, 2008) points out that accurate prediction is impossible in individuals due to complexity of underlying factors and that assessment should relate to the current situation rather than trying to predict a particular event.

³⁸⁸⁵ Arendt ea (2007) suggest that some people may use cannabis to help curb aggression.

³⁸⁸⁶ E.g. *Violence Risk Appraisal Guide* and *Offender Group Reconviction Scale*. The *Buss-Durkee Hostility Inventory* (Buss & Durkee, 1957) is a 75-item self-report questionnaire that measures aspects of hostility and aggression. There are eight subscales: assault, indirect hostility, verbal hostility, irritability, negativism, resentment, suspicion, and guilt. The *State-Trait Anger Expression Inventory* (Spielberger, 1991) is a 44-item scale.

In the Werner ea (1983) study, psychologists and psychiatrists agreed which patients would be violent and what the critical predictor variables were, but empirical correlations of violence with these variables indicated that the judges' predictions were rarely accurate. Sensible precautions are necessary to minimise violence against staff, particularly in the community.

Rampton special hospital, England (Larkin ea, 1988)

Violent incidents more common than in general psychiatric hospitals

A small number of patients accounted for most of incidents

Female patients accounted for 75% of incidents but only 25% of hospital population

Nurses Assaulted three times more often than were patients

St Brendan's Psychiatric Hospital, Dublin (O'Shea, 1988)

Male psychiatrists attacked more frequently than female colleagues

Novice psychiatrists at higher risk from patient-perpetrated violence than are experienced colleagues

Acute psychiatric wards, Exeter (Wildgoose ea, 2003)

Most staff experienced at least one incident of actual/threatened violence within previous year

This was reflected in scores on measures of psychological distress

Factors that may reduce likelihood of violence on a psychiatric ward (Davison, 2005)

Adequate staffing levels

Predictability of ward routine

Pleasant environment

No overcrowding

Wide range of meaningful things to do

Sufficient privacy and dignity

Adequate observation

English national psychiatric ward audit (Chaplin ea, 2006)

Questionnaire and environmental inspection

78% of nurses reported experience of violence

37% of service users reported experience of violence

Concerns over staffing levels, training, provision of activities, ward design/ambience

National Epidemiologic Survey on Alcohol and Related Conditions in US (Elbogen & Johnson, 2009)

Incidence of violence is higher for mentally ill *but only significantly so if there is drug abuse/dependence*

Severe mental illness on its own does not predict future violence

Future violence predictors: past violence, juvenile detention, physical abuse, parental arrest record; clinical (drug abuse, perceived threats); age, sex, income; recent divorce, unemployment, and victimisation

Anonymous questionnaire study of psychiatrists working in Republic of Ireland (Kavanagh & Watters, 2010)

Potential number of respondents = 330; response rate only 48.2%

Being longer in psychiatry in not reduce the rate of being assaulted – however, respondents were only asked if they at one of 3 stated grades at the time of the assault and most of one's career would presumably be as a senior practitioner (O'Shea [1988] broke down level of experience into 5-year chunks and found that lack of experience predicted being a victim)

Standard safety equipment is far from ubiquitous and many psychiatrists had not been trained in safety techniques

The first victim support scheme in Britain was established in Bristol in 1974, and by December 1987 there were 350 schemes. A central advisory body, the National Association of Victim Support Schemes, was formed in 1979. These schemes supply 'everything from emotional support to information about compensation'. A British government enquiry, launched after eight people had been killed in the NHS since 1980, found that only 5% of cases of violence against staff were reported.

Relationship between broadly defined mental disorder and violence (Walsh and Fahy, 2002; see also Wallace ea, 2004; Friedman, 2006; Swanson ea, 2008; Large ea, 2008)

Modest relationship between psychosis and violence

Untreated schizophrenia, major depression, and bipolar disorder

Anxiety disorders not associated with violence

Greatest risk is with personality disorder, drug abuse, and the severely mentally ill who also misuse drugs

Being male, young and poor contribute more to violence than does mental disorder

Not all violence committed by the mentally ill stems from their psychiatric disorder
 Falling UK homicide rate despite communitisation **or** rise in homicides attributed to mental disorder to mid-1970s in England and Wales followed by a fall whilst other homicides continued to rise
 Victim of violence against self in the past
 Homelessness
 Poor medical health
 According to the RCPsych (1996) about 100 homicides each year were committed in England and Wales by people judged to be mentally abnormal at the time of the act
 Rise in homicide by schizophrenic patients in one part of Australia paralleled a general increase in societal violence
 Total number of homicides and those attributed to mental disorders³⁸⁸⁷ in England and Wales rose steadily until mid-1970s but those attributed to mental disorders fell after 1981 to early 1950s levels (Mayor, 2008)

The fact that a patient has a lifetime history of schizophrenia does not automatically mean that diagnosis explains homicide.(Shaw ea, 2006) Mullen (2006) reminds us that schizophrenic patients do kill others and that we cannot underestimate its impact on others.(see also Dean ea, 2008)

Serious violence following threats to kill (Warren³⁸⁸⁸ ea, 2008)
 10 year review of 613 people **convicted** of threats to kill
 2.6% (16) committed suicide³⁸⁸⁹
 3 were murdered
 44% convicted of further violent offending, including 3% homicides
 History of psychiatric contact at time of index offence (40%) was associated with higher rate (56%) of subsequent violence
 Highest risk factors: drug misuse, mental disorder, youth, and no prior criminal conviction
 Most frequent association with homicidal violence: schizophrenia

It is important that psychiatrists do not overstate their capacities to predict or prevent dangerousness.(Mullen, 2000) Doyle and Dolan (2006) suggest that current social functioning, mental state and contextual factors, backed up by measures such as the *Historical Clinical Risk – 20 items scale* (HCR-20³⁸⁹⁰: Webster ea, 1997; Gray ea, 2008), assist the clinician in rationally estimating risk of community violence in discharged patients.

Violence: Repetitive acts of violence are associated with an increased incidence of abnormal brain function as shown by neuropsychological tests, EEG and CT scan.(e.g. Krieger, 1985) These abnormalities tend to be located mainly in three brain areas: frontal cortex, amygdala, and temporal cortex. These cerebral regions coincide with the areas indicated in the genesis of aggression in animal studies. PET scans may reveal abnormalities in the left temporal lobe of patients with a history of repetitive, purposeless violence,(Volkow & Tancredi, 1987) and a lifetime history of aggressive impulsivity may relate to prefrontal metabolic abnormalities (negatively correlated with regional cerebral glucose metabolic rate) on PET scanning in patients with personality disorders.(Goyer ea, 1994) Volkow and Tancredi (1987) discuss three basic syndromes associated with

³⁸⁸⁷ Homicides attributed to mental disorders = not guilty by reason of insanity, diminished responsibility, unfit to plead, infanticide, or offender committed suicide around same time as homicide.

³⁸⁸⁸ Australian study, including P E Mullen.

³⁸⁸⁹ Asnis ea (1997) reported that 91% of outpatients who had attempted to kill another person had also tried to kill themselves and that 86% of patients who had thoughts of killing others also thought about suicide.

³⁸⁹⁰ See earlier.

neurological impairment and violence: the prefrontal area³⁸⁹¹, limbic areas³⁸⁹², and association areas³⁸⁹³. The medial frontal cortex (on MRI) may be excessively thin in violent people with antisocial personality disorder.(Narayan ea, 2007) Poor (electrodermal) fear conditioning at age 3 years was prospectively found to predispose to crime at age 23, suggesting a neurodevelopmental aetiology.(Gao ea, 2010) High serum or salivary testosterone levels have been linked with violent crimes. Murderers with sociopathic personalities may have sub-sensitive serotonergic systems.(O'Keane ea, 1992) An excess of vasopressin may have a role in aggression. Violence may occur in patients on high doses of antipsychotic drugs, e.g. haloperidol 60 mg/day.(Herrera ea, 1988)

Neurobiological basis of violence (Siever, 2008)

Neurobiological susceptibility more likely with repeat offenders
 'Top-down' control systems (prefrontal cortex, PFC) fail to modulate aggressive acts triggered by anger provoking stimuli
 Imbalance between PFC inhibitory influence and hyper-responsive amygdala and limbic regions with role in affective evaluation
 Lack of 5-HT facilitation of 'top-down' control
 Excess stimulation by catecholamines
 Subcortical glutamine/GABA imbalance
 Abnormal neuropeptide systems

Women are at particular risk of male violence. (Clare, 2000; but see Home Office, 1998 above) Men who are more controlling are more likely to be violent against their partners; and variation in prevalence around the world suggests that such violence is not inevitable.(Garcia-Moreno ea, 2006)

Intermittent explosive disorder³⁸⁹⁴

In DM-IV section on 'impulse control disorders not elsewhere classified' (diagnosis of exclusion)
 Syndrome with long and controversial history (Mullen, 2000)
 Discrete episodes of failure to resist aggressive impulses (loss of temper) leading to serious assaults/destruction of property
 Starts in adolescence or early adulthood and may diminish in intensity in the twenties; there may be a history of child abuse
 Medical help tends to be sought only when there are adverse consequences of temper outbursts
 Are such patients prone to react to narcissistic injury, real or imagined?³⁸⁹⁵
 Behaviour not explicable by another diagnosable condition
 Reported by 2.6% of population (12-month prevalence rate) in National Comorbidity Study replication (Kessler ea, 2005)
 Is it a disorder of personality (cluster B)?
 Form of epilepsy?³⁸⁹⁶
 Another Axis I disorder?³⁸⁹⁷

³⁸⁹¹ Higher cognition: consciousness, abstraction, etc. Possibly unable to understand right from wrong or to appraise the consequences of a violent act.

³⁸⁹² Generation of affects and emotions: do feelings arise spontaneously with associated outbursts of rage and violence and poor impulse control? May have an excess of EEG abnormalities.

³⁸⁹³ Derangements in perception could evoke assaultive behaviour when a stimulus is perceived as threatening.

³⁸⁹⁴ The old 'episodic dyscontrol syndrome'.

³⁸⁹⁵ Threats of attack, abandonment, rejection, or other blows to self-esteem have been suggested.

³⁸⁹⁶ EEG abnormalities are non-specific, mild abnormal neuropsychological findings (e.g. letter reversal), and neurological soft signs have been reported. Low CSF and platelet 5-HT levels have been reported.

³⁸⁹⁷ Patients themselves and their close relatives may have an excess of drug use or affective disorders.

Is it one end of a continuum with normality? (Lambert et al., 2003, pp. 1108-9; Cohen, 2003, p. 454)

Selected reported associations with violence

1952. Denis Hill reports on EEG in psychopaths.

1963. Bandura reports that aggressive models increase the likelihood of aggression in children.

1969. Williams confirms Hill's EEG findings. He also showed that among males convicted of violent offences those with habitual aggressiveness had abnormal EEGs (espc. anterior temporal) whereas those with single aggressive outbursts more usually had normal EEGs and the outbursts were usually environmentally provoked.

1983. Pfeffer and others report that aggression in parents strongly predicts aggression in their children.

1987. Volkow and Tancredi, using PET, reported abnormal metabolism in frontal and temporal areas in males with personality disorder.

1988. Lewis and co-workers report that CSA and physical abuse in childhood is common in the histories of criminals.

1990. Looked at > 9,000 crimes in 11 countries; 2 out of 3 violent offenders were drinking alcohol at the time of the crime, and almost half of the victims were intoxicated when victimised.

1992. The more aggressive rhesus monkeys had low CSF 5-HIAA and high CSF noradrenaline. Males often die early and females occupy low positions in their troops. Being reared by peers rather than the mother is associated with low 5-HIAA levels.

1993. Most assaultive psychiatric inpatients: bipolar disorder, personality disorder, and chronic organic mental disorders.

Homicide in US homes associated with: illicit drug use, a history of physical fights at home, or having guns in the house.

1994. Conflicting evidence to suggest that lowering cholesterol levels may lead to violence, possibly by reducing brain serotonin levels.

Based on eyewitness accounts, violent incidents involving psychiatric hospital inpatients are most commonly preceded by (a) agitated/disturbed patient, (b) restrictions placed on patient by hospital regimen and (c) provocation by other patients/relatives/visitors. Incidents arising from staff members initiating contact with patients were very rare.

Male rhesus macaques (*Macaca mulatta*) with reduced CSF 5-HIAA levels show more violent forms of aggressive behaviour and greater risk taking.

Murderers had reduced metabolism on PET in lateral and medial prefrontal cortex compared to controls.

Goyer and co-workers, using PET, found that the lower was glucose metabolism in the frontal cortex of personality disordered persons the more likely was there to be a history of aggression.

1996. Shooting of children by other children is a major problem in the USA.

Finnish study of homicides found that schizophrenia without alcohol disorder increased homicide risk 7 and 5 times for males and females respectively; if with alcohol disorder these figures climbed to 17.2 and 80.9 respectively.

1997. Substance abuse associated with greater risk of violence on the part of patients in an American private psychiatric hospital.

Flunitrazepam (Rohypnol), especially when combined with illicit drugs was associated with date rape (as is gamma-hydroxybutyrate); banned in US; Roche Pharmaceuticals changed the formulation in the hope of reducing misuse.

Psychopathy associated with different pattern of relative cerebral blood flow than seen in controls when processing emotionally laden words.

PET study of males with schizophrenia and schizoaffective disorder found reduced glucose uptake in right plus left anterior inferior temporal lobes in non-repetitive offenders but only on left side in repetitive offenders.

1998. Non-compliance plus alcohol/drug abuse in seriously ill patients is associated with serious violence in the community.

Young male Finnish schizophrenic males who abuse alcohol are 25.2 times more likely to commit violent crimes than are normal men; non-alcoholic males with mental illness only 3.6 times more likely to commit violent crimes than are normal men.

Decreased prefrontal regional cerebral metabolic rates for glucose in murderers, especially in ventromedial brain regions, especially in those patients from stable backgrounds – suggesting genetic rather than environmental input.

1999. Americans want childproof handguns and personalised weapons (activated by fingerprint or code)!

Maternal smoking during pregnancy associated with violent offences in offspring only if the offspring experienced delivery complications.

Maternal smoking during pregnancy associated with violent offences in offspring if mother was a single teenager who did not want the pregnancy or if developmental motor lags occurred.

Low cholesterol associated with impulsivity in personality disordered people

2000. Increased rates of offending in the community (Victoria, Australia) by schizophrenic patients parallels that in the general population.

In DSM-III-R patients with various diagnoses, reduced CSF 5-HIAA levels are associated with aggressiveness regardless of suicidal behaviour.

The US Brady Handgun Violence Prevention Act of 1994 may have reduced the use of such weapons for suicide purposes in older people but has not reduced either the homicide rate or overall suicide rates. People have observed a waiting period before buying a gun while their background is being checked; and illegal sources of guns are difficult to check reliably.

No evidence for an association between recorded adolescent psychopathology and criminally violent behaviour. The latter was associated with a history of emotional or physical abuse, contact with social or mental health services, and previous criminal behaviour.

11% reduction in prefrontal grey matter volume on MRI in males with antisocial personality disorder.

Violence is easiest to enact when one dehumanises the object of anger.

Low cholesterol associated with aggressiveness/impulsivity in personality disordered people

Mild intellectual disability is associated with higher rate of offending compared to normal IQ peers; more severe intellectual disability is rarely associated with serious crimes

2001. Clozapine is superior to haloperidol and risperidone for aggression in schizophrenia.

Offenders with borderline personality disorder and those with repeated self-harm or alcohol misuse had low 5-HT function. 5-HT function inversely correlated more with impulsivity than with aggressive acts. Plasma testosterone is associated with aggressive acts. Psychopathy is associated with lower initial cortisol and higher testosterone concentrations.

Repetitively violent alcoholics with antisocial personality disorder showed a negative correlation between dorsal hippocampal volume and psychopathy score; since hippocampus is involved in fear conditioning, is there a problem in neural circuit involving prefrontal and temporolimbic areas?

High activity COMT homozygosity in schizophrenia may be associated with more aggression (the COMT gene inactivates catecholamines).

Women who are abused in childhood are at risk of domestic violence in adulthood.

2002. PET study suggests that diminished activation of inhibitory regions of the brain (e.g. anterior cingulate) in impulsively aggressive patients in response to a serotonergic stimulus, m-CPP, may contribute to poor modulation of aggressive impulses.

2003. Childhood psychotic symptoms (and, to a lesser degree, childhood physical aggression) were a strong risk factor for violence in adults with schizophreniform disorder.

2004. Being on an atypical (vs conventional) antipsychotic may be more likely to reduce violence among community-based schizophrenic patients.

16% and over one-tenth of all violent crimes in Sweden during 1988-2000 were committed by people with hospital discharge diagnoses of alcohol abuse and drug misuse respectively.

Swedish study suggests that previous studies have underestimated psychiatric morbidity in homicide offenders: 20% were psychotic and 54% had a personality disorder.

2005. Meta-analysis showed that violence in the visual electronic media increases short-term aggressive and fearful behaviour in younger children, especially in boys; evidence for long-term is inconsistent.

2006. Swedish study found population attributable risk fraction ³⁸⁹⁸ of 5.2% for severe mental illness on violent crime, higher in women than in men.

Dopaminergic transmission is implicated in aggression/hyperactivity and such externalising behaviour is negatively associated with cognitive ability; in people lacking a 7-repeat allele in third exon of D4 receptor gene externalising behaviour negatively correlated with IQ, whereas in those with at least one copy externalising behaviour and IQ did not correlate.

2007. Patients discharged from medium secure forensic psychiatry services: most were not subsequently convicted; patients with pre-admission convictions were at highest risk of violent reconviction.

2008. Genes and environment interact in complex ways to produce externalizing behaviour.

US children are more aware of location of household guns/ammunition than parents realise.

Approaches to reducing violent tendencies include mood stabilisers to dampen limbic irritability, SSRIs to enhance top-down control, teaching alternative coping strategies, and re-inforcing reflective delays ³⁸⁹⁹. (Siever, 2008)

Handling emergencies³⁹⁰⁰ (RCPsych, 1998): Always have enough hands to restrain the patient comfortably. Do not confront. If the patient is armed and is unwilling to put it in a neutral location³⁹⁰¹ with a dangerous weapon call the police and stay clear. Avoid drugs in those who are intoxicated. A shared cup of tea and a calm chat sorts out many

³⁸⁹⁸ Population attributable risk fraction = proportion of violent crimes in the whole population that may be attributable to individuals with severe mental illness.

³⁸⁹⁹ During the early 1980s the author prescribed clopenthixol depot injections for a young man who had recently begun hitting his wife without warning whilst watching TV. After a couple of weeks the patient told the author that 'this drug is great. I feel like hitting her but it makes me stop and think about it. But then I hit her anyway!' Unfortunately the man turned out to have a malignant primary cerebral tumour which caused prolonged coma before he died.

³⁹⁰⁰ Sedation is covered under common law in any setting. It is specifically covered under the *Mental Health Act* 1983 for informal patients in England and Wales. It should be noted that the making of a contract with a patient that he or she will do no harm to him/herself provides no medico-legal protection – a comprehensive assessment (documented in the notes) should not be omitted.

³⁹⁰¹ Do not ask an armed patient to hand a weapon directly to you.

problems. Oral medicines (e.g. olanzapine velotabs) are generally safer than parenteral drugs. Examples of emergency drugs include olanzapine as velotabs or (see below) IM, lorazepam 2-4 mg IM³⁹⁰² (McAllister-Williams & Ferrier, 2002), haloperidol 5-15 mg IM or slowly IV³⁹⁰³, haloperidol (10 mg) plus promethazine³⁹⁰⁴ (Phenergan, 25-50 mg) IM, (Alexander et al, 2004; Raveendran et al, 2007; Huf et al, 2007) or clopenthixol (Acuphase) 25-100 mg IM every 3 days. (see also Raveendran et al, 2007) Oral medications are safer than parenteral ones, e.g. lorazepam 2-4 mg plus risperidone 1-2 mg every 8 hours. In one study (Currier et al, 2004) risperidone 2 mg and lorazepam 2 mg given orally was as effective for psychotic agitation as was haloperidol 5 mg plus lorazepam 2 mg given IM. Compliance is increased with use of syrup. Lorazepam (Ativan) has a half-life of 12-14 hours, it acts quickly, and is better absorbed from IM sites than is diazepam. (Tardiff, 1996) It is preferred (as is oxazepam) in cases with hepatic impairment and when predictable elimination is desirable³⁹⁰⁵. Lorazepam, which has no active metabolites, is metabolised by kidney and liver.

Tyrer et al (2008) found that risperidone, haloperidol, and placebo each decreased aggression in non-psychotic intellectually disabled patients substantially by four weeks. They hold that antipsychotic drugs should not be given routinely in such circumstances. This is not a total prohibition. Whilst behavioural interventions are ideal, staff may be neither trained or willing to become involved. (Matson & Wilkins, 2008)

Olanzapine (Zyprexa IM: 10 mg Powder for Solution for Injection) is an IM preparation for use in the acutely agitated psychotic patient. 10 mg of this is roughly equivalent to 7.5 mg haloperidol in reducing agitation, measured 2 hours after administration. The effects last about a day. It should only be given intramuscularly, never IV or SC. It can be given on a maximum of 3 consecutive days. The starting dose is 10 mg (elderly or in people with hepatic or renal impairment = 2.5-5 mg). A second injection of 5-10 mg can be given 2 hours later if necessary. The maximum daily dose is 20 mg (combined oral plus IM). No more than 3 injections should be administered over a 24-hour period. These instructions should be strictly adhered to.

Dealing with a violent patient

Anticipate problems – hostility, agitation, restlessness, abusiveness, or lack of control.

Do not sit behind desk – sit nearer than patient to an open door.

Don't be angry/threatening/patronising.

You should not approach the patient too quickly – respect personal space.

Check your gut feeling³⁹⁰⁶ – feel scared? Do not interview alone. Ask the patient if he has a weapon on his person and have it removed.

Offer anything reasonable – assistance, food, medication – praise patient for strength and self-control.

Should restraint be required: hold hands/arms/legs; do not restrain without sufficient help; be kind/firm; one person should co-ordinate all; and do not bargain; search for drugs/weapons/syringes.

If oral medication is refused offer an injection and give injection if patient still refuses.

³⁹⁰² 4 mg/ml ampoule.

³⁹⁰³ Very high doses may rarely cause arrhythmias, including *torsade de pointes*. If haloperidol is given by IV line, the latter should be flushed with saline first, because heparin may precipitate heroin within a vein. **DO NOT USE** haloperidol in an emergency unless reasonable (and documented) efforts are made to outrule any cardiac risk factors; get an ECG as soon as possible – if there is a prolonged QTc check serum magnesium level; olanzapine is probably a safer option (although this author has used parenteral haloperidol for many years without mishap!); when in doubt use benzodiazepines for the moment and monitor in the recovery position for respiratory depression. It has been suggested that IV haloperidol causes less EPS than when it is administered orally. (Menza et al, 1987)

³⁹⁰⁴ A Vermont guitarist (Diana Levine) won damages in 2009 because the US Supreme Court found that the manufacturer's labelling on Phenergan wasn't strong enough in warning of the danger of gangrene and amputation from inadvertent intra-arterial injection. The patient argued that labelling should have advocated that an IV drip be employed instead of a direct IV injection.

³⁹⁰⁵ E.g. the delirious, medically ill patient.

³⁹⁰⁶ Your 'psychoscope'.

Observe patient carefully if sedated/restrained – do not leave him alone.
 Consider admission if the patient intends to harm anyone (or won't discuss this), is abusing drugs/alcohol, is psychotic/cognitively disordered/will not or cannot co-operate with treatment.
 Should there be a potential victim you have a duty to warn directly or via police – this includes staff.
 Follow up observation (frequency and nature stated clearly in writing) and documentation.
 Get information from informants.
 Never forget to look for an organic aetiology.

Seclusion

Seclusion has been used in psychiatry for many years, an early advocate being Cullen in the early 19th century. Published research in the use of seclusion often failed to offer consistent guidelines for its use. (Angold, 1989) It should be supervised by senior staff and subject to frequent appraisal. Details of why it is being used, on whom, its form and duration, its effects, and what use of it has been made in the past and what were its effects, should be recorded. A regular medical review of secluded patients is essential. It should not be used as a punishment or to obviate staff shortages.

Rehabilitation in psychiatry

32

A Short History of Psychiatry

Brian O'Shea

'It is a matter of history that psychiatry as we know it has developed as a branch of Western medicine'. (Mumford, 1999)

'Gone is the image of the madman with the strength of ten: it seems that the image of madness in the twenty-first century will rather be one of dilapidation and waste'. (Tantam, 1999)

'The asylum was not instituted for the practice of psychiatry; psychiatry rather was the practice developed to manage its inmates'. (Porter, 2002)

Psychiatry³⁹⁰⁷ is in the broadest sense is as ancient as insanity and has provoked varied social attitudes and responses. (Porter, 2002) When doctors began to discover that certain types of brain dysfunction could be associated with physical signs and discernible brain changes some broke away from psychiatry to become neurologists, leaving alienists ('mad doctors', psychiatrists) to manage idiopathic disorders with no known cure³⁹⁰⁸. Skulls have been trepanned³⁹⁰⁹ since about 8000 BC. It may be that our ancestors wanted to release

spirits causing madness or epilepsy, although they could have been treating depressed skull fractures. Ancient China had institutions for the insane whose inmates remained until they regained lucidity. Yoga, from Vedic India, prescribed measures for the development of a mature personality. Magic played a central role in aetiological and therapeutic considerations until relatively times. Both religion and physical therapy co-existed harmoniously in ancient Memphis circa 3000 BC. According to Homer³⁹¹⁰, illness is based on man as a social creature. In Homer's, the heart was the seat of the emotions, intellect and will, moving to the brain in Hippocratic times³⁹¹¹. (Berrios & Mumford, 1995) Hippocratic medicine owes much

to the earlier rationalism of natural philosophers from the Ionian city of Miletus. (Longrigg, 2001, p. 28) According to the latter³⁹¹², the environment is explicable in physical terms and a supernatural explanation is not required. In other words, disease is impersonal. During mummification in ancient Egypt, the heart, regarded as the seat of the mind, was left inside the body, whilst the brain was pulled out through the nose

³⁹⁰⁷ *Psyche*, mind; *iatros*, a healer. The term was coined by the German professor of medicine Johann Christian Reil (1759-1813) in 1808. Reil was professor in Halle and later on in Berlin. He died of typhus.

Heinroth was appointed to the first chair of psychiatry in 1818. (Leipzig) Von Feuchtersleben introduced the term psychosis in 1844.

Johann Christian Reil

The term 'forensic' comes from the fact that criminals were tried in the ancient Roman *forum*. Roman law held that insane people could not form a malicious intent.

³⁹⁰⁸ This accounts in part for the long delay in establishing psychiatry as a discipline with scientific leanings. (Häfner, 2002)

³⁹⁰⁹ Trephined with sharpened stone tools.

³⁹¹⁰ 8th century BC - of *Iliad* fame.

³⁹¹¹ 5th century BC.

³⁹¹² 6th century BC.

with a hook. The gods measured moral worth by the weight of the heart. (Magner, 1992, pp. 24 & 34) The most famous temple of physical and mental³⁹¹³ healing in ancient Greece was at Epidaurus, which was associated with the god of healing, Asclepius³⁹¹⁴. A brief stay in a culturally valued, non-threatening healing temple is still likely to improve psychopathology in today's India. (Raguram et al, 2002) The *Talmud* recognised the existence of mental illness and the *Koran* enjoins us to treat the insane with humanity and care. Moses, in *Deuteronomy*, warns his flock that failure to heed God's laws will cause Him to 'smite you with madness and blindness and confusion of mind.' Aretaeus of Cappadocia³⁹¹⁵ gave a vivid description of melancholia³⁹¹⁶ in *On the Causes and Signs of Diseases*. He is said to been the first to stress the disturbance of sleep in that condition ('...start up from a disturbed sleep', although Job beat him to it³⁹¹⁷) and is often credited with identifying what would later be known as bipolar affective disorder³⁹¹⁸. Maimonides (1138-1204) was a Rabbi and physician who gave an early description of psychosomatic medicine. Interestingly, he prescribed alcohol for depression, even for Muslims!³⁹¹⁹ Maimonides was a strong believer in patient autonomy despite living in an era of paternalism. (Gesundheit et al, 2008)

Britain & the wider World³⁹²⁰

'As a professional discipline, psychiatry in Britain in Victorian times – if it existed at all – was in an embryonic state'. (Rollin, 2003)

Roman law dictated that authority over a lunatic and his goods belonged to either the paternal line or to the clan, and laws relating to such apparently modern concepts as testamentary capacity were well developed. A return was made to demons and the casting out of evil influences by violent means as the Empire collapsed. A hospital for the mentally and physically infirm was founded at St. Alban's in the last decade of the eighth century by visiting monks. Lessons learned during the Crusades led to the acknowledgement of a difference between psychic and external causes of lunacy.³⁹²¹ A special ward for the insane could be found in a hospital built by al-Mansur in Cairo in 1283 (Udwadia, 2000) with soporific music and distracting tales providing much of the therapy.

First asylums in Continental Europe (Stone, 1997)

Granada, 1365
Hamburg, 1375
Valencia, 1410

Friar Jofré (1350-1417) was so incensed by the public ridicule of the mentally ill that he campaigned for the building of a mental asylum. With monies from local merchants the construction of the Hospital for Lunatics, Insane and Innocents (*Spital Dels Folls, Orats, e Ignocents*) began in 1410 in Valencia, Spain. (Aldana et al, 2010)

St. Mary of Bethlehem (Bethlem, Bedlam) Hospital, a priory³⁹²² until 1375, was founded at Bishopsgate³⁹²³, London in 1247. It moved to Moorfields³⁹²⁴ in 1676, to Lambeth³⁹²⁵ in 1815, and finally to Beckenham in Kent. (Russell, 1997) As mentioned in Shakespeare's *King Lear*, inmates had to beg in the streets: *Tom-o'-Bedlams*. Its early history makes for disturbing reading. (Arnold, 2008, e.g. p. 192) It is interesting that these beggars simulated mental illness using symptoms very similar to what we now call

³⁹¹³ *L. mens* = mind.

³⁹¹⁴ Also known as Aesculapius.

³⁹¹⁵ Lived c.150-200 AD.

³⁹¹⁶ *Melan*, black; *khole*, bile.

³⁹¹⁷ '...nothing of my own but nights of grief. Lying in bed I wonder, "When will it be day?" Risen I think, "How slowly evening comes!"' (See *Job* 7: 1-4, 6-7.)

³⁹¹⁸ Falret's *folie circulaire* and Baillarger's *folie à double forme*.

³⁹¹⁹ See *Koran* prohibition on alcohol: 2:219;5:90-91.

³⁹²⁰ Because British law applied to Ireland until the 1920s, unless otherwise stated this section focuses on British history.

³⁹²¹ 'Lunacy' refers to the belief that the moon affects our minds, e.g. a full moon causes madness or the mad become disturbed during a full moon. There is evidence against such a malign influence. Early negative research was reported by the Bethlem apothecary John Haslam (1764-1844) in 1809. O'Shea (1989) found that a belief in a lunar effect was brought into psychiatric nursing but that it waned with experience.

³⁹²² Order of the Star of Bethlehem.

³⁹²³ Now Liverpool Street Station.

³⁹²⁴ Mary Lamb killed her mother in 1796 and was placed in Bethlem. She and her brother Charles would become famous for their *Tales from Shakespeare*.

³⁹²⁵ Now the Imperial War Museum.

schizophrenia (Turner, 2010, p. 7), possible evidence against the Fuller Torrey and Miller (2001) theory that schizophrenia is a consequence of modern industry-driven urban living.

Bedlam map about 1558

Lieutenant David Davis shot at Henry John Temple (Lord Viscount Palmerston, War Secretary) on April 8 1818 and was committed to Bethlem on May 1818 from which he sent his auto-amputated penis to Palmerston! Scotland's first mental hospital was founded in 1781 by Mrs Susan Carnegie: the Montrose Lunatic Hospital³⁹²⁶. The Narrenturm³⁹²⁷ of Vienna was built in 1784. An 1812 inscription on the foundation stone of Dundee Lunatic Asylum³⁹²⁸ read: 'To restore the use of reason, to alleviate suffering and to lessen peril where reason cannot be restored'.

Narrenturm

The manner in which the insane were treated varied from incarceration to canonisation³⁹²⁹. Medicine took a detour when it came to mental illness, madness becoming the business of priests. The *Papal Bull* of Innocent III in 1484 gave birth to the Inquisition to be 1489 by *Malleus Maleficarum*³⁹³⁰ composed by the monks Sprenger and Kraemer, a guide to witch identification³⁹³¹. (Baigent & Leigh, 1999) The rare medical man protested the spiritual innocence of epileptics or melancholics. Moslems built special facilities for the mentally ill and employed diets, baths, perfumes, drugs and entertainment in their treatment. Emergence from the Dark Ages led to changed ideas concerning the origins of madness. The *Poor Law Act*, 1601, held pauper support to be a parish responsibility, destitute lunatics included. However, ways were devised to decrease the likelihood of people seeking aid from the parish: they could be thrown out of the parish and so become someone else's problem or they could be housed in one of the new and inhospitable

³⁹²⁶ Later the Royal Scottish Asylum.

³⁹²⁷ German: 'lunatic's tower'.

³⁹²⁸ The asylum was opened in 1820/1 with 50 inmates, the latter rising to 300 in the late 1870s.

³⁹²⁹ James Norris, confined in Bethlem from 1804-1813, was riveted into an iron harness and chained to a post by an iron collar. The great witch-hunts of the Inquisition found many victims among the mad. This was a time of mass hysteria in nunneries and the whipping of the base flesh.

³⁹³⁰ 'Hammer of Witches': this notes that Irish fairies are generally benevolent creatures! See section on the German physician Johannes Weyer.

³⁹³¹ King Coloman 'the Scholar' of Hungary (ruled 1095-1116) banned inquisition against witches since 'no such creatures exist'. (Csorba et al, 2003, p. 30) Laws prescribing the punishment of witches in England were repealed in 1736.

1180

workhouses. Vagrant paupers were placed in Bridewells³⁹³² if they refused to work. If a madman broke the law he was cast into prison. Better-off lunatics were boarded out with doctors or priests. Private lunacy houses³⁹³³ were developed eventually and provided a high percentage of places for the confined mad in England for many years. These were outside the law with the lunatic inmate at the proprietor's mercy. It was in the second half of the 17th century that Bedlam earned its infamous title. (Porter, 2004, p. 128) The inmates were prodded by paying visitors through bars³⁹³⁴, a practice that lasted up to circa 1770³⁹³⁵. (Porter, 2001a, p. 94) Some lunatics who remained at home were chained in outhouses under conditions more reminiscent of chicken runs.

The second half of the 18th century saw the opening of public madhouses. Interventions now offered to madmen make for strange reading today, e.g. ice-cold baths, leeches, phlebotomy, stretching on the rack, and scarification. These approaches were little different from those used in other branches of medicine. (e.g. Robins, 1995, p. 48) Opinions on the benefits of bloodletting varied within medicine, William Battie (1703-1776) of St Luke's stating it to be harmful in *A Treatise of Madness*, and John Monro (1715-1791) of Bethlem praising its usefulness in his *Remarks* on Battie's treatise (The Monro dynasty at Bethlem spanned four generations: James, John, Thomas, and Edward, with a fifth generation, at St Luke's Hospital for Lunatics³⁹³⁶ and Brooke House Asylum in Hackney, represented by Henry.). In 1791 Philippe Pinel struck the chains³⁹³⁷ from the male inmates of *Le Bicêtre* in Paris; he did the same for the women of the *Salpêtrière*³⁹³⁸ a few years later.

Salpêtrière

Together with his fellow Quakers, William Tuke³⁹³⁹ (1732-1822), upset by what passed as therapy for the insane, opened *The Retreat* at York in the last decade of the 18th century; the theoretical model employed, a type of humanistic Christianity, was called 'moral' treatment.

York retreat

A 1763 Select Committee of the House of Lords reported that some asylum admissions were purely an answer to family and social problems³⁹⁴⁰. (Leigh, 1961)

³⁹³² The original Bridewell, a house of correction, was in London. The name stuck elsewhere, including in Dublin.

³⁹³³ 'Trade in lunacy'. The English *Vagrancy Act*, 1744, distinguished between lunatics and paupers, thereby spurring the development of the private asylum. Inmates either paid themselves or were funded by parishes.

³⁹³⁴ Lunatics were displayed in wooden cages for the amusement of paying visitors in Vienna until the mid-19th century. (Moussaoui, 2002, p. 60)

³⁹³⁵ Public executions at Tyburn continued until 1783.

³⁹³⁶ Founded 1751.

³⁹³⁷ Largely figuratively. (Duffin, 2000)

³⁹³⁸ Built as an arsenal in the early 17th century, later an asylum for beggars, prostitutes and insane; largest poorhouse for women.

³⁹³⁹ A retired tea merchant, Tuke and others were dismayed by the poor treatment and demise of a Quaker from Leeds (Hannah Mills, a melancholic) in the York Asylum in 1790.

³⁹⁴⁰ An early version of the 'gaslight' phenomenon or an acknowledgement of Michel Foucault's (Foucault, 1961) 'great imprisonment of madness' (also called the 'great confinement') aimed at excluding the unruly insane? Second sons were over-represented in Irish asylums probably because of lack of prospects, frustration, and alcohol abuse. López-Ibor (2002, p. ix) points out that asylums were a repository for people deemed a nuisance to society.

The *Criminal Lunatics Act* of 1800 was unsatisfactory. A subsequent official enquiry led to recommendations for the setting up of county asylums. The asylums were to be financed by local rates and admissions and discharges were to be under legal control. The disposal of criminal lunatics³⁹⁴¹ remained problematic: the first provision for this group consisted of a special wing at Bethlem Hospital³⁹⁴² under Home Office control. Ireland's Central Mental Hospital at Dundrum opened in 1850. Broadmoor Hospital in England was opened in 1863.

The *County Asylum Act* of 1808 gave rise to many large mental institutions³⁹⁴³. Early asylums³⁹⁴⁴ were relatively cheap to build, the general standard of living being low. Paying patients might be admitted in order to lower rates on the county and the physician was paid on a *per capita* basis. Until well into the nineteenth century, physicians were confined to treating the physical ailments of inmates. (Häfner, 2002) An early distinction arose between short-stay wards and 'back wards'. (Jones, 1991) Outrage at the conditions of inmates³⁹⁴⁵ led to the formation of visiting committees (justices) reporting to the Home Department.

The first American insane asylum was at Williamsburg, Virginia (1773). Moral treatment³⁹⁴⁶, a lay-instigated and non-medical approach characterised by 'gentle humanitarianism coupled with enlightened rational optimism', (Goldstein, 2004) was employed at the Friends Asylum for Persons Deprived of the Use of their Reason, built in 1813, the first private American asylum. Thomas B Kirkbride (1809-1883), an important figure in the early Association of Medical Superintendents of American Institutions for the Insane³⁹⁴⁷, trained at Friends. Kirkbride, influenced by Dorothea Dix, wrote *On the Construction, Organization and General Arrangements of Hospitals for the Insane* (1880) and viewed asylum care as superior to "inhumanity and barbarity"³⁹⁴⁸.

Dorothea Dix (1802-87)

The New Hampshire Asylum for the Insane, founded in 1842, had many patients with diagnosed "religious excitement", which did not prevent their being treated with obligatory attendance at religious service! Clifford Beers, a former patient, exposed the wretched living conditions of American asylum residents in 1908. He, Adolph Meyer, and William James founded the National Association for Mental Health in 1909.

³⁹⁴¹ Those insane who had fallen foul of the law.

³⁹⁴² It opened in 1816 following the firing of shots at King George III by Hadfield in 1800. Hadfield was found not guilty by reason of insanity. Physical treatments such as cold baths and drugs were also used.

³⁹⁴³ English and Welsh county and city asylums contained just over a thousand inmates in 1827, increasing to 77 asylums and over 74,000 inmates in 1900. During the same period the average number of inmates in an asylum jumped from 116 to 961. (Andrews, 2004, p. 302) By 1944 there were 17 public county asylums, 11 mixed public-private asylums, and 139 private licensed houses. (Andrews, 2004, p. 301)

³⁹⁴⁴ "Stately homes for the lower classes". James and Barrett (2007) make the point that the asylum inmate was further isolated by the fact that asylums were built in the countryside when the rural population were fleeing to cities. They also say that isolation is compounded today by residence in suburbia which empty during working hours!

³⁹⁴⁵ Historical judgements on the living standards in asylums often conveniently forget the abysmal living standards of most citizens that existed up until recent times. (cf. for example Robins, 1980, 1995) This is not to say that they were ideal, far from it. (Robins, 1993, p. 120) For rules governing approved centres in the Republic of Ireland see *Mental Health Act 2001 (Approved Centres) Regulations 2006*.

³⁹⁴⁶ Meaning psychological/non-somatic but with moral undertones: included in the package might be isolation from external sources of stress, questioning of aberrant thinking, physical restraint, entertainment, etc.

³⁹⁴⁷ 13 superintendents met at Jones Hotel in Philadelphia in 1844 to form this organisation, its first president being Samuel Woodward of Worcester, Mass. It would become the American Medico-Psychological Association (MPA) in 1893, and the American Psychiatric Association (APA) in 1921. (Butler, 1887)

³⁹⁴⁸ Oregon State Hospital, 1883-2008, developed its asylum milieu based on Kirkbride's ideas of moral treatment. It was the location for the movie *One Flew Over the Cuckoo's Nest* (1975), based on the book by Ken Kesey (an Oregonian) who had at a Californian VA hospital. Cremated remains of thousands of former inmates were kept in storage room and discovered in 2004! (Lazarus, 2009)

Adolf Meyer (1866-1950)

The use of pet animals for the comfort of patients in 19th century asylums continues to find advocates.(Allderidge, 1991)

In the 1830s the total abolition of restraint was advocated by John Conolly (1794-1866) at Hanwell Asylum, itself opened as the result of the exposure of brutal practices elsewhere. It was Conolly who was responsible for the opening of Colney Hatch Asylum in 1849³⁹⁴⁹. There, medical duties were divided between administration and the classification of inmates.

John Conolly

The *Madhouse Act* of 1828 sought to prevent collusion between the certifying physician and the owners of asylums. The *Lunacy Act* of 1845 gave birth to a National Lunacy Commission with responsibility for all types of institutions throughout the country, from prisons to madhouses. Few asylums were built after 1920³⁹⁵⁰.

A Swiss doctor, Guggenbuhl, founded the first special residential institution for the mentally handicapped in 1841 in Abendberg. Jean Mark Gaspard Itard (1774-1838), a Parisian asylum doctor, tried to treat, Victor, the twelve year old feral³⁹⁵¹ 'Wild boy of Aveyron' in 1801, giving up in failure after six years. Edouard Seguin (1812-1880) opened his own school for the mentally retarded after training under Itard³⁹⁵². In British India, from the early 19th century, a policy of repatriation of the mentally ill back to England was used to disguise such vulnerability from the natives. Indian asylums were internally segregated according to race, class and sex.(Ernst, 1991)

It should be noted in passing that medical registration was established in 1858, the profession being disparate and unorganised before that date.

Treating the insane: rotating chair

³⁹⁴⁹ Friern Hospital from 1937 until it was closed in the 1990s.

³⁹⁵⁰ In England and Wales the number of lunatic asylums increased from nine in 1827 to almost 100 in 1920, the average number of inmates per asylum increasing from about 100 to nearly 1,000 in the same period.

³⁹⁵¹ The boy was probably autistic.

³⁹⁵² Later, in the USA, Seguin used peripheral stimulation in the hope of improving central nervous function, so-called 'sense training'.

The superintendent of the Devon County Asylum, Sir John Charles Bucknill (1817-97), of Exeter, founded the *Asylum Journal* in 1853. The original Association of Medical Officers of Asylums and Hospitals for the Insane (AMOAHI) dates back to Dr Samuel Hitch. (Foster, 2004) He was resident superintendent of the Gloucestershire General Lunatic Asylum. Hitch wrote to colleagues in England, Ireland and Scotland in 1841 suggesting that an association be formed³⁹⁵³. The AMOAHI was replaced by the Medico-Psychological Association (MPA), the first president being W A F Browne, Commissioner of Lunacy for Scotland³⁹⁵⁴. The early MPA felt that it had to persist in its endeavours despite a hostile public perception of psychiatry. (Turner, 1991) In 1926 the MPA received a Royal Charter, becoming the RMPA. Its first president was John R Lord of Epsom³⁹⁵⁵.

The first words of *The Asylum Journal*³⁹⁵⁶ were: 'From the time when Pinel obtained the permission of Couthon to try the humane experiment of releasing from fetters some of the insane citizens chained to the dungeon walls of the *Bicêtre*³⁹⁵⁷, to the date when Conolly announced, that in the vast Asylum over which he presided, mechanical restraint in the treatment of the insane had been entirely abandoned and superseded by moral influence, a new school of special medicine has been gradually forming'. The *Journal of Mental Science* replaced the *Asylum Journal* and was itself replaced by the *British Journal of Psychiatry*³⁹⁵⁸ since 1963.

*The American Journal of Insanity (of Psychiatry)*³⁹⁵⁹ from 1921), the official journal of the Association of Medical Superintendents of American Institutions for the Insane, was founded in 1844.

The *Idiots Act* of 1886 made the simple distinction between greater (idiot) and lesser (imbecile) degrees of mental handicap. The first psychiatric ward attached to a general hospital was opened at Guy's Hospital in 1728. The first such unit to be opened in the USA was at the Albany Hospital in 1902. Ireland's first such unit was opened in Waterford³⁹⁶⁰ in 1967.

³⁹⁵³ The AMOAHI originally had chairmen (of meetings or sessions) – the first was Andrew Blake of Nottingham in 1841, but the most famous was John Conolly (1843 and 1851). Presidents were introduced in 1854 (A. J. Sutherland of London), and included Conolly (1858), Bucknill (1860), Joseph Lalor (Richmond Asylum, Dublin, 1861) and Henry Monro (Clapton).

³⁹⁵⁴ Other presidents included Maudsley of Hanwell (1871), James F. Duncan [took over from his father at Farnham House private asylum, Finglas – he was also vice-president of the College of Physicians] of Dublin (1875), J A Eames of Cork (1885), Conolly Norman of the Richmond Asylum (1894), Oscar T Woods of Cork (1901), W R Dawson of Dublin (1911), and Michael J Nolan of Downpatrick.

³⁹⁵⁵ Other holders included R R Leeper of St. Patrick's Hospital, Dublin, (1931) John Dunne (Grangegorman, formerly the Richmond Asylum; 1955), William McCarten of Northern Ireland (1961), Desmond Curran (London, 1963), and Erwin Stengel (Sheffield, 1966). The first female president was A H A (Helen) Boyle (1939).

John Dunne

³⁹⁵⁶ November 15, 1853, price 6d.

³⁹⁵⁷ A former Carthusian monastery and part of the General Hospital of Paris from 1610.

³⁹⁵⁸ The editors of the latter were Eliot Slater, Edward H Hare, J L Crammer, Hugh Freeman, and Greg Wilkinson, the current editor being Peter Tyrer.

³⁹⁵⁹ Its first editor, until 1849, was Amariah Brigham (1798-1849), superintendent of the New York State Lunatic Asylum. The current, and twelfth, editor is Robert Freedman who took over from Nancy C. Andreasen of Iowa.

Amariah Brigham

³⁹⁶⁰ Tom Lynch (1922-2005; see picture) in charge: later Professor of Psychiatry, Royal College of Surgeons, Dublin.

The *Lunacy Act* of 1890 maintained that a patient could be received into a mental institution if a relative, supported by two doctors, petitioned a justice. Other provisions entertained by the Act included an emergency order of short duration and special inquiries in the case of aristocrats. The same legislation allowed and for uncensored forwarding of certain letters written by inmates and for the relegation of restraint to the status of a specific medical intervention rather than something which any member of staff might apply.

Daniel McNaghten³⁹⁶¹ was found 'not guilty by reason of insanity' by the House of Lords in 1843³⁹⁶². McNaghten had wanted to kill the Prime Minister, but killed his private secretary, Edward Drummond³⁹⁶³ instead. The verdict was changed to 'guilty but insane' after Queen Victoria had been attacked³⁹⁶⁴. The modern version of the McNaghten Rules is as follows: (a) England - 'not guilty by reason of insanity' (changed back to this more recently); (b) Ireland (where the insanity defence is rarely used, probably because its acceptance means prolonged detention) was 'guilty but insane' (3/41 and 3/58 murder cases in 2002 and 2003 respectively) until the *Criminal Law (Insanity) Act* of 2006 when it became 'not guilty by reason of insanity'.

In 1879, Dr Abraham Cowles of the McLean Asylum, Massachusetts, started the first training school for attendants of the insane. Similar teaching was to commence in Scotland shortly after this. The MPA published *The Handbook for Attendants* in 1885, at the same time instituting an examination for doctors for a Certificate of Efficiency in Psychological Medicine, itself replaced by the Diploma in Psychological Medicine (DPM) in 1948.(Renvoize, 1991) The University of Edinburgh had already founded its Diploma in Psychiatry in 1912. The Membership of the Royal College of Psychiatrists (MRCPsych) examination was introduced in 1972.

During the 1890s Connolly Norman³⁹⁶⁵ of the Richmond Asylum³⁹⁶⁶ in Dublin insisted that attendants seeking promotion should pass an exam. Psychiatry became a compulsory part of undergraduate medical education in 1893.

St Brendan's Hospital, Dublin

³⁹⁶¹ An illegitimate wood turner from Glasgow. It is generally held that McNaghten was a paranoiac (delusional disorder) or, favoured by Rollin, (1996) had a schizophrenic disorder. McNaghten was placed in Bethlem Hospital but was eventually moved to Broadmoor Asylum, dying there on 3rd May 1865 aged 52 years.

³⁹⁶² A year later it became possible to transfer a sentenced prisoner to a criminal lunatic asylum (now 'special hospitals').

³⁹⁶³ 20 January 1843: shot in the back.

³⁹⁶⁴ Hit over the head by Lieutenant Robert Pate's walking stick and shot at by John Francis, William Bean and Edward Oxford.

³⁹⁶⁵ President RMPA and vice-president RCPI.(Walsh, 2009b)

³⁹⁶⁶ Ivor Browne's reaction when he saw this hospital (Grangegorman, St Brendan's) in 1959 (Browne, 2008, p. 67) was: 'There was a cacophony of sound and I felt as though I was lost in some kind of hell'.

Connolly Norman

The 1913 *Mental Deficiency Act* described mentally handicapped persons who from an early age showed strong 'vicious or criminal propensities' that were uninfluenced by punishment. A consequence of this Act was the locking away in asylums for long periods of retarded individuals who had outraged public morals, including girls who had become pregnant.

The case of Sir Roger Casement provides an example of how homosexuality was viewed publicly in the early part of the 20th century: following the 1916 rebellion in Ireland, Casement was sentenced to death. 'There were murmurs of a demand for reprieve. To silence these, the British government circulated passages, perhaps genuine, from Casement's diary, showing that he was homosexual. The demand was silenced. Casement was hanged.' (Taylor, 1981)

The theory of 'autointoxication' was popular early in the 20th century. For example, Henry Cotton of Trenton in the USA (d. 1933) pulled out patients' teeth and removed their colons in a vain attempt to cure mental disorder. Earlier, in the 1860s, Gustav Broun cauterised the clitoris and uterine cavity to reduce masturbation in women. (Porter, 2001b, p.105) Robert Battey made the removal of normal ovaries a popular procedure for women suffering from a variety of nervous disorders from the 1870s. (Porter, 2001b, p.228)

Masturbatory insanity (*onanism*³⁹⁶⁷)

Masturbation, a common human activity,³⁹⁶⁸ may be more overt among the mentally ill and may have become more obvious to medical practitioners when patients started to be admitted to asylums. Physicians who decried the myth were accused of supporting immorality. Denial of masturbation was often met with disbelief and guilty depressives often exaggerated their sins. Onan (*Genesis* 38.7-10) was punished for spilling his seed upon the ground, i.e. *coitus interruptus*. St Thomas Aquinas (1225-1274) stressed that sex was for marriage and only for procreative purposes. In 1708 the Dutch physician Herman Boerhaave (1668-1738) wrote that 'too lavish' a discharge of semen led to a wide variety of nervous problems that included convulsions, and dullness of the senses! S A D Tissot, a Swiss physician, published an influential book on the subject in 1758 which contained similar dire warnings. Benjamin Rush of Philadelphia published a book in 1812 in which he mentions masturbation as a cause of madness, impotence, poor sight, amnesia, and death! The effects of masturbation were considered to affect the health of offspring, perhaps an early attempt at epigenetic theorising! The Victorian gynaecologist Isaac Baker Brown FRCS (1812-1873: Fleming, 1960; Sheehan, 1985; Hare, 1998, ch. 8) practiced clitoridectomy³⁹⁶⁹ on women to prevent masturbation (a cause of insanity in his eyes) and as a cure for nymphomania! He was expelled from the Obstetrical Society in 1867 and his theories about masturbation were contradicted by Henry Maudsley, although Maudsley had earlier been an adherent of masturbatory insanity himself.³⁹⁷⁰ Kraepelin, writing in the 1890s, was categorical that masturbation never causes madness. Krafft-Ebing believed that homosexuality could stem from masturbation. Whilst belief in masturbatory insanity lingered on into the first half of the twentieth century it eventually gave way, in orthodox circles at least, to the view that, apart from religious considerations, the main consequence of masturbation *per se* was guilt.

A not dissimilar theory was that suppression of the flow of body fluids (e.g. nose bleeds, breast milk, and menstrual fluid) led to insanity.

³⁹⁶⁷ Onanism is a broader term than masturbatory insanity and includes penile withdrawal during intercourse.

³⁹⁶⁸ This was known to the great John Hunter who opined in 1786 that a rare phenomenon like lunacy could not be ascribed to a common practice like masturbation.

³⁹⁶⁹ Labia resection was to follow in due course. Males were sometimes subjected to infibulation (wring of the foreskin to prevent its movement)!

³⁹⁷⁰ Maudsley eventually came to the view that masturbation might be a symptom rather than a cause of madness. However, he believed that neurotic disorders could be caused by masturbation.

Forced sterilisation of the mentally ill began in Germany in 1936, with Hitler signing an order three years later which allowed for the gassing (carbon monoxide) of incurables, a situation which was opposed by a minority of psychiatrists (and others). (Meyer-Lindenberg, 1991; Burleigh, 2000, especially pages 29, 57, 126, 349, 379)

Perhaps the most famous case of post-influenzal depression was that of the American president, Woodrow Wilson, who was to suffer from it in 1919 during the peace conference in Paris (Churchill, 1933). In 1958, the South African, Joseph Wolpe (1915-97: later worked in Philadelphia), published *Psychotherapy by Reciprocal Inhibition*, and went on to develop the treatment known as systematic desensitisation. The Mowrers invented the bell and pad treatment for nocturnal enuresis in 1938.

Joseph Wolpe

The 1930 *Mental Treatment Act* allowed for three admission categories, one of which recognised the person who might be admitted voluntarily (and might discharge himself by giving three days notice). This was later replaced by the 1959 Mental Health Act, which removed judicial involvement in civil admissions and replaced the term 'voluntary' with 'informal'. The earlier association of asylums with only involuntary care may have branded them as places one sent people to as a final resort. (Porter 2001b) The current legislation is the *Mental Health Act* 1983 (England & Wales) although this is likely to change soon. The English *Homicide Act* of 1957, reflecting a long tradition in Scotland (Walker, 1968), permitted a defence of diminished responsibility to a charge of murder. If successful, the conviction is of manslaughter, allowing the judge wider choice of disposal. This reduced the use of the 'not guilty by reason of insanity' plea (*vide supra*). The *Irish Criminal Law (Insanity) Act* 2006 permits a defence of diminished responsibility.

An out-patient clinic³⁹⁷¹ was opened at St Thomas' Hospital, London, by Dr T Rayner in 1889, one year after John Chapin had done the same at Pennsylvania General Hospital. (Shorter, 1997) By 1936 the number of such clinics in England and Wales stood at 166. Dr J Carse of Graylingwell Hospital, Chichester, started the 'Worthing Experiment' in 1957: a day hospital³⁹⁷², out-patient clinic, and domiciliary service reduced admissions from Worthing by 59%. (Carse et al, 1958) The first occupational therapy school was opened at Dorset House, Bristol by Dr Elizabeth Casson in 1930, and the Association of Occupational Therapists was formed six years later.

The launch of the National Health Service in 1948 initiated the difficult process of integrating mental health services with the general body of medical services, thus, at least *de jure*, freeing them from 'the taint of the Poor Law and lunacy code'. (Webster, 1991) The National Institute of Mental Health (NIMH), part of the federal National Institutes of Health of the US Department of Health and Human Services, was founded in 1946 with responsibility for research on causes, treatment and prevention of mental illness.

The 1950s saw the start of the 'open door movement'. In fact open doors were to be found in Fife and Kinross Asylum in the 1870s under Dr John Batty Tuke, no relation of the York Tukes. By 1956 there were seven hospitals in England with no locked wards, after a renewal of locking-up during the staff-shortages of World War II. In 1963, John F Kennedy gave the only presidential message to Congress on mental illness and intellectual disability, leading to the establishment of Community Mental Health Centres (CMHCs). These were poorly funded and catered for the less mentally disturbed. Jimmy Carter established a President's Commission on Mental Health in 1977 which increased funding for community psychiatry³⁹⁷³. However, Ronnie Reagan repealed this legislation in 1981, before it could be implemented. More recently, Americans have experienced managed care and privatisation. (Duckworth & Borus, 1999)

³⁹⁷¹ Gk., *kline*, a bed.

³⁹⁷² Joshua Bierer opened the Marlborough Day Hospital, in a house that once belonged to Charles Darwin's associate Thomas Huxley, around the same time. A night hospital was situated in the stables, at first operating weeknights but later also at weekends. (Browne, 2008, p. 70)

³⁹⁷³ Via an Act of 1980.

'Total institution' (Goffman, 1961)³⁹⁷⁴

Described the worst aspects of asylum life³⁹⁷⁵

Inmates did everything in the one spot

Everything was regulated

Absence of social roles found in general life

Nurses decided on medical visitation and 'carried' the hospital culture

Progressive loss of patient autonomy

The British *Criminal Procedure (Insanity and Unfitness to Plead) Act* of 1991 abolished automatic detention for an indefinite period for defendants found unfit to plead, so ending what professionals had long viewed as an injustice. People found unfit to plead before this legislation could be detained in hospital without any finding as to guilt or innocence.

Seebohm Report (UK)

In 1974 social services were reorganised

Provision of social work services to hospitals became a local authority responsibility

Specialist psychiatric social workers³⁹⁷⁶ (PSWs) were absorbed into the pool of 'generic' social workers

The Swede Magnus Huss introduced the term alcoholism³⁹⁷⁷ in 1851, although Thomas Trotter, a former Navy doctor, had described the 'habit of drunkenness' as a 'disease of the mind' in his 1804³⁹⁷⁸. In 1915, Lloyd George introduced restrictions on drinking hours to promote sobriety in the workforce which helped to reduce alcohol consumption for a decade. During *Prohibition* in America the number of deaths from hepatic cirrhosis fell significantly, but organised crime became a major problem. Alcoholics Anonymous (AA), taking its name from a book title, was founded in Akron, Ohio in 1935 by two alcoholics³⁹⁷⁹. Gamblers Anonymous (GA) was founded in Los Angeles in 1957.

The first report of Mad Hatter's disease (mercurialism) came from New Jersey in 1860, five years after Lewis Carroll's *Alice in Wonderland*. (O'Carroll et al, 1995) It is said that Carroll³⁹⁸⁰ suffered from temporal lobe epilepsy which might account for his characters passing through mirrors or changing in size. The professional history of anorexia nervosa (AN) goes back at least to 1694 and Richard Morton's 'nervous consumption', distinguishing such cases from tuberculous *phthisis*; and Lasague coined the term 'hysterical anorexia' in the same year as William Gull (1874) published his paper containing the modern name of the condition in its title, although Gull had discussed the problem at Oxford and in the *Lancet* six years previously. (Gull, 1868) Lasague of Paris is credited with the simultaneous description of AN, calling it *anorexie hysterique*. Between 1914 and 1949 it was confused with Simmond's disease, AN patients being treated with pituitary extract. Gerard Russell (1979) described his 'ominous variant' of AN, bulimia nervosa, (BN) twenty years before binge eating disorder was described by Stunkard in 1959. (Stunkard, 1959) although the latter may overlap considerably with non-purging BN. (Garfinkel, 1999) In 1993, using loss of 'disability adjusted life years' or DALYs, the World Bank concluded that psychiatric illness was second only to cardiovascular disease worldwide in economic terms. (World Bank, 1993) Subspecialty status for the psychiatry of old age was granted by the Royal College of Psychiatrists in 1989. The two major classification systems used in psychiatry date from 1948 (*International Classification of Diseases* of the World Health Organization: ICD-6) and 1952 (*Diagnostic and Statistical Manual* of the

³⁹⁷⁴ The sociologist Andrew Scull (2010), in a very negative overview of psychiatry, suggests that modern medicines had only a minor role in the closure of large Victorian institutions and that the main reasons for such changes were to save money. Scull also warns us to beware of pharmaceutical industry sponsorship (e.g. non-publication of 'inconvenient data'). It was Scull (1979) who described asylums as 'museums of madness'.

³⁹⁷⁵ Rare disasters have occurred in closed asylums, such as the deaths of many inmates from fire. (Rollin, 1989)

³⁹⁷⁶ The 'approved' social worker, with a statutory role in committal procedures, was a child of the Mental Health Act 1983.

³⁹⁷⁷ The word alcohol comes from the Arabic for essence, *Al kahl*.

³⁹⁷⁸ In his classic *Essay Medical Philosophical and Chemical on Drunkenness*.

³⁹⁷⁹ 'Bill W', (1895-1971) a New York stockbroker, and 'Dr Bob S', (1879-1950) a surgeon from Akron. The first meeting in Europe was held in the Country Shop Restaurant, St Stephen's Green in Dublin on November 18, 1946.

³⁹⁸⁰ His real name was Charles Lutwidge Dodgson (1832-1898).

1188

APA: DSM-I³⁹⁸¹). The current forms, which are less divergent in content than their predecessors, are ICD-10 (1992) and DSM-IV (1994) respectively.

Ireland

A number of terms were commonly used in Ireland during the seventh and eight centuries (see box), the time of the *Brehon Laws*. *Brehon* refers to justices who travelled early Christian Ireland. Under these Laws, the *conn* or guardian of an insane perpetrator was often held responsible for his actions.

Some old Irish terms

Cailleach - old hag who was able to transfer mental illness from one person to another

Madman's wisp - pre-Christian ball of straw or grass thrown in someone's face by a Druid, unfortunate victim going mad

Dásachtach - potentially violent manic person ('battle madness' of the Celts)

Mer - a less dangerous deranged person

Drúth - intellectually disabled person or a professional clown who mimics a mad person

Glen-na-Galt (Valley of the Madman) - possibly on the Dingle Peninsula in County Kerry, although there were many such valleys; mentally ill people who drank there from a holy well known as *Tobair-na-Gealt* were often said to recover their senses

St Dymphna, an Irish princess, fled to Belgium from her incestuous father, only to be murdered by him at Gheel, which later developed into a famous home-care centre for the mentally ill and retarded.

Following the death in 1745 of Jonathan Swift, Dean of St Patrick's, and using money that he left in his will, St. Patrick's Hospital, Dublin 8, was founded a year later³⁹⁸².

St Patrick's Hospital, Dublin

During the early 19th century, 'mad' peasants were sometimes kept in a hole in the cabin floor with a crib over the opening.(Shorter, 1997) Many Irish lunatics were incarcerated in gaols and houses of industry.(McClelland, 1988) In 1773, the House of Industry was opened at North Brunswick Street³⁹⁸³ for the relief of the poor of Dublin City³⁹⁸⁴. The *Prisons Act* of 1787 allowed for the establishment of lunatic wards in Houses of Industry.

Norman Moore (1911-1996)

³⁹⁸¹ DSM-I was a response to the Veteran's Administration post-war diagnostic handbook.

³⁹⁸² Its first inmates were received some years later. The St Edmundsbury Estate (Lucan) was added in 1898.(Malcolm, 1989)

³⁹⁸³ Under 1772 legislation.

³⁹⁸⁴ Other similar houses were opened in Clonmel, Cork, Waterford, and Limerick.

Money became available to start building the Richmond Asylum in 1810.(O'Shea & Falvey, 1996) This Asylum remained as the 'Lower House' (of St. Brendan's Hospital) until it was closed in 1989, having had its first admission in 1814. The first Irish asylum for the mentally handicapped was opened in Dublin in 1869: the Stewart Institution for Imbecile Children.

1817 saw the establishment of a national asylum system for Ireland, far ahead of other countries³⁹⁸⁵. Also, Irish admission rates increased faster than in England. Now, as then, single males are the most commonly admitted group, and it has been speculated that 19th century inheritance and emigration practices (young women leaving, second or other sons being admitted for violence rather than illness) favoured this outcome. Families were the main initiators of admission, not doctors or politicians.(Malcolm, 1999) Immigration was thought to have left lunatics and idiots behind without healthy people to look after them. Also, returned emigrants may have become mentally ill as a result of their experiences. Society gradually became less tolerant of the insane and overcame any reluctance to incarcerating them. Increased longevity may have made the mentally ill more obvious in society.(Walsh & Daly, 2004) Also, asylums gave jobs to the local community (often over many generations), which may have played a part in resistance to their closure. Lastly, there was the 'pressing need to remove lunatics from prisons and workhouses'.(Stevenson, 2004, p. 1505)

Connaught Lunatic Asylum (St Brigid's) opened 1833

A French Law of 1838 'played a critical, if indirect, role in' establishing 'a collective professional identity' among French psychiatrists/alienists.(Goldstein, 2004) It mandated the building of a national network of asylums staffed by doctors appointed by the Minister of the Interior³⁹⁸⁶. French physicians could not understand the absence of full-time doctors in British (or Irish) asylums.(Goldstein, 2004; see Walsh & Daly, 2004, p. 85)

1846 saw the opening of an Office of Lunacy in Dublin Castle. Dr Francis White was appointed Inspector of Lunatics, joined some time afterwards by Dr John Nugent³⁹⁸⁷.

In 1884 there were 45 asylums in all of Ireland³⁹⁸⁸. According to a Select Committee of 1814/15, corpses were simply left in some rooms where there were patients, and two or three patients were in the one single bed. In 1861, Ireland officially had 7,065 lunatics and 7,033 idiots, both categories being divided equally between the sexes. On 31.12.1883 the total number of registered lunatics in Ireland amounted to 14,088. These were kept in the various asylums and in the 163 poor houses. (Miles, 1988) An 1867 Act³⁹⁸⁹ authorised magistrates to commit dangerous lunatics and idiots to mental asylums, shortly becoming the main instrument by which any mentally disordered person could be compulsorily detained in an asylum,(Reynolds, 1992) being criticised by Norman (1886) as a social policing policy, and leading inevitably to gross overcrowding in district asylums. McClelland (1988) posits two chief reasons for the increase in Irish asylum provision³⁹⁹⁰: recognition of the numerical frequency of the problem in the community and the prevailing poverty that meant that relatives could not afford home-based care.(see Walsh, 2008) By World War I, Ireland had a resident insane population of 0.5% of total population³⁹⁹¹.(Bartlett & Wright, 1999) Overcrowding was a major obstacle to any hopes of rehabilitating inmates.(Andrews, 2004, p. 315)

³⁹⁸⁵ 1838: France & Switzerland; 1845: England & Wales; 1848: Norway; 1850: Belgium; 1857: Scotland.

³⁹⁸⁶ It also inspired the founding of a psychiatric journal (*Annales médico-psychologiques*) in 1843.

³⁹⁸⁷ Nugent had been physician to Daniel O'Connell.

³⁹⁸⁸ 22 district, 22 private, and one criminal.

³⁹⁸⁹ 30 + 31 Vic. c. 118

³⁹⁹⁰ The total number of registered insane in 1890 was 16,159 (8,115 males, 8,044 females): 11,180 in district (public) asylums; 4,165 in poor-houses; 637 in private asylums; 176 criminally insane; and one (!) in gaol.(Anonymous, 1891)

³⁹⁹¹ England and Wales had a figure of 0.37% by 1909; and Scotland had similar rates of residence.

Cover of Ireland's first textbook of psychiatry

In 1810, William Saunders Hallaran³⁹⁹² (1765-1825) of Cork, viewed as one of the founders of Irish psychiatry, published the first edition of *An Enquiry into the Causes producing the Extraordinary Addition to the Number of Insane together with Extended Observations on the Cure of Insanity with Hints as to the Better Management of Public Asylums for Insane Persons*³⁹⁹³, anticipating therein much of the basic ideas of moral treatment, although he was the 'inventor'³⁹⁹⁴ of a rapidly revolving chair for the treatment of insanity. (Williamson, 1970) He also advocated art therapy and early discharge. Kelly (2010), while discussing the modern early intervention in psychosis debate, suggested that Hallaran advocated early, frequent and prolonged use of emetics in psychotic patients and quoted Hallaran as insisting that patients became more subdued as a result of this intervention!

The Irish Division of the MPA was formed in 1872, but many Irish alienists were members before this time. The Resident Medical Superintendent (RMS) became the undisputed authority, albeit answerable to a Board of Governors, in 1862. In 1892, the post of visiting physician was abolished, removing a former source of power struggles with RMSs. The first female member of the MPA, Eleanora Fleury, a clinical assistant at Dublin's Richmond Asylum, was nominated by its president, Connolly Norman (1853-1908), in 1894.³⁹⁹⁵ Walsh (1992a) hailed Norman as 'probably the most far-sighted and perceptive of all Irish psychiatrists'.

Asylums become known as psychiatric hospitals following the 1925 *Local Government Act*. In 1947 the law for the first time allowed for the admission of voluntary patients to Irish psychiatric hospitals under the *Mental Treatment Act* of 1945. (Robins, 1986) A *Health (Mental Services) Act* of 1981 never came into effect and the *Mental Health Act 2001* is the current legislation³⁹⁹⁶. The last Act is a product of concern over civil liberties. (Mills, 2001)

The Brothers of St John of God arrived in Ireland in 1879 and, starting from Clonmel, offered services for the mentally ill and handicapped throughout the country. The headquarters is at Stillorgan.

In recent years the high walls around institutions were torn down, community-based services were developed to a variable degree, psychiatric in-patient and outpatient services were developed at general hospitals. (Rose, 2001) Sectorisation³⁹⁹⁷ was pressed by the Government. Ireland has similar problems to the UK when funding its community-based endeavours. (O'Shea, 1998b)

³⁹⁹² He is known as the 'first Irish psychiatrist'. 1799 saw the opening of a private Cork asylum, Citadella, which he opened. He was a former pupil of William Cullen of Edinburgh. Alexander Jackson (1767-1848) was the first physician to the Richmond Asylum, Dublin, from 1815; started private asylum, *Farnham*, at Finglas north of Dublin.

³⁹⁹³ The 1818 edition was titled *Practical Observations and the Causes and Cure of Insanity*. Both editions were published by Edwards and Savage of Cork.

³⁹⁹⁴ In fact he was inspired by Dr Edward Mason Cox (1763-1818) of Scotland who invented his own suspended chair. (Kelly, 2008)

³⁹⁹⁵ Dominic Corrigan, the famous Dublin physician, was abhorred!

³⁹⁹⁶ The Government there seemed set on increasing social control through psychiatry according to Moncrieff. (2003). The 2001 Act has considerable resource implications and caused some unease when it was introduced. (Clinton, 2002)

³⁹⁹⁷ A sector is a unit of 25-30,000 population, and run by a consultant psychiatrist.

Involuntary admission rates remained high compared to England & Wales and Italy.(Daly & Walsh, 2000) Italian legislation in 1978 forced a movement out of mental hospitals and into the community and acute in-patient units, but ‘many in-patient facilities [show] significant limitations in terms of architectural and logistic characteristics’.(De Girolamo et al, 2007)

Pope John XXII³⁹⁹⁸ cut attempted suicides off from the sacraments until they had repented. The Brahmins of India practiced suttee where widows fell on the pyre of her late husband³⁹⁹⁹. The Code Napoleon decriminalised suicide in France in 1810. An 1823 Act in Britain abolished the practice of burying suicides and murderers in unconsecrated ground.(Arnold, 2007, p. 187) Under the provisions of the *Suicide Act 1991*, Ireland caught up with Britain (*Suicide Act 1961*) and suicide ceased to be an illegal act, although anyone who counsels or procures the completed or attempted suicide of another shall be liable to conviction or indictment to imprisonment for a term not exceeding ten years (14 years in England). Examples of mass suicides are Masada in Israel where Jews died on top of a mountain in order to avoid capture by the besieging Romans in AD 73, Saipan in 1944 where Japanese civilians jumped off Banzai Cliff to evade US soldiers, and Jonestown, Guyana in 1978 where 918 Americans, including 274 children, led by Jim Jones, founder and leader of the ‘Peoples Temple’ committed suicide.

Anthony Clare (1942-2007)

Finally, in 2002, the then Irish Division of the Royal College of Psychiatrists spawned separate Sections for the Republic and for Northern Ireland. This move, following hard on the heels of the inauguration of the Irish Psychiatric Association, was in response to the necessity of having a separate organisation to deal with issues directly relating to the Republic. In 2002 the Republic Section of the Irish Division became the Irish College of Psychiatrists (*Coláiste Síciatraithe na hÉireann*). Political changes in Britain spurred moves to an autonomous Irish college, The College of Psychiatry of Ireland⁴⁰⁰⁰ (*Coláiste Síciatrachta na hÉireann*) which came into being on January 1, 2009.(Walsh, 2009a)

Psychiatric Nursing

During the 18th century, Dr Nathaniel Cotton of St Albans insistent on high quality environment and nursing, emphasising calmness, relaxation, civility, and humanity. Dr William Battie, in the same period, noted that staff was ignorant, disinterested, and transient. William Tuke founded the York Retreat in 1796. He hoped its quietude would promote mental healing. His first attendant, George Jepson, employed a humanitarian approach, with Bible readings, discussions on healthy living, and seaside outings. Dr Thomas Story Kirbride of the Pennsylvania Hospital commenced formal instruction in 1843. In 1851, Dr W A F Browne, of the Crichton Royal Hospital, Dumfries, in Scotland, started an organised course for attendants. The world’s first School of Nursing, at McLean Hospital, was opened in 1879 (some authors date it from 1882), another being opened at Buffalo State Hospital in 1883.

In 1885, the MPA introduced *The Handbook for the Instruction of Attendants on the Insane*, renamed *The Handbook for Mental Nurses* in 1923. The first national training scheme for mental nurses/attendants started in 1891, successful candidates receiving a Certificate of Proficiency in Nursing the Insane. Males were not accepted as members of the Royal College of Nursing⁴⁰⁰¹ until 1960.

The Asylum Workers’ Association was formed in 1896 to improve the low status of asylum workers. The Asylum Workers’ Union started in 1910, followed eight years later by industrial action. Working

³⁹⁹⁸ Pope from 1316 to 1324.

³⁹⁹⁹ However, Sanskrit had a negative view of suicide.

⁴⁰⁰⁰ The logo consists of a snake and three candles of illumination with Wisdom (*Eagna, Logos*), Learning (*Léann, Sophia*), and Compassion (*Chomhbhá, Pathos*). The College incorporates the Irish Psychiatric Training Committee, the Irish College of Psychiatrists, and the Irish Psychiatric Association. The first president was Justin Brophy.(Vize, 2009)

⁴⁰⁰¹ It was known as the Royal British Nursing Association pre 1919.

conditions were very poor. According to Nolan (1991), the introduction of courses and certificates did little to improve the lot of attendants, and may have helped to prompt the formation of unions in protest at poor working conditions.

Lena Peat of Warlingham Park Hospital, Surrey, with the backing of the hospital's medical superintendent T P Rees, became the first community psychiatric nurse⁴⁰⁰² in Britain in 1954. A nursing post created to look after the chronically ill in the community has become increasingly aligned with primary care and, arguably, the less severely ill. 1963 saw the introduction of the first psychiatric nursing journals⁴⁰⁰³ in Britain.

Project 2000 in England removed nurse education from hospitals (apprenticeship model) and into universities (theoretical model). An 18-month foundation programme⁴⁰⁰⁴ was followed by a further 18-month period of largely theoretical specialisation. Clinical experience is given much less emphasis than in the past. Gournay (2001) suggested that an anti-psychiatry ambience may be alive and well in 'many university departments of nursing' and he bemoaned the loss of those elements of apprenticeship 'which are so valuable to the training of nurses'. Similar trends have appeared in Ireland in recent years, compounded by a serious lack of entrants to nurse training. Apart from pay and career issues, the present author does not believe that matters are helped by the closure of (cheap) nurses' homes and the (prohibitive) 'points system' employed by universities to award places in nursing departments. There is also the danger that newly qualified nurses will not wish to undertake many traditional nursing duties⁴⁰⁰⁵.

Child Psychiatry

Elementary school attendance was made compulsory in Britain in 1880, highlighting a 'surprisingly high proportion' of poor copers due to learning (syn. intellectual) disability, emotional and behavioural problems. (Wardle, 1991) The first British school for mentally subnormal children was Whites School for Imbeciles, opened at Bath in 1846. The first asylum in Britain dedicated to this group was The Asylum for Idiots, Park House, Highgate in London, established two years later.

In 1896, Cattell and Witmer started a multidisciplinary clinic in the US. In 1904/5, Alfred Binet and Simon published their intelligence test, introducing the concept of mental age based on knowledge of average intelligence level at a particular age; Lewis Terman of Stanford University devised the Stanford-Binet Test in 1916; and David Wechsler of New York designed his Adult Intelligence Test (WAIS) in 1939. Starke Hathaway, a psychologist, and J Charnley McKinley, a psychiatrist produced the MMPI, the most commonly used test of personality, in 1937.

Meyer introduced a psychiatric social worker at Manhattan Hospital in 1906. Three years later, Cyril Burt became the first educational psychologist to London County Council (LCC). In the US, the Smith College opened its school of social work in 1918. The Tavistock Clinic had its first child patient in 1920 and by 1923 there were 15 demonstration child-guidance clinics (CGCs) in America. Mapother encouraged child clinics at the Maudsley during the early 1920s, and an East London CGC was started in 1927. Lowenfeld started a play-therapy group during the following year. Training and demonstrations were organised at a London CGC which had been opened by Moodie in 1929. Klopp established an in-patient unit in the US one year later (the Maudsley unit did not open until 1947), and a neuropsychiatric clinic started in America in 1931. Birmingham CGC opened in 1932⁴⁰⁰⁶. Three more years saw the publication of Kanner's textbook of child psychiatry.

H Bickel, J Gerrard and E M Hickmans reported in 1953 that removing phenylalanine from the diet of children with phenylketonuria prevented further intellectual deterioration.

Some historical aspects of drug treatments in psychiatry

Perhaps the oldest drug is mead⁴⁰⁰⁷, fermented from honey.

The bromides, useful in epilepsy, were originally used to reduce sexual urges⁴⁰⁰⁸. Chloral hydrate⁴⁰⁰⁹ was synthesised by Justus Von Liebig in 1832 and introduced by Liebreich as a hypnotic in 1869.

⁴⁰⁰² CPN, more recently dubbed 'community mental health nurse' or CMHN.

⁴⁰⁰³ *Perspectives in Psychiatric Care* and the *Journal of Psychiatric Nursing and Mental Health Services*.

⁴⁰⁰⁴ Sometimes it had little psychiatric content.

⁴⁰⁰⁵ A fear shared by many experienced nurses.

⁴⁰⁰⁶ Other early innovations were an adolescent unit at Epsom in 1947, and, in the next year, child psychiatrists officially became involved in assessing maladjusted children.

⁴⁰⁰⁷ This alcoholic drink dates to circa 8000 BC. (Belzung et al, 2002)

⁴⁰⁰⁸ And hence 'masturbation insanity'!

1193

Paraldehyde⁴⁰¹⁰, formerly used as a hypnotic and for the treatment of prolonged convulsions, was synthesised by Wiedenbusch in 1829 and was introduced to medicine by Covello in 1882.

Morphine⁴⁰¹¹ was isolated in 1803 by W F A Setürner of Paderborn. Bayer had introduced the newly developed heroin in 1898. Hyoscine was synthesised by Schmidt in 1888.

Barbituric acid, (malonylurea) prepared by Von Baeyer in the 1860s and named after St Barbara, gave rise to a new group of synthetic psychotropics, the barbiturates⁴⁰¹².

Amphetamine was developed in 1927 by Gordon Alles as a substitute for ephedrine in the treatment of asthma, but never achieved the hoped-for popularity in the treatment of depression, except in the USA where the amphetamines are employed in attention-deficit disorder and refractory depression⁴⁰¹³.

Opiates and scopolamine were also used for a time in psychiatry, to quieten disturbed patients.

In 1943, Hoffmann⁴⁰¹⁴ took lysergic acid diethylamide (LSD) himself and confirmed the psychic phenomena reported by volunteers.

Albert Hoffman (1906-2008)

Salvarsan, an arsenical, the 'Magic Bullet', was introduced by Paul Ehrlich in 1910 for the treatment of general paralysis of the insane⁴⁰¹⁵. In 1917 Wagner Von Jauregg of Vienna used malarial therapy⁴⁰¹⁶ for GPI.

Julius Wagner-Jauregg (1857-1940)

Again in Vienna, Manfred Sakel used injections of insulin in 1927 to induce hypoglycaemic coma⁴⁰¹⁷. 'Modified' insulin treatment followed - drowsiness short of coma. The extra care given by enthusiastic staff

⁴⁰⁰⁹ Now chloral betaine, a pro-drug that must be metabolised to trichlorethanol to produce its hypnotic effect. It is still used as triclofos. Chloral hydrate with alcohol (Mickey Finn) was used to knock out sailors who were being shanghaied. Trichlorethanol slows ethanol metabolism and the latter quickens chloral hydrate's conversion to trichlorethanol.

⁴⁰¹⁰ Now obsolete. It had to be administered in a glass syringe and could cause metabolic acidosis, sterile abscesses, nerve damage and sloughing of skin. Paraldehyde is not as safe in people with liver dysfunction as once thought and is mostly metabolised by the liver with only a small proportion being excreted via the lungs.

⁴⁰¹¹ Gk., *Morpheus*, god of dreams.

⁴⁰¹² Phenobarbitone was introduced in 1912. The toxicity and dependence associated with barbiturates have severely restricted their use. Suphonal, a powerful tranquilliser derived from acetone in 1886, is no longer in use. Diphenylhydantoin (phenytoin), a much less toxic agent than phenobarbitone, was discovered by Merritt and Putnam (1958) from the examination of a series of phenyl compounds. They reported their findings in San Francisco in 1938.

⁴⁰¹³ They are also dependence producing, may induce a paranoid psychosis, and can lead to severe depression.

⁴⁰¹⁴ A chemist at Sandoz Laboratories. Patients given LSD during the late 1950s and early 1960s are now seeking legal compensation. (Dyer, 1995) Medical uses of LSD included treatment for everything from homosexuality to alcoholism, and the induction of 'model psychoses'.

⁴⁰¹⁵ *Dementia paralytica* or GPI.

⁴⁰¹⁶ John Dunne brought this therapy to Ireland.

⁴⁰¹⁷ It was claimed to be beneficial in schizophrenia, although Sakel's original curiosity was aroused by noted similarities between hyperthyroidism and the opiate withdrawal syndrome – he used insulin as a 'thyroid antagonist' to treat this abstinence state before turning to treat schizophrenic patients.

may have offered non-specific benefits. Insulin therapy fell into disuse because coma induced by barbiturates gave equally good results⁴⁰¹⁸. (Ackner et al, 1957)

Manfred Sakel

Giuseppe Epifanio of Turin had employed barbiturate narcosis in the treatment of severe mental disorder as early as 1917.

Just before the time of Galen, Scribonius Largus⁴⁰¹⁹ applied electric eels to the forehead for headache. (Krzyzowski, 1989; Finger, 2000) In 1785, W. Oliver reported giving camphor⁴⁰²⁰ to a patient with mania. After a generalised convulsion the patient recovered temporarily (Oliver, 1785). Ladislav Von Meduna believed, erroneously, that schizophrenia and epilepsy could not co-exist. After using camphor oil to induce convulsions he switched to Cardiazol (soluble solution of synthetic camphor⁴⁰²¹) in 1934. Other agents were eventually added to the list of epileptogens, such as picrotoxin. Cerletti and Bini introduced electroconvulsive therapy (ECT)⁴⁰²² after some preliminary tests in Roman slaughterhouses. This was later modified by the use of a general anaesthetic and a muscle relaxant. Wilder Penfield, a Canadian neurosurgeon, removed a scar on the brain in 1927. He then worked with Otfried Foerster in Breslau on the removal of atrophic epileptiform lesions, leading to an enormous number of operations on epileptics in later years. Penfield discovered that some epileptics showed bilateral and symmetrical EEG patterns during seizures which led to his theory that seizures arose from the central brainstem, i.e. centrencephalic epilepsy. Egas Moniz, the originator of cerebral angiography, founded modern psychosurgery by cutting pathways in the prefrontal areas in 1935. In 1945 Freeman introduced a more extensive operation in America. The German neuropsychiatrist Hans Berger (1873-1941) developed electroencephalography (EEG) in 1929. The Gibbs (Frederic and Erna) and William Lennox recorded the EEG in epilepsy in 1935.

Antipsychotic drugs

Reserpine (a *Rauwolfia*⁴⁰²³ alkaloid) - used for many of purposes, including the treatment of psychosis
Methylene blue - has a phenothiazine nucleus and was used briefly as an antipsychotic
Phenothiazine - synthesised by August Bernthsen in 1883; first used as an antihelminthic in 1934
Chlorpromazine - synthesised by Charpentier in 1950 at Rhone-Poulenc laboratories⁴⁰²⁴
Laborit⁴⁰²⁵ used chlorpromazine to induce artificial hibernation during operations, noticing a certain 'detachment' in his patients

⁴⁰¹⁸ The analyst Smith Ely Jelliffe believed insulin therapy to work by 'withdrawing the libido from the outside world and fusing it with the death impulse for the maintenance of the narcissistic ego'! (Shorter, 1997)

⁴⁰¹⁹ *Compositionis Medicamentorum*, 43-48 AD.

⁴⁰²⁰ Camphor was given IM in oil at first, nausea and vomiting were common, and it was impossible to forecast the time or duration of the fit. Weickhardt also used camphor to induce fits in 1798.

⁴⁰²¹ Pentylene tetrazol (Cardiazol in Europe, Metrazol in US) given IV; anxiety before fit was common and painful thrombosis could follow.

⁴⁰²² Electricity became popular among asylum doctors in the second half of the 19th century because of major developments in electrical science and because of its scientific appeal. They did not seek convulsions, the latter being considered undesirable. Electrification of the skin was the therapeutic aim at first, but later on the electrodes were applied to the head (Beveridge and Renvoize, 1988). Robert Remak, in his *galvanotherapie* of 1858, recommended the use of the constant current in abnormal brain conditions associated with mental disorder.

Emil du Bois-Reymond (1818-1896) of Berlin, a student of Johannes Peter Müller and a friend of Hermann von Helmholtz, is credited with the discovery of the nerve action potential.

⁴⁰²³ Leonhard Rauwolfia, a Bavarian physician, travelled in the Middle East during the 1570s and was the first European to describe the preparation and drinking of coffee. (Savage-Smith, 2001, p. 52)

⁴⁰²⁴ During attempts to find more suitable phenothiazine derivatives than promethazine (Phenergan).

⁴⁰²⁵ French surgeon Henri Laborit (1914-95).

Jean Delay⁴⁰²⁶ (1907-87) and Pierre Deniker (d. 1998), Parisian psychiatrists, introduced chlorpromazine to psychiatry in 1952 as a tranquilliser (Moussaoui, 2002) and described the neuroleptic⁴⁰²⁷ malignant syndrome in 1968

Montreal psychiatrist Heinz Lehmann (1911-99) introduced chlorpromazine in North America
Other early antipsychotic drugs: the butyrophenones haloperidol⁴⁰²⁸ (1959), benperidol (1965), and droperidol (1963), the thioxanthenes clopenthixol (1959) and flupenthixol (1963), and the depot neuroleptics fluphenazine enanthate (1963) and fluspiriline (1968)

Clozapine⁴⁰²⁹ ('first atypical neuroleptic') synthesised in 1958 by Hünziker and co-workers; found effective in chronic schizophrenia four years later, although its development was delayed by reports of granulocytopenia in 1975 (McKenna & Bailey, 1993)

Risperidone (another atypical antipsychotic) available to clinicians from 1993

In 1963, the Swedes Carlsson and Linqvist noting elevations of homovanillic acid in cerebrospinal fluid postulated that the then available neuroleptics blocked dopamine receptors. The American *Omnibus Reconciliation Act* of 1987 was meant to tackle the perceived overuse of antipsychotic drugs in nursing homes, a problem that persists closer to home. (Anonymous, 2003)

Alfred Garrod (1859) used lithium⁴⁰³⁰ to treat gout. There were even instances of its use in the 19th century for 'gouty mania'. (Schou, 1992) In the 1940s, a number of patients died when lithium chloride was used as a salt substitute in patients with heart disease. In 1949, after work involving the injection of the urine of manic patients into guinea pigs⁴⁰³¹, John Cade of Australia reported excellent results with lithium in the treatment of mania.

John Cade 1912-1980

The anticonvulsants, especially carbamazepine and sodium valproate have encroached on the prophylactic hegemony heretofore enjoyed by lithium for episodic mental illnesses; their psychotropic actions were described in Japan by Okuma and associates in 1973 and in France by Lambert in 1965, respectively. Roland Kuhn reported on the antidepressant effects of imipramine⁴⁰³², an iminodibenzyl derivative, at Zurich in 1957. (Kuhn, 1958) This was followed by amitriptyline. The first monoamine oxidase inhibitor (MAOI) antidepressant, iproniazid, was discovered during a search for agents active against Koch's bacillus. This hydrazine derivative was developed from a fuel used to propel Nazi V2 rockets! (LeFanu, 1999) Iproniazid is chemically very similar to isoniazid. Barry Blackwell first reported the hypertensive crisis associated with tyramine-MAOI interactions in 1963. An MRC trial in Britain made the MAOIs appear ineffective because of the use of excessively low doses. (Healy, 1999) Modern serotonin reuptake inhibitors or SSRIs include fluvoxamine, introduced in 1987, followed by fluoxetine, sertraline, and paroxetine, with citalopram and then escitalopram following later. Some modern psychotropics were in clinical use before their unacceptable toxicity led to their withdrawal from the market, such as thalidomide, remoxipride, zimelidine⁴⁰³³, nefazodone (hepatic failure), and nomifensine, the latter being in clinical use for seven years. Thalidomide is making a comeback as a treatment for certain diseases, such as erythema nodosum leprosum, multiple myeloma, and wasting in AIDS. L-tryptophan was withdrawn because of an

⁴⁰²⁶ Jean Delay was the first president of the World Psychiatric Association (umbrella organisation of psychiatric societies) when it started in 1950.

⁴⁰²⁷ Term 'neuroleptic', to seize a neurone, coined in 1955 by Jean Delay.

⁴⁰²⁸ Synthesised by Paul Janssen (1926-2003) from meperidine.

⁴⁰²⁹ 'ein 5-Stellung basisch substituierte 5-H Dibenzo [b,e]-1, 4-diazepine'.

⁴⁰³⁰ Discovered in petalite by Arfvedson, 1817/8.

⁴⁰³¹ The urine of both patients and controls killed the animals!

⁴⁰³² Derived from chlorpromazine in the vain hope that it would be an antipsychotic drug.

⁴⁰³³ The first SSRI, created by Arvid Carlsson and co-workers in 1971 in Sweden.

association with the eosinophilic myalgia syndrome, which may have been due to contamination. Following the withdrawal of certain anti-appetite agents because of cardiac complications a new generation of anti-obesity drugs, including orlistat, took their place. Chlordiazepoxide was introduced in 1960, and it's more famous relative, another benzodiazepine⁴⁰³⁴, diazepam, became available three years later. Aesrinsky and Kleitman had discovered rapid-eye movement (REM) sleep in 1953.

Drug abuse has become a major universal problem since the 1970s,(Ghodse, 1995) although alcohol, which is legally available in most countries, is still the most problematic chemical, and particularly so in the former Soviet Union following relaxation of state controls.(Ryan, 1995) The changing fashions in the official handling of drug abuse (restricted methadone prescription practices changing to more liberal provision of methadone, condoms, and clean syringes) has been discussed by Berridge.(1999)

Community-based studies of psychiatric morbidity have become popular and large, e.g. two major US experiments: the *Epidemiologic Catchment Area Study* (> 20,000 adults aged 18 years and over) and the *National Comorbidity Study* (> 8,000 persons aged 15-54 years in 48 states).(Kessler et al, 1994)

Selected prominent names in psychiatric history⁴⁰³⁵

From Freud came Jung's 'analytic psychology' and Adler's 'individual psychology'. Other early influences included Abraham, Ernest Jones, Ferenczi, Reich, and Rank. The main American neo-Freudians were Fromm, Sullivan, and Horney. Anna Freud, Melanie Klein, Winnicott and Balint practised psychoanalysis and analytic psychotherapy, the first three with children, the last developing psychotherapy for primary care physicians. Bion and Foulkes were interested in group psychotherapy. Foulkes and Main developed family and marital therapy, with Main being interested in social therapy, as was Maxwell Jones. Other important contributors were Rogers (encounter), Moreno (psychodrama), Perls (gestalt), Lowen (bioenergetics)⁴⁰³⁶ – influenced by Wilhelm Reich's 'character armour' (Lowen, 1958), and Janov (primal therapy). John Bowlby's⁴⁰³⁷ work on attachment, separation and loss was strongly influenced by Harlow's and Lorenz's simian and avian experiments respectively as well as separation of children from their parents in WW II and experience with conduct-disordered adolescents.

Famous Names in Psychiatric History (cf. O'Shea, 2001a)

Hippocrates, 470-400 BC, the Father of Medicine, should come first. He believed that insanity resulted from a disordered brain. When certain humours (from which comes 'good' and 'bad' humour: Wilson, 2004, p. 390) such as bile, or elements such as fire, were not in balance, illness ensued. Four bodily humours are described, each characteristic of personality type: black bile (from spleen, gloomy) – melancholia, blood – sanguine (optimistic, confident), yellow bile (from liver) – choleric (having a bad temper), and phlegm – phlegmatic (placid, apathetic). Five forms of madness followed: phrenitis – acute with fever; mania – acute without fever; melancholia – a chronic condition; epilepsy – seizures; and hysteria – a 'female' paroxysmal disorder. *Plato*, 427-347 BC, also asserted that mental life resided in the brain. *Aristotle*, 384-347 BC, however, placed mental life in heart, the brain being relegated to the lowly role of body temperature regulation.

Arateus of Cappadocia, c30-39 AD, opposed coercion and cruelty in the management of the insane. He also described various mental disorders, such as mania. Galen, 129-199 AD, subscribed to the Hippocratic views of madness and prescribed physical treatments such as diets, baths and, a not asocial habit in Roman times, vomiting.

St Thomas Aquinas, 1225-1274, held that internal (psychic) and external (environmental) causes of madness are in operation, a particularly modern view.

Paracelsus, 1493-1541, a Swiss, believed that anyone could suffer a mental breakdown. He promoted a medical approach to mental disorder, decrying the use of exorcism. A humane practitioner, he favoured psychotherapeutic measures and, aware of defences and other unconscious mechanisms, he emphasised the importance of personality factors in predisposition. His name for hysteria was chorea lasciva, which, like Freud, he believed had sexual origins.

Johann (or Johannes) Weyer, 1515-1588, German physician and author of *De Praestigiis Daemonum* (The Devil's Signs, 1563) rejected the notion of witchcraft and condemned any clergy who supported it. He attributed phenomena like hallucinations to a combination of natural and supernatural factors. Weyer stressed the need for careful clinical evaluation and the importance of the therapeutic relationship in psychotherapy.

William Cullen, 1710-1790, who was born in Lanarkshire but based in Edinburgh, coined the term neurosis. While his elaborate taxonomy of diseases of 1769 included 'neurosis', the latter embraced many unrelated conditions, e.g. hysteria, seizures, diabetes, and psychosis. Disease, according to Cullen was due to an excess or dearth of 'nervous energy'.

⁴⁰³⁴ BZD, so-called because the fusion of **benzene** and **diazepine** rings.

⁴⁰³⁵ For convenience, these are listed alphabetically in tables: general and more *purely* psychoanalytical respectively.

⁴⁰³⁶ Posture has psychological meaning and exercises release tension with alleged underlying emotional change.

⁴⁰³⁷ British analyst (1907-90).

1197

Franz Joseph Gall, 1758-1828, founder of phrenology and a physician from Vienna who received the M.D. in 1785, tried to correlate personality traits with cranial contours⁴⁰³⁸. Being hounded from Vienna, he settled in Paris. His co-worker was Johann Gaspar Spurzheim, 1776-1832.

F J Gall

Franz Anton Mesmer, 1734-1815, invented 'mesmerism', a belief that 'animal magnetism', a type of cosmic force, was a useful therapy. Although disgraced following a French Royal Commission enquiry of 1784 (appointed by Louis XVI and consisting of Jean Bailly, Antoine Lavoisier, Joseph Guillotin, and Benjamin Franklin), his basic ideas were to rise again as hypnotism. (Gilman, 2004) *Phillippe Pinel*, 1754-1826, wrote the classic *Traité Médico-Philosophique Sur L'Aliénation Mentale ou La Manie*. He struck fetters from the inmates of Parisian psychiatric institutions, taking 6 years to remove them. He understood that the gastrointestinal tract was involved in the genesis of lunacy and employed laxatives and purgatives in their management, and he further held that a bout of diarrhoea could herald a remission. His treatment for premenstrual emotionality was early marriage and frequent pregnancies!

Phillippe Pinel

Benjamin Rush of Philadelphia, 1745-1813, was a Quaker who believed in phlebotomy. Madness, for Rush, was chiefly cerebrovascular in origin. A graduate of Edinburgh and a signatory of the American *Declaration of Independence*, Rush wrote first American textbook of psychiatry.

William Tuke, 1732-1822, a Quaker from York, founded the York Retreat in 1792 and became its manager cum treasurer. His grandson, Samuel, 1784-1857, published *Description of the Retreat* in 1813 and was made an honorary member of the Medico-Psychological Association (MPA), despite lacking a medical qualification. Samuel's youngest son, Daniel Hack Tuke, 1827-1895, studied law and medicine. He was physician to the Retreat and the York Dispensary, lecturer on mental diseases at York School of Medicine, governor of Bethlem, lecturer at Charing Cross Hospital, a founder of the Mental After-Care Association in 1879, editor of the *Journal of Mental Science*, and president of the MPA in 1881.

Alois Alzheimer, 1864-1915, Bavarian by birth, studied medicine in a number of German universities during 1882-87. He trained in neuropathology at Frankfurt, where he worked with Franz Nissl on histological stains (basophilic dyes like cresyl violet stain stacked rough endoplasmic reticulum, i.e. the Nissl substance of neurones). Later, he was invited to work with Kraepelin at Heidelberg. There, and later on in Munich, Alzheimer provided classical descriptions of the neuropathology of many conditions, such as Huntington's disease and Wilson's disease, and, in 1904, the first full neuropathological description of general paralysis of the insane. In fact his living reputation was based on his work on the pathology of syphilis⁴⁰³⁹ rather than on the condition that would bear his name. He reported the case of a demented 55-year-old woman⁴⁰⁴⁰ in 1906. Her brain showed loss of cerebral cortical neurones and thick, coiled masses of fibres within the cytoplasm of many nerve cells, a condition eventually bearing his name. Paul Blocq and Georges Marinesco had described senile plaques as far back as 1892.

Alois Alzheimer

⁴⁰³⁸ The novelist 'George Eliot' had her head shaved for phrenological examination!

⁴⁰³⁹ Syphilis was extremely common in asylums at that time and, perhaps because only 5% of people lived to age 65 years, Alzheimer's disease was a rarity.

⁴⁰⁴⁰ Mrs Auguste D, the D standing for Deter.

John Conolly, 1794-1866, the son of an Irishman, abolished restraints at Middlesex Asylum at Hanwell (later St Bernard's) in 1839. He wrote about the erection and administration of asylums in 1847, but appears to have changed his mind about the usefulness of asylums when he went into private practice! In fact, most asylum superintendents who tried Conolly's approach concluded that was 'idealistic and impractical', there being too many violent and suicidal acts to justify this 'utopian' vision. (Bynum *et al.*, 2006, p. 199)

Emil Durkheim, 1858-1917, wrote the classic sociological study of suicide in 1897: *Suicide. A Study in Sociology*. According to Durkheim, suicide rates are low if society is integrated and regulated. Increased suicide rates occur if there is a lack of meaningful social interaction (norms lose their significance - egoistic suicide) or if individual interests are not subordinated to those of society (loss of guiding standards - anomie). They are also high if there is an expectation of self-sacrifice under conditions of excessive integration (as in war - altruistic) or if there is excessive social regulation (as in prison - fatalistic).

Havelock Ellis, 1859-1939, published an influential treatise on sexual disorders (1897) in England called *Sexual Inversion*.

Jean/Étienne Dominique Esquirol, 1772-1840, founded the first psychiatric teaching clinic in Paris. He emphasised the role of social and emotional factors in the genesis of mental ill health and wrote on the medical, hygienic and legal aspects of psychiatric illness. Esquirol also supplied the modern definitions of hallucination and illusion. He introduced the term *lypémanie* (Gk. *lype*, sadness), one of the many pseudonyms for depression.

Wilhelm Griesinger, 1817-1868, who was born in Stuttgart, was a renowned lecturer. He became professor of neurology and later neurology (after Moritz Romberg) and psychiatry (the world's first chair of psychiatry) in Berlin. Griesinger published *Pathologie und Therapie der Psychischen Krankheiten* (Pathology and Therapy of Mental Diseases) in 1845. He believed that mental illness is organic in origin and that all mental disorders are expressions of a single entity (Einheitspsychose: 'unitary psychosis'). It should be recalled that similar beliefs for the unitary nature of disease were sometimes held outside psychiatry. (Porter 2001a, p.101)

Emil Kraepelin, 1856-1926, a German patriot and anti-Semite was responsible for the birth of modern psychiatric taxonomy and the concept of 'dementia praecox' (chronic poor prognosis schizophrenia with 'negative' symptoms⁴⁰⁴¹). He was aware of the problem of intermediate cases that do not fit into neat taxonomic categories. His close friend, Ernst Rüdin (1874-1952, Swiss born), participated in the Nazi racial hygiene programme. The concept of the 'praecox feeling', that invisible wall between patient and examiner, was introduced by the Dutch psychiatrist H C Rümke, 1893-1967, in 1941. Kraepelin lumped people with psychotic unipolar depression together with manic-depression cases and separation of unipolar from bipolar came later courtesy of Angst and others.

Emil Kraepelin

⁴⁰⁴¹ **Component syndromes of schizophrenia** predate Kraepelin. Some authors espouse a viral cause due to low reporting prior to 1800. Others suggest that schizophrenia became less common because of the decline in incidence of diseases like measles and diphtheria, suggesting either an immunisation effect or increased herd immunity. Foerstl (1989) quotes from case histories published prior to 1800, and Carpenter (1989) alludes to the bias against reporting poor prognosis cases, both disclaiming any novelty for schizophrenia. Schizophrenic patients may simply have died early before 1800, and 'lunatics' of the pre-asylum era were poorly classified and often lodged in prisons (psychosis is still not uncommon in prisons). Narrowing of diagnostic criteria over time or over-reliance on admission data may give a false impression that schizophrenia is disappearing. O'Shea and Falvey (1985) diagnosed schizophrenia in 42% of a sample of 50 in-patients based on information in an 1880 hospital ledger (schizophrenia accounted for 37% of admissions to the same hospital in 1980). Waddington and Youssef (1994) reported a fall in morbid risk in part of Ireland between those born during 1920-39 and those born after 1940, more so for females. Walsh (1992b), however, could find no evidence that schizophrenia became less common in Ireland over a period of 150 years. Nixon and Doody (2005) found no significant change in the incidence of schizophrenia in Nottingham from 1881-1994. In the 1880s Emil Kraepelin coined the term dementia praecox, roughly covering modern chronic schizophrenia. Chronic schizophrenia may develop *de novo* or follow a history of acute schizophrenia. Kraepelin viewed the chronic condition as a dementing process with a uniformly poor prognosis. Eugen Bleuler, in 1911, widened the concept to include cases of lesser severity, dropped the idea of dementing illness, felt that some cases fared not too badly, and called the subsumed collection of syndromes the group of schizophrenias. Bleuler's concept of schizophrenia bears more of the hallmarks of a dimensional than a categorical approach, thus blurring the boundaries with normal experiences. (Nasrallah & Smeltzer, 2002, p. 18) Rümke of the Netherlands introduced the term 'praecox feeling' in 1941 to denote the perceived psychological gap between physician and patient.

⁴⁰⁴¹ According to Jablensky (2003, p. 203), the attributes that define schizophrenia are inferential and are highly dependent on the patient relating private mental activity, there being no 'test' for schizophrenia. The word *schizophrenia* comes from two Greek words meaning a disconnection or splitting of the psychic functions and has no connection, except in popular fiction, with the Jekyll and Hyde character, the latter being more likely a psychopath. Bleuler's 'schizophrenia' is reminiscent of Kraepelin's 'intrapsychic ataxia' (splitting/fragmentation of functions of the mind). According to ICD-10, *psychosis* 'simply indicates the presence of hallucinations, delusions, or a limited number of several abnormalities of behaviour, such as gross excitement and overactivity, marked psychomotor retardation, and catatonic behaviour'.

1199

Henry Maudsley, 1835-1918, who hailed from Yorkshire, offered money to London County Council for the construction of a hospital that would be a medical school cum psychiatric hospital that treated patients with early illnesses either as in- or out-patients. Maudsley died before the hospital, which bears his name, opened in 1923. Among the hospital's famous medical men was Sir Aubrey Lewis. In 1865, Maudsley was able to get psychiatry placed on the curriculum of the University of London; later, a single question on the subject appeared in the final medical paper. He became professor of medical jurisprudence at University College London in 1876. He is commemorated in an annual Maudsley Lecture. Delamothe, in 1988, described Maudsley as British psychiatry's greatest exponent of the theory of degeneration: some past 'unnatural excitement' of civilisation left a genetic taint which deteriorated across generations, eventually destroying descendants; alcoholism, masturbation and syphilis were 'implicated' (Noguchi and Moore demonstrated the spirochaete in syphilitic brain in 1913). Maudsley became a semi-recluse toward end of his life, probably to look after his dementing wife.

Benedict-Augustin Morel, 1809-1873, the famous French alienist who was influenced by an apparent explosion of mental illness and fears of declining human quality, hypothesised that hereditary *degeneration* lay behind mental illness. Neurotic or drunken parents bred mentally alienated children. The latter bred imbeciles who in turn bred sterile offspring. Kraepelin translated morel's term *démence précoce* as dementia praecox.

Eric Berne, who died in 1970, was a graduate of McGill University in Montreal. He was the founder of transactional analysis (TA). Berne taught that we have three communication levels or 'ego states', namely the 'parent', the 'adult', and the 'child'. The therapist analyses the transactions between these states, e.g. the adult in one person talking to the child in another. The 'life script' was likened to a piano player who thought he was making music whereas the real 'player' was a drum inside the instrument, i.e. we are programmed to act in a certain way from an early age. Therapy supplies the solution to a dilemma in the form of an 'antiscrypt'. Berne served in the US Army Medical Corps during the Second World War with the rank of major. He became a consultant in psychiatry and neurology to the Surgeon General. His published works include *The Mind in Action* and *Games People Play*. He also wrote *A Layman's Guide to Psychiatry and Psychoanalysis* (Penguin).

Eugen Bleuler, 1857-1939, used the term schizophrenia in 1911 to cover a heterogeneous group of disorders. He considerably widened Kraepelin's concept of dementia praecox. A variety of prognoses then became possible in schizophrenia. Bleuler's pupils included Jung and Ernest Jones. Bleuler broke with psychoanalysis, made a special study of the inner world of the psychotic, and was the first to use the terms 'autism' and 'ambivalence'. His son, Manfred, 1903-1994, professor of psychiatry at Zurich, performed an ultra-long follow-up of schizophrenic patients of the Burghölzli and reported that the condition's progress tended to plateau after the first tumultuous few years.

Eugen Bleuler

An Australian, **John FJ Cade**, 1912-1980, spent three and a half years as a POW of the Japanese, later taking charge of a veterans' psychiatric hospital. His animal studies revealed a calming effect for lithium. Cade introduced lithium to psychiatry in 1949 - Hammond made this recommendation back in 1871 - and demonstrated its efficacy with the start-stop-start technique. Earlier, unsuccessful medical uses of lithium included the treatment of gout by Alfred Garrod (1859) and epilepsy (bromide salt), and as a salt substitute in cardiac cases in the 1940s in USA, the latter leading to many deaths which set back its use in America for many years. **Ugo Cerletti**, 1877-1963, who was born in Lombardy, worked with Franz Nissl and Alois Alzheimer. He demonstrated the origin of neuroglial fibres from glial cells and found senile plaques in elderly normal brains. Cerletti became professor of neuropsychiatry at Bari in 1925 and in Rome in 1935. He provoked canine convulsions in a study of the genesis of epilepsy (Ammon's horn). With Lucio Bini, 1908-1964, he gave electric shocks to animals. In April of 1938 he gave the first course of ECT (to a 39-year-old man from Milan), and noted that cardiazol-induced hyperexcitability did not occur with ECT; also, recovery was smoother with electricity. In 1950 he suggested that ECT released 'acrogonine' in the brain.

Ugo Cerletti

The Norwegian, **Asbjørn Følling**, 1888-1972, described phenylketonuria in 1934 after parents had asked his advice on their two mentally retarded children. Many colleagues felt that he should have received the Nobel Prize.

1200

A Frankfurter whose family immigrated to England when he was a toddler, *Max Hamilton*, 1912-1988, is best remembered for his psychometric approach to the assessment of depressive illness, especially his *Rating Scale for Depression*. He qualified in medicine from University College Hospital in 1934, joined the RAF during WW2, and later worked at the Maudsley, King's College Hospital, and University College London. He worked at the latter with Sir Cyril Burt, 1883-1971, a psychologist and disciple of W. McDougall, 1871-1938. Hamilton worked at Springfield Hospital, south London, where he continued research into reliable objective assessments of affective variables. His other appointments included senior lecturer (1953) and then professor and head (1963-77) of psychiatry at the University of Leeds, and president of the British Psychological Society (1973).

The Parisian psychologist-turned-medical man who studied under Charcot (see **Charcot's picture below**) at the Salpêtrière, *Pierre Janet*, 1859-1947, introduced the concept of 'dissociation' ('separation' of one part of the mind from another), an important defence in hysterical states such as amnesia, fugue, twilight state, and so-called 'multiple personality'. He believed that more primitive psychological functions appear when higher ones were impaired.

Jean-Martin Charcot (1825-1893)

Karl Jaspers, 1883-1967, was born at Oldenburg in Germany. He met Nissl, Ranke and Mayer-Gross at Heidelberg, where he became professor of psychology. His classic, *General Psychopathology*, was first published in 1913. Jaspers died while professor of philosophy in Basel.

Karl Jaspers

The son of a Bavarian Lutheran pastor, *Karl Leonhard*, 1904-1988, described cycloid psychosis, he characterised the defective conditions of schizophrenia, differentiated bipolar from unipolar affective disorder, and defined frontal lobe syndrome. Leonhard was an early exponent of behaviour therapy and a pioneer in the study of human sexuality and human expressive behaviour.

Sir Aubrey Lewis, 1900-1975, the son of London Jewish watchmaker, was born in Adelaide Australia and studied psychiatry in America and Germany. He arrived in England in 1928 and joined the Maudsley. Lewis led part of the Maudsley to Mill Hill in 1939 and attracted Hans J Eysenck (1916-97) and Maxwell Jones to work with him. He became professor of psychiatry at the University of London (1946), succeeding Mapother. He united the Bethlem and Maudsley hospitals to form the Institute of Psychiatry. Lewis is best known for his social inquiries (including industrial health), metabolic studies, and his influence on a generation of psychiatrists.

The Swiss psychiatrist, teacher of Aubrey Lewis, and spouse of the first American psychiatric social worker, *Adolf Meyer*, 1866-1950, founded the 'psycho-biological' approach to psychiatry at John Hopkins: every aspect of the client, including physical, rearing and social, had to be considered. His special interest was preventive psychiatry. Various illness categories were described as 'reaction-types', e.g. schizophrenic reaction-type. Modern psychiatric history taking and examination of the mental state date to Meyer in 1918.

'Egas Moniz' (born Antonio Caetano de Abreu Freire in Portugal), 1874-1955, professor of neurology in Lisbon, took the name of a hero against Moors! He performed first frontal lobotomy (through hands of Almeida Lima, the neurosurgeon) in 1935. His efforts were rewarded with the Nobel Prize in 1949. Moniz also invented cerebral angiography. He held the chair of neurology in Lisbon. Aged 65, he was shot by a leucotomised schizophrenic patient, but survived!

Lobotomy

Eliot Slater, 1904-1984, joined the Maudsley in 1931 where he was encouraged by Aubrey Lewis and received statistical advice from R A Fisher. He undertook genetic research in 1930s Munich. Slater married Lydia Pasternak, daughter of the Russo-Jewish novelist, was a co-author of *Clinical Psychiatry* (with Mayer-Gross and Martin Roth), and proposed a monogenetic theory of schizophrenia that

1201

was later supplanted by a polygenic paradigm. He established the famous Maudsley twin register; viewed hysteria as a non-genetic, communicative, problem; reported on the schizophrenia-like psychoses of temporal lobe epilepsy; was editor of the *British Journal of Psychiatry* (1961-72); and received a PhD when 77 years old for work on Shakespeare's plays (comparing the frequency of unusual words). Slater resigned from the National Hospital of Nervous Diseases, Queen Square, after neurologists questioned the scientific maturity of psychiatry! He has been described as "an intellectual giant...yet capable of bizarre judgement, as when he devoted the whole of the first number under his editorship of the *British Journal of Psychiatry* to his own work".

Chief players in psychoanalytic history (O'Shea, 2001b)

Men

Sigmund Freud (1856-1939), father of psychoanalysis and a neurologist was born in Freiburg, now Pribor, in Moravia, for Jacob Freud and Amalia Natanson. Sigmund's half-brother Philip made Amalia pregnant, which may have been influential in the origin of the Oedipus Complex. A refugee of the Third Reich himself, four of Freud's five sisters died in Nazi camps. Early on, Freud published neurological and neuroanatomical works, including a monograph on aphasia that Erwin Stengel (1902-1973) translated into English in 1953. Freud married Martha Bernays, studied under Charcot and published, with Josef Breuer (1842-1925: of reflex fame) *Studies on Hysteria* in 1895. He was possibly addicted to cocaine; his colleague, Carl Koller (1857-1944), discovered its local anaesthetic properties. In 1894 and 1899, he had nervous breakdowns. During this period, immortalised in *Traumdeutung* (1900), Freud corresponded with Wilhelm Fliess, inventor of the concept of a nasal reflex neurosis. Freud analysed himself, so starting a family of analysts, and each member thereafter being analysed by someone who was analysed by someone else. Freud's claims for cures have been much criticised in recent years, with talk of former patients dying in mental hospitals. He provided a framework allowing the conceptualisation of mental processes where there had previously been only demonology and degeneracy. Mapother believed that Freud was more of an artist than scientist. Freud may have got major ideas from the German philosopher Friedrich Nietzsche (1844-1900). Merskey attacked Freud's idea of 'repression', believing that it has been used unethically to produce false memories of sexual abuse in infancy.

Freud suffered from carcinoma of maxilla and palate from 1923 and received repeated surgery and radiotherapy. On September 23, 1939 in London, his physician and friend Max Schur administered an overdose of morphine at Freud's request.

Sigmund Freud

Alfred Adler (1870-1937) was born in Vienna, had rickets as a child, trained as an eye specialist, converted to Christianity from Judaism, and died at Aberdeen. He met Freud eight years before Jung. He later broke with Freud, rejected libido theory, founded 'individual psychology', and taught that contemporary environmental factors were more important than sex in determining human behaviour. Adler tried to understand how an individual arrived at his present life-style. Current problems were given due attention in therapy. According to Adler, we all have an 'inferiority complex' and compensate for this via the 'masculine protest'.

Alfred Adler

Carl Gustav Jung, (1875-1961) leader of the school of 'analytical psychology' and a pastor's son, was born in Switzerland and worked with Bleuler at Zurich. Janet was one of his teachers. Jung corresponded with Freud from 1906 and met him in Vienna a year later. From 1908 to 1914 he was Freud's closest disciple. Jung was concerned with the inner world of fantasy and with interpreting unconscious material in dreams and artistic production. He spoke of a 'personal unconscious', containing unique drives and memories, and 'collective unconscious', an inherited, deeper level composed of collected ancestral memories: we are programmed to act in archetypal ways (e.g. the 'hero'). Well-known archetypes (ancient stereotypes) include the 'persona', our social mask, the 'anima', the inner soul-self that is in touch with the unconscious, and the male counterpart of the anima, the 'animus', and the 'shadow', the latter containing unconscious tendencies that must be 'revealed' in therapy. Jung wrote about 'introversion' and 'extraversion', whereby libido is directed inward or outward. The 'Self's' objective is to maintain an integrated, stable personality. 'Individuation' is the struggle for self-realisation, this process being disturbed in neurosis.

Carl Jung

Harry Stack Sullivan, (1892-1949), born Norwich, New York, stressed interpersonal dynamics and he defined personality in terms of relative and enduring patterns of recurring interpersonal behaviour. Sexual problems are but one aspect of a person's difficulties. Treatment should be centred on the patient-therapist relationship. Sullivan discussed everyday events with his clients and used pointed questions and provocative statements in preference to theory-based interpretations. A homosexual himself, Sullivan believed that patients need a same-sexed therapist.

Women

Bertha or Elsa Pappenheim (Anna O: 1859-1936) is the best known patient of Freud and Breuer. Lessons learned during her treatment were used in the writing of *Studies on Hysteria*. She would later become interested in separation anxiety. Merskey argues she had a depressive disorder, morphine and chloral hydrate dependence, hysterical conversion, and cyclothymia! Other patients of Freud included Ida Bauer (*Dora*) and Sergej Pankejeff (*Wolf Man*).

Anna O

Anna Freud CBE, (1891-1982 –**picture on right**), a school teacher and child analyst, was Freud's youngest child and closest disciple. She observed children at play, was analysed by her father, had no medical qualification, and remained a spinster. Her main contribution was *The Ego and the Mechanisms of Defence*, developed from her father's work.

Karen Horney (1855-1952), a native of Hamburg, rejected Freud's 'penis envy' and blamed woman's inhibition on the strictness of her upbringing. She held that aggression is not inborn but learned.

Melanie Klein (1882-1960) placed the Oedipus complex in infancy! Objects, for the infant, are good or bad; part is confused with whole: breast is equated with mother. At about six months the baby is biting objects (oral sadistic stage) and fears mother will punish him for this hostility. Through denial and projection (attributes of self are imagined to belong to others) the infant assumes a 'paranoid position'. Ambivalence towards objects may lead to guilt and a 'depressed position'. Klein's 'projective identification' (subject projects part of self onto object, then identifies with object or elicits response in object corresponding to qualities of the projection) was further developed by Wilfred Bion (1897-1979). Klein's first 'patient' was her own daughter, Melitta Schmideberg, who later became an analyst working with delinquent adolescents and who resented her own mother's intrusions so early in life!

Helene Deutsch (1884-1982) wrote *The Psychology of Women* and challenged Freud's dictum that the 'enigma of the female' could not be understood by either sex.

Concluding comments

While the standing of psychiatry improved due to its efforts at early treatment of military casualties and better selection for military roles in World War Two, psychiatrists greatly overestimated the number of psychiatric victims from the Blitz. (Parker, 1990) Derek Russell Davis performed his Cambridge cockpit experiments during the war in order to test the psychological stresses and fears of pilots. Lieutenant General George Patton Jr found that it did not pay to slap a 'psychiatric casualty' and call him a 'goddamned coward' on August 3 1943 near Palermo, Sicily! (Shephard, 2002, p. 219) It cost him his command.

The exodus of psychiatrists from Nazi Germany is discussed by Peters. (1996) Ernst Rüdin (1874-1952), the Swiss psychiatrist, geneticist and eugenicist, gave his support to Hitlerite policies (**picture on left**). At least 140,000 institutionalised psychiatric patients died of mistreatment or starvation in Germany during the Nazi era. (Schmiedebach, 1997, p. 115) Post-war exposure of Soviet abuse of psychiatry, leading to the withdrawal of the *All-Union Society of Neurologists and Psychiatrists* from the WPA in 1983, revealed a regime dependent on styling their detractors 'mad' (or suffering from 'sluggish progressive

schizophrenia' – brainchild of Andrei Snezhnevsky [1904-1987] of Moscow's Serbsky Institute) rather than 'bad'!(Bloch & Reddaway, 1977; Tomov, 1999) Concern was raised over the misuse of 'sluggish schizophrenia', a slowly evolving type of schizophrenia described in the USSR, and its potential use to label democrats.(Merskey & Shafran, 1986) Readers were also disturbed by the haunting images of inmates of the 'Psychopathic Colony' on the Dodecanese island of Leros⁴⁰⁴² being collectively hosed down in open courtyards.(Henderson, 1999) Even in 2003, patients in Slovenia, Hungary, Slovakia, and the Czech Republic were being kept in padlocked, caged beds!(Krosnar, 2003)

Conversion hysteria was not uncommon in Western soldiers in World War One and in Indian servicemen in World War Two, but was still not uncommon in Indian villages toward the close of the twentieth century.(Mumford, 1999) However, Shorter (1997) has described both chronic fatigue (ME, Royal Free disease) and multiple chemical sensitivities as the 'grandchildren' of neurasthenia⁴⁰⁴³ (the latter being retained in the ICD because of its use in countries such as China): old disorders may simply don the cloak of modernity. New disorders have also stepped in to replace the afflictions of yesteryear, e.g. AIDS⁴⁰⁴⁴ and borderline personality disorder; the first case of variant CJD⁴⁰⁴⁵ in Ireland was reported by St Vincent's Hospital, Elm Park, in June, 1999.

AIDS timeline

1876	Moritz Kaposi (1837-1902) described the cancer now called after him
1981	Centers for Disease Control and Prevention in USA report 5 cases with strange immune deficiency
1982	Terence Higgins Trust launched in London
1984	HIV identified in American and French laboratories
1985	Actor Rock Hudson (b. 1925) dies from AIDS
1986	Needle exchange programme in UK
1987	Robert Gallo (USA) and Luc Montagnier (France) recognised as co-discoverers of HIV
1987	AZT, first antiretroviral drug, licensed
1991	Queen rock band star Freddie Mercury (b. 1946) dies from AIDS
1993	American black tennis star Arthur Ashe (b. 1943) dies from AIDS ⁴⁰⁴⁶
1996	UNAIDS ⁴⁰⁴⁷ set up
1998	American trial of vaccine for HIV
2006	Over 25 million deaths from AIDS since 1981
2008	Françoise Barré-Sinoussi ⁴⁰⁴⁸ and Luc Montagnier ⁴⁰⁴⁹ of France share Nobel Prize for discovery of HIV ⁴⁰⁵⁰

Modern forms of psychotherapy such as interpersonal psychotherapy (Klerman et al, 1984) and Beck's cognitive therapy (Beck et al, 1979) have largely replaced longer-term analytic approaches. Beck's ideas were not new. Epictetus (c. 55-135 AD), a Greek stoic philosopher and former slave, believed that good came from restraining the passions and that we are not upset by things but by the meaning we attach to them. Albert Ellis (1913-2007), the American psychologist who developed rational emotive behaviour therapy in the mid-1950s, approached therapy with the armour of reason and persuasion in contrast to Beck's use of theories that are tested by the patient in order to gauge their accuracy. Donald Meichenbaum of Ontario developed self-instructional training during the 1970s aimed at modulating impulse control problems through verbal self-regulation.

Asper colony during the middle ages and an Italian and Greek prisoner-of-war camp. Approximately 3,000 chronic them intellectually handicapped, were sent their chained in Greek naval ships!(Browne, 2008, p. 157)

Neurasthenia was described by George Beard in 1869.

⁴⁰⁴⁴ The likely origin of HIV-1, a lentivirus (slow to multiply and cause damage), are the simian immunodeficiency viruses (SIVs). Such viruses have been isolated from a western equatorial Africa subspecies of chimpanzee (*Pan troglodytes troglodytes*). Hunters and eaters of raw bush meat may have picked up the virus.

⁴⁰⁴⁵ Creutzfeldt-Jakob disease described 1920-1 by Germans Hans Creutzfeldt (1885-1964) and Alfons Jakob (1884-1931). The concept of a 'slow virus' as the cause of scrapie dates from 1954 and the Icelandic virologist Björn Sigurdsson (1913-59).

⁴⁰⁴⁶ Acquired via blood transfusion given for cardiac surgery.

⁴⁰⁴⁷ Joint UN Programme on HIV/AIDS.

⁴⁰⁴⁸ Born 1947.

⁴⁰⁴⁹ Born 1932.

⁴⁰⁵⁰ 2008 Nobel Prize was shared with Harald zur Hausen (Germany), discoverer of link between HPV and cervical cancer.

Aaron Beck

Insurance-led changes in America added another nail to the coffin of full psychoanalysis. Also, factors common to all psychotherapies may be independent of school of origin.(Storr, 1979) In practice, public psychotherapy provision is poor.(Amies, 1996) Post-traumatic stress disorder, the term dating from studies of Vietnam veterans, is now viewed as stemming from a wide variety of combat and not-combat situations, including 'ethnic cleansing'.(Weine et al, 1995)

Transcranial magnetic stimulation, which has been used by neurologists for some time for various purposes, such as the mapping of cortical function, is now being studied by psychiatrists as a treatment for depression. Whether it will replace ECT remains to be seen.(Reid et al, 1998)

Pneumoencephalography was the first method used to visualise living brain. Introduced by Dandy, an American, in 1918, it involved injecting a gas such as air into the cerebrospinal fluid spaces and then taking X-rays. Using this technique, Jakobi and Winkler (1927) described ventricular enlargement in schizophrenia. Purcell described the phenomenon of magnetic resonance (Nobel Prize, 1952) in 1946, two years before the first successful measurement of cerebral blood flow using nitrous oxide.(Kety et al, 1948) 1980 saw the first clinical demonstration of intracranial pathology using magnetic resonance imaging (MRI). (Hawkes et al, 1980) Computerised tomography had been introduced earlier.(Hounsfield, 1973) 1993 saw the discovery of the gene for Huntington's disease⁴⁰⁵¹, the genetic abnormality being similar to those found in the fragile X syndrome, spino-bulbar muscular dystrophy, and myotonic dystrophy.(Huntington's disease Collaborative Research Group, 1993)

George Huntington (1850-1916)

The polymerase chain reaction (PCR), described in the mid 1980s and employed in the amplification of nucleic acid sequences, was a major boost to genetic research. The mouse genome was thoroughly mapped (Vincente & Kennedy, 1997) and then the human genome revealed many of its secrets. Cloning and somatic gene therapy, the introduction and expression of recombinant genes in somatic cells for the purpose of treating disease, have arrived.(Wise, 1997) Concern was expressed in May, 1999 that 'Dolly', the cloned sheep, was showing signs of excessive genetic, but not somatic, ageing - did one have to add six years, the age of the ewe from whose somatic cell 'Dolly' was cloned, to the new sheep's age?(Wilmut et al, 2000) Trials of gene therapy were suspended in France in 2002 when a boy being treated for X-linked severe combined immunodeficiency syndrome (SCID) developed leukaemia; in the same year, an 18-month-old boy was successfully treated for X-linked SCID in London: bone marrow cells are deliberately infected with modified retrovirus (virus carries the corrective gene for a functioning immune system). Lack of power to compel discharged treatment in the community to comply with treatment is a concern for modern psychiatry.(Dillner, 1995; O'Shea, 1995) Many states in the USA have provisions for legally requiring a patient to comply with extra-mural treatment – so-called 'outpatient commitment': authorities may seek and detain the patient when medication appointments are missed.(Rand & McKee, 1998) The *Mental Health (Patients in the Community) Act 1995* in Britain introduced supervised discharge orders, although it does not provide effectively for compulsory adherence to treatment.(Pinfold et al, 1999) According to Burns and Priebe (1999), psychiatrists must lead in advising governments about services;

⁴⁰⁵¹ An abnormally long trinucleotide repeat sequence.

otherwise the vacuum will be filled by pressure groups and voluntary agencies whose convictions may exceed the evidence for feasibility or value of their proposals. A strong argument against an institutional basis for negative symptoms⁴⁰⁵² is the finding that these symptoms persist for at least nine years after discharge from hospital. (Johnstone et al, 1981) Recent escalation of the suicide rate in young males poses enormous medical, political, and social dilemmas, not all of which can be redressed by psychiatrists. (Porter, 1997) although there are signs of a reversal in this trend. (McClure, 2000) Shorter (1997) attributes the apparent increase in the incidence of 'depression' to a widening of its definition to include normal variations in mood and habits. A law of Northern Territory, Australia, allowing the terminally ill to take their own lives - using a computer-controlled lethal injection - was overturned in March, 1997; the Dutch authorities allow physician-assisted suicide, despite lack of statutory provision, and Belgian doctors failed to resist its introduction; and the American Supreme Court passed down decisions about physician-assisted suicide to the state legislatures, although the battle between the latter and the former continues. (Steinbrook, 2002)

In 1997, the Liggett Group, the smallest US tobacco company and makers of *Chesterfield* cigarettes, agreed to settle all claims against them⁴⁰⁵³ in return for immunity from litigation, thus opening an ever-widening legal attack on the industry. (Beecham, 1997)

Richard Speck was sentenced to death in 1996 for slaying eight nurses in Chicago, despite having the XYY sex-chromosome constitution. The state of California passed the first antistalking law in 1990.

The Editor of the *Irish Medical Journal*, noting that out-patient clinics in the Republic of Ireland in 1996 were held at 251 locations with 233,512 attendances, described the situation as 'a staggering burden on our psychiatric community services'. (Editor, 1998) According to Jones (1999), those who devise mental health policies are financially motivated and the diversification of services inherent in extra-mural psychiatry hindered the collection of meaningful information on service efficiency.

According to Thornicroft & Maingay (2002) mental illness accounted for 12.3% (and rising) of the global burden of disease; it also accounted for 31% of all years lived with disability; only one in four countries had mental health legislation; 28% of countries had no specified mental health budgets; and one-third of all people resided in nations that invested less than 1% of the total health budget in mental health.

We are embracing the era of Health-Maintenance Organisations, (HMOs) evidence-based medicine (but which evidence to use?), subcellular third-messenger systems, freedom of information and 'transparency', 'key workers', rising power in the para-medical professions ('You prescribe and I'll treat!'), disturbingly high levels of reported child sexual abuse, the *Protection for Persons reporting Child Abuse Act 1998* (Ireland), *Viagra* (sildenafil) - when combined with *ecstasy* it is sold on the streets as *sextasy*, cybersex (teledildonics - virtual sex computer programmes), ambivalence over community-based psychiatry, (Bartlett & Wright, 1999; Moncrieff & Smyth, 1999) comorbidity, ageing populations, and a long list of bewildering changes, not the least strange being a proposal to pay patients to take their medication. (Giuffrida & Torgerson, 1997) By way of personal reassurance, the author is reminded of the theme⁴⁰⁵⁴ of an article published in 1970, (Allderidge, 1970), and will avoid empty prognostication.

Appendix

It is often assumed that readers are classic scholars! Alas this facility is not as common as heretofore. For the benefit of those who are bewildered by the use of Greek letters and Roman numerals in the literature the editor has included the following guide:

Commonly used Greek letters

Aα [Alpha](#), Ββ [Beta](#), Γγ [Gamma](#), Δδ [Delta](#), Εε [Epsilon](#), Χχ [Chi](#), Κκ [Kappa](#), Λλ [Lambda](#), Μμ [Mu](#), Ππ [Pi](#), Φφ [Phi](#), Σσς [Sigma](#), Θθ [Theta](#), Ττ [Tau](#), Ωω [Omega](#)

Less commonly used Greek letters

Νν [Nu](#), Ξξ [Xi](#), Οο [Omicron](#), Ρρ [Rho](#), Ζζ [Zeta](#), Ηη [Eta](#), Υυ [Upsilon](#), Ιι [Iota](#), Ψψ [Psi](#)

Roman numerals

I = 1, II = 2, III = 3, IIII or IV = 4, V = 5, VI = 6, VII = 7, VIII = 8, IX = 9, X = 10, XI = 11, XVI = 16, XX = 20, L = 50, LV = 55, LIX = 59, C = 100, CL = 150, M = 1,000, MMX = 2,010

A numeral with a line over it means that you multiply by 1,000, e.g. X with a line over it = 10,000
