Textbook of Psychological Medicine

Fifth Edition

Edited by Brian O'Shea

DEDICATION

For Anne, John and Gerard and their families for their priceless companionship; for Gerald and Brian Cramp for their invaluable support; for James Coakley* for making the body interesting and understandable; for Michael G. Kelly* for my start in psychiatry; for Bryan Alton* for a good start in medicine; for Mark Hartman* who introduced me to the idea that unpaid work can be rewarding; for Jim Maguire* who made us laugh at adversity; and, for my parents Michael* and Theresa* for doing far more than their duty. (*RIP)*

Preface

'In our times the field of science is broad and extensive and its increase on every side so rapid and so various that he who wishes not to be left completely behind must employ all his energies with continuous and unremitting assiduity'. (Robert Graves, 1864, p. 860)

This book started life back in the early 1980s as a very slim volume and expanded over the years. The College of Psychiatry of Ireland approached the author through its president Justin Brophy to make it available on-line. This request immediately struck the undersigned as being eminently more sensible than having it expand anonymously on his personal computer. Because of time constraints it has been decided to use those chapters that have been prepared by the author and to add other chapters (forensic psychiatry, intellectual disability, old age psychiatry, rehabilitation, psychotherapy with children, and child and adolescent psychiatry) when they become available. I hope that those who read the book will find it helpful when studying for examinations, when faced with clinical problems or as a resource for up-dating their knowledge of psychiatry. It is the intention of the writer to oversee the completion of the text by eliciting and editing the extra chapters. Thereafter he will hand over stewardship to the College of Psychiatry of Ireland with the sure knowledge that his endeavours will have found a good home.

A note on the title of the book is in order. This has been the title throughout the previous four editions. In recent years the Americans have adopted 'psychological medicine' for what we call consultation-liaison psychiatry. In an earlier (psychoanalytical) life this branch of psychiatry either did not happen or was referred to as 'psychosomatic medicine'. Other transatlantic differences in usage of terminology abound, e.g. 'learning disability' which has completely different meanings in the UK and the US. The College may eventually wish to change the title to something else.

I would like to thank those colleagues who have agreed to write additional chapters for this book. I would also like to express my thanks to Hemal Thakore for his help with the nuts and bolts of delivering the text to its readership. I would like to thank Justin Brophy for his encouragement. Justin described this undertaking as a "labour of love". I agree that the motivation needed was more likely of limbic than prefrontal origin!

I would particularly like to express my gratitude to Jane Falvey who was involved in the earliest editions of the book.

Most readers will not be intimately aware of the time required to research, write, and edit a work of this size but I can assure them that my family *is* aware – to them, for their patient sacrifice, I express my heartfelt gratitude.

Some reviews of the Fourth Edition of *Textbook of Psychological Medicine* (O'Shea B, 2002)

'I would recommend this book to trainees in psychiatry and although the text is primarily focused on the psychiatric membership examination, I feel it will find a place on many a physician's bookshelf in due course.'

Alan Byrne, *Irish Psychiatrist* 2003;**4**:71.

'... an invaluable reference source. Current research is critically appraised, and detail is attended to throughout, making this an extremely useful textbook for examination candidates. The style is relaxed and approachable....a user-friendly, practical reference source for any mental health professional in Ireland today.'

Emma Dineen, *Irish Medical Journal* 2003;**96**:157.

'..... this fourth edition is well worth the spend and every teaching library and practice in the country should make it available..... of particular merit is the rich historical detail that pervades each page.'

Maurice Guéret, *Medicine Weekly* 2004;**8**(1):48.

'It is packed with the type of information which appears in multiple choice examinations, but also tries to give the reader a thorough understanding of clinical concepts for use in everyday practice.'

Brian Ferguson, *Irish Journal of Psychological Medicine* 2005;**22**:37.

Note: DOI numbers refer to the Digital Object Identifier System for identifying objects (such as journal articles, including those published ahead of print) in the digital environment. It is managed by the International DOI Foundation. For example the DOI reference for *Br J Psychiatry* 2009;194:434-8 is 10.1192/bjp.bp.108.052605. The letters *aop* stand for advance online publication.

Cautionary note

The reader is strongly advised to consult up to date data (indications, contraindications, precautions, interactions, side effects, toxicity, cost, etc) from reliable sources (e.g. manufacturers' data sheets, *Martindale*, *BNF*, *MIMS*, *Irish Drug Reference*, and *Irish Medicines Formulary* – *Physician's Desk Reference* in US) before prescribing medication.

The editor: Dr Brian O'Shea works as a Tribunal Psychiatrist with the Mental Health Commission. He was Clinical Director and Consultant Psychiatrist at Newcastle Hospital, Greystones, Co Wicklow, Republic of Ireland, until December 2006. He qualified from University College Dublin in 1974 and was a Consultant Psychiatrist at St Brendan's Hospital, Dublin for two years before moving to Co Wicklow in 1985. He has published c. 400 articles and was an examiner in all parts of the Membership Examinations of the Royal College of Psychiatrists in the UK for two decades. He is Editor of *Irish Psychiatrist*, a member of the Editorial Board of the *Irish Journal of Psychological Medicine*, and has acted as an Assessor for Irish, British and North American journals.

Other books by Brian O'Shea

A Textbook of Psychological Medicine. 4 editions (1985-2002)

Essays in Psychiatry. 2 volumes (1984, 1989)

Core General Psychiatry: 'Functional' Syndromes. (2007)

¹ In references only (BP refers to bipolar [affective] disorder in text).

Foreword

It gives me great pleasure to write the foreword of this fifth edition of the *Textbook of Psychological Medicine*. There are several remarkable aspects to this publication which makes it most welcome. This continuously revised textbook has been under the direct authorship and stewardship of Dr Brian O'Shea since its inception. This is a singular achievement and almost unparalleled in regard to contemporary medical publishing. The remarkable effort and diligence in compiling this work is a great gift to our speciality and Dr O'Shea deserves special thanks and regard by the profession in this light.

Also remarkable is the fact that he has without hesitation made it available as to be the first electronic textbook available to Irish psychiatrists through the offices of the College of Psychiatry of Ireland. Coming as it does shortly after the first year of its beginning, the College is extremely proud to have this work available to members and we feel it marks an auspicious and important beginning to our academic programme. The fact that it has been made available to members free of charge and that it is available in electronic format makes it particularly accessible.

The standing of the textbook is such that it is available as an open resource for all students of the discipline, introductory, those in training, and those undergoing continuous professional development. The high level of detail and scientific integrity makes it suitable to span all such needs and it is a most welcome addition as a medical resource of great scope.

Any single author textbook runs the risk of omissions, oversights, and imprecision. The textbook will remain under Dr O'Shea's editorship until the current edition is complete. At that stage, when he hands it over to the College, we expect to recruit editors of sections who will take submissions in regard to supplements, corrections and any other comments which will enhance the work. This marks a first in publishing of this kind and means that truly the textbook becomes the property of the profession and that the knowledge of peers and experts can be collected in one place for the benefit of all.

On behalf of the profession I would like to thank Dr O'Shea for his scholastic diligence and his exceptional generosity in agreeing to make this available at this time. We hope that it marks the beginning of what will be a truly wonderful resource for us all in the future.

Dr Justin Brophy
President - The College of Psychiatry of Ireland

Assessing, Describing and Classifying Brian O'Shea

'You know, Charles, I don't like psychiatrists'. (Winston Churchill, February 19, 1953, in Moran, 1966)

'They said I was mad: and I said they were mad: damn them, they outvoted me'. (Nathaniel Lee, 1649-1692, Bedlam, quoted in Russell, 1997)

'...we must not lose the human face of psychiatry as it becomes progressively more scientific'. (Andreasen, 2001)

'Increasing complexity is accompanied by the potential for complex aberrations'. (Weller & Eysenck, 1992)

'No perspective on its own can offer a complete account of a patient's mental functioning'. (Szmukler, 2007)

This chapter focuses mainly on the fundamentals² of the initial psychiatric history and mental state examination. This process is both an enquiry and a therapeutic process. There are no short cuts and practice is essential. The relationship between psychiatrist and patient is a fiduciary one.³ Psychiatrists, like other clinicians, may be less proficient in essential clinical skills than they would like to imagine. (Maguire, 1993) This is despite the fact that 'Our most profound understanding is derived from the intermeshing of various parts of the patient's self with parts of ourselves.' (Giovacchini, 1990) A *therapeutic alliance* should be established and maintained with the patient. This is necessary in order to ensure a collaborative working relationship. Otherwise it may be more difficult to ask patients to undertake distressful measures, e.g. revealing a history of abuse, resisting hand-washing in compulsive states, facing feared circumstances in specific phobia or agoraphobia, ignoring certain behaviours of children, or suffering early side effects of psychotropics.

Comfortable seating and lack of disturbance are essential.⁴ After initial introductions (including your own name, title, and position), the interview proceeds. As in general medicine, observation⁵ is the keynote to success.⁶ Facial expressions⁷, unless consciously suppressed, reveal much useful information.⁸ Body language may unmask feelings that the face keeps hidden. (Elkman & Friesen, 1974)

A good medical communicator shows interest in the patient, elicits beliefs and concerns, acknowledges and responds to signs of distress, uses language the patient understands and gives information in digestible dosage, collaborates with and empowers the patient⁹, and maintains privacy and confidentiality. (Royal College of Physicians and RCPsych, 2003; Sholinghur, 2008; Murphy, 2009; RCPsych, 2009)

Some qualities of a good psychiatrist¹⁰

Prioritises patient care and does not take advantage of vulnerable others

Up to date, uses new research evidence wisely, works within limits of competence

² There are many short publications available that deal exclusively with the examination of patients, e.g. Casey ea.(2004) and, from a US standpoint, APA.(2006) Excellent advice for the old MRCPsych was to be found in Holden (1987,1990a) and Trigwell ea (1996) but the examination has changed greatly in detail over the years.

³ Based on trust.

⁴ Often lacking.

⁵ *Kinesics*: study of nonverbal gestural communication.

⁶ This becomes less obtrusive with experience.

⁷ Experienced clinicians, according to Ekman (1986) may detect fleeting 'micro-expressions' on a person's face (Spillane, 1983) that give away true but otherwise hidden feelings, such as the transient glimpse of despair in the normally smiling patient. It should be noted that one may have paresis of voluntary or involuntary (mimetic) facial movements so that a patient who cannot smile when asked may do so spontaneously when responding to a humorous remark. Loss of muscular tone may lead to vacant expression in GPI. Pendular eye movements plus rhythmic jaw movements (oculomasticatory myorhythmia) may found in Whipple's disease.

⁸ This repertoire of expressions is probably common to all cultures, and even blind children have very similar expressions to sighted ones. (Izard, 1971)

⁹ Empowerment and improved social networks may combat self-stigmatisation. (Brohan ea, 2010)

¹⁰ Adapted from RCPsych, 2009.

Gets on with people, respectful, good communicator, respects autonomy
 Good team player¹¹ and positive role model
 Willing to allow second opinion, consults other professionals as appropriate
 Respects a patient's right to be accompanied by carer, family, friend, or advocate
 Honest, trustworthy, acts with integrity, does not violate boundaries¹²
 Maintains confidentiality¹³
 Ethically attuned, including when involved in research
 Accessible when on duty/on call
 Uses resources available (prioritise based on clinical need) and presses for improvements when necessary
 Considered and measured approach when raising concerns about another professional's weakness
 Does not discriminate based on patients' contribution to illness (e.g. lifestyle)

It is important not to assume that patients who have reduced ability to show emotion (e.g. Parkinson's disease or the misleadingly 'calm' patient on an artificial respirator¹⁴) cannot over hear what one is saying about them (or other patients).

The psychiatric history, an outline

Demography: Name, address, age, marital status, and occupation.

Presenting complaint(s) and its (their) approximate duration. Details of these complaints may be elicited now or later.

Past history of psychiatric illness: Receipt of psychiatric treatment in the past: if so, where, for how long, by whom (GP, psychiatrist, psychologist, priest, counsellor, etc), and in what manner -e.g. psychotherapy, antidepressants, ECT, etc?

Past history of important physical illnesses, e.g. TB, rheumatic fever, amputation, and allergies.

Childhood: birth and early milestones; home or institutional environment; relationship between and with parents; relationship with and details (chronologically) of siblings and other close friends and relatives; so-called 'neurotic traits' (enuresis, nail-biting, nightmares, night-terrors, etc.)

School years: details of schools attended; reasons for change; relationship with teachers and classmates, attitude towards, and self-appraisal of ability to, study; truancy; school refusal and phobia; bullying, scapegoating; games played; exam results; feelings about level achieved; etc.

Employment history: jobs held; redundancies; periods unemployed and why; efficiency; pay; military duty; work abroad; relationship with employer, employees and colleagues; hopes for the future.

Social history: hobbies, pastimes; friends; social skills (literacy, driving of motor vehicle, dating, etc); tobacco, alcohol; other drugs. One unit of alcohol is roughly a half-pint of beer, a single measure of spirits or a glass of table wine.

Sexual/Marital: The experienced interviewer is more able to put the patient at ease. Do not start off this section with blunt questions about masturbation, infidelity, and sexual deviancy. Details of such matters as menstruation and the number of pregnancies should be elicited with a concerned but professional approach. Remember that pregnancy remains possible for the first couple of years after the commencement of the menopause¹⁵. *Empathy* (actively feeling with another whilst keeping own emotional perspective – distinct from identifying with) is superior to sympathy (feeling for). *Without empathy there is poor communication and little chance of treatment adherence.* Source of information on facts of life; attitudes towards sex and the sexes; puberty; menopause and climacteric; dating; sexual experience; marriage; children. Many trainees ask 'too little or too much' about their patients' sexual lives. (Kopelman, 1994)

Family history: Consider both parents' families. Details of psychiatric or serious medical/surgical problems. 'Did any one of your relatives ever suffer from nervous problems?' Draw a diagram of the family tree: ¹ for males and O for females, fill these in for members affected by the disorder in question, e.g. ■, put an oblique line through the symbol for members who are deceased, and use a double oblique line to indicate divorce.

System review: Enquire about changes, especially recent ones, in, for example, weight, appetite, sleep, sexual appetite (*libido* – in psychoanalysis this refers to 'psychic energy'), and ask questions about somatic systems.

Legal history: Get appropriate details: 'Have you had any dealings with the police?'

Some interviewing tips:

Single question: avoid multiple questions at one time – some may not be answered and they can be a source of upset, especially for the cognitively impaired.

Facilitation: help the interviewee to develop a theme; it can be verbal, anything from a grunt to a statement such as 'Perhaps you might expand a little', or non-verbal (smiles, movements of head or facial parts, postural shifts).

Empathic statement: an invitation to the patient to continue or expand on a theme, e.g. 'It must have a terrible experience'.

Clarification: question designed to find out what a person means by their statement, e.g. 'What do mean when you say you feel depressed?'

Negotiation: indicating that you wish to explore further with the client's permission, e.g. 'I know this may be upsetting for you, but it is important that I understand exactly how this matter has affected you'.

Recapitulation: feeding a summary of the subject matter to the patient, e.g. 'As I understand it, you....'

Exposition: explaining diagnosis and management and answering questions that arise.

¹¹ Collaborative approach; keeps patients' interests to the fore.

¹² Do not enter into a non-clinical relationship with patients or ex-patients.

¹³ **Clinical confidentiality** is the duty, extending even beyond death, owed by the clinician to safeguard private information given to him/her in trust by someone else.

¹⁴ Asking the patient to indicate 'yes' or 'no' or asking an experienced ICU nurse to lip read may be revealing.

¹⁵ In 2008 a woman in her late 50s was diagnosed with a 'tumour' – she had one: a baby!

Termination: ending the interview with appropriate statements or gestures; follow-up appointments, prescriptions, and other arrangements should be seen to be understood.

Mental state examination¹⁶

'There is a tendency for the literature to dichotomise normality and illness, whereas most disorders lie on a continuum of severity.' (Butler & Brayne, 1998)

'The skilled examiner often makes a diagnosis others have missed simply on the basis of looking carefully where others have neglected to look.' (Nicholi, 1999)

Trethowan¹⁷ & Sims (1985) remind us that 'Just as a knowledge of pathology is fundamental to the understanding of physical disease, so is a knowledge of psychopathology fundamental to the understanding of psychiatry'.¹⁸

Psychopathology, the study of abnormal mental states, can be divided into *phenomenological* (an objective description of findings), *psychodynamic* (inferring subconscious mechanisms), and *experimental* (do something to change one phenomenon and observe what effects this has on other phenomena, e.g. cognitive therapy to alter ways of thinking may change mood/affect) subtypes.

Mental state examination: basic outline

Get a general picture of his/her appearance and behaviour. Think about the way the patient talks. What does he say and how does he say it? (*content v form*) Record examples. *Mood* (how he feels; subjective, pervasive and sustained emotion colouring perception of the world – old English *mod* and German *mut*) and *affect* (how you evaluate his mood¹⁹) should be evaluated. What is the patient's current emotional responsiveness as witnessed by observer? It may be congruent or incongruent with mood). *Reactivity* is defined as the ability to temporarily alter mood under certain conducive circumstances, as when the patient becomes cheerful when told good news. Delusions are classically defined as false, fixed belief, held with conviction in the face of contrary rational argument or proof, not in keeping with past education or culture. Sims ea (2000) prefer to define delusions as 'overriding rigid convictions which create a self-evident, private and isolating reality requiring no proof'. Some authors believe that delusions are a defence against low self-esteem. (Lyon ea, 1994) Certainly, events may influence delusion content, e.g. Raune ea, (2006) in a study of first-episode psychosis, found that intrusive events were associated with persecutory themes, loss events were negatively associated with losses, and (counterintuitively) danger events (but not loss events) were associated with depressive delusions. In clinical practice it is not so much the falsifiability of the belief as the reasons given for believing it that signify the presence of a delusion. (Mullen ea, 2000)] Misinterpretations (illusions), hallucinations, so-called 'anomalous' experiences (e.g. alterations in colour, shape, size, loudness of real objects), obsessional thinking or compulsive acts, and experiences of unreality are sought. Orientation for time, place and person are examined. Immediate (repeat digits forwards and backwards), recent (what bus he got to the clinic, what was eaten for breakfast) and remote memory (birthplace, dates of world wars, famous public figures) are tested - short-term memory may involve activation of short synaptic circuits via neurochemical transmission; long-term memory may mean intraneuronal protein and RNA synthesis, which then contain a code. Also tested are ability to attend to what is going on and to concentrate on matters at hand (e.g. serial subtraction of 7s from 100 – if this is problematic use serial 3s or counting backward from 20; practice effects are overcome by serial 7s from 101)²⁰; general information (Taoiseach²¹, President, Queen of England, President of USA, where and what is the White House, capitals of major countries, date of ending of World War II - 1945, six large towns in Ireland or country of origin); general impression of the *intelligence* (ability to understand, recall, mobilise and constructively integrate previous learning in meeting new situations); *insight* (why does he think he is being examined by a psychiatrist or why is he being prescribed medication?) and *judgement* (what would he do if he ran out of medication some time before his next appointment, if he saw a house on fire or discovered a stamped, addressed envelope on the street?). In disorders where cognitive ability recovers (e.g. delirium) reorientation occurs in the following order: to person, to place, and to time. The rare *idiot savant* suffers from significant learning disability, autistic disorder, or Asperger's syndrome. (Goldstein ea, 2002) yet performs feats of memory, computation, or puzzle solving in sharply circumscribed intellectualised areas, such as telephone numbers. However, such feats are not translated into positive life change.

Memory

Memory, retained learning and experience, can be divided into: *short-term or primary* - limited capacity; does not require understanding of material; decays rapidly if not rehearsed; displaced by new input; test with digit span (probably of limited value; can be intact in advanced dementia; concentration-dependant; schizophrenic patients may disengage from strings of digits that are shorter than controls can engage with:

¹⁶ The first person to use the term mental 'status' examination appears to have been Adolf Meyer in 1918. (Nicholi, 1999)

¹⁷ Sir William Henry Trethowan (1917-1995), London-born professor of psychiatry at Sydney and (emeritus) Birmingham, with special interest in unusual psychiatric disorders and social anthropology.

¹⁸ A sentiment echoed by Mullen. (1997) See (Casey & Kelly, 2007) for an overview of psychopathology.

¹⁹ Latin *affectus*, mood. Unfortunately, some authors use these terms differently, e.g. *mood* as the enduring feeling state (like climate) and *affect* as observed or patient-reported present/cross-sectional feeling state (like weather).

²⁰ These are tests of attention, not of mathematical prowess and so should be pitched at the patient's educational level.

²¹ Prime Minister, Republic of Ireland.

Keefe, 2003); and *long-term* - encoded mainly as meaningful concepts; durable; or, as is usual clinically, *immediate (working)*, *recent* and *remote*. (Note: different authors classify memory differently, e.g. Sims [2003] divides it into immediate ['sensory store' – held for < 1 second], short-term/primary/working [15-30 seconds; tested with digit span, and long-term/secondary [minutes to decades].)

Alternatively, it can be classified as *episodic* - for specific events, such as a telephone message, or *semantic* - for understanding words, concepts and facts, e.g. who was Ireland's first female president (?) or name all the animals you can in one minute, or *implicit* - for automatic²² skills, e.g. driving, grammatical speech.

Asking the patient to recall words can test *explicit* (i.e. consciously known) memory, and implicit memory can be tested using a word-stem or word-fragment completion task.

Semantic and implicit memory do not decline with age; knowledge increases throughout life; there is a small decrease in episodic information over time, possibly because of reduced frontal lobe function.

Working memory, an elaboration of short-term memory, (Lishman, 1987) is used in solving and understanding problems, i.e. brief storage of information in the service of current cognitive activity; a limited amount of data is kept immediately accessible for current employment or manipulation. It consists of an articulatory/phonological loop (holds data in mind by using subvocal speech), a visuo-spatial scratch pad (maintains data as visual images), and a central executive (directs 'slave systems' such as visuo-spatial scratch pad and articulatory loop). (Baddeley, 1986)

Management of impaired memory may involve compensatory mnemonic strategies (overt/covert rehearsal, organisational approaches, use of visual imagery, etc), external aids (e.g. notebooks, electronic organisers, notice boards, etc), special teaching methods (acquiring specific skills and knowledge specific to a domain – utilises implicit learning ability), and drug therapy (e.g. anticholinesterases after traumatic brain injury or thiamine in alcoholics).

Pre-morbid personality²⁶

Get a thumbnail sketch of the kind of person he was before this present problem arose.²⁷ The patient may lack insight²⁸ or be psychotic and therefore give an inaccurate account of his pre-morbid personality. Many

²² I.e. one is not necessarily conscious of having remembered something. People with an amnesic syndrome can learn how to do certain things or how to approach certain problems without being aware of having done so. *Procedural memory* (e.g. remembering how to ride a bicycle) is one type of implicit memory; it is dependent on frontal lobes, cerebellum, and basal ganglia but not the hippocampus; it is particularly affected by subcortical dementia.

²³ Protein synthesis and development of dendritic connections. Is the notion of **consolidation** of new experiences correct? Cueing patients with amnesic syndrome may improve performance. They may perform better on recognition tests than during free recall. Also, as pointed out by David and Kopelman (2009, p. 38), lack of consolidation as a reason for extensive retrograde amnesia would infer that of consolidation takes many years to occur!

²⁴ The **amygdala** is involved in encoding fearful memories and aversive conditioning. Both fear (acute, external threat) and (anticipatory) anxiety are included here. Fear activates the sympathetic nervous system via the locus coeruleus giving rise to physical symptoms such as tachycardia. Fear awareness is a property of the (especially frontal) cortex. The cingulate cortex mediates activity between cortex and deeper structures.

²⁵ This may be hippocampus independent and the cortical location depends on the sensory modality involved.

²⁶ **Questions about pre-illness personality functioning:** Worrier; moods & consistency of moods; finds it difficult to make/keep relationships; finds it hard to express feelings; violent; independent; assertive; can plan ahead; hopes/ambitions; hobbies/interests; view of self; reactions to stress; abuse of tobacco, alcohol, drugs; able to tolerate frustration; and can learn from experience?

²⁷ In his own eyes and in those of his friends and not so friends.

²⁸ Schizophrenic patients may have full insight, be aware of being ill but misattribute their symptoms, or be unaware of being ill. Mysore et al (2007) found misattributing group to be cognitively intact but the unaware group to be impaired on executive and memory tests. Karow et al (2007) found better insight in schizophrenia was associated with subjectively worse quality of life and greater integration into social networks. According to Haq et al (2008) insight is poorer during phases of psychosis associated with positive symptoms and improves with their disappearance, a surmise, as the authors admit, that needs to be tested in longitudinal studies. Unsurprisingly, Haq et al (2009) found, in stable schizophrenic and schizoaffective patients, that there was a significant negative relationship between attitudes to medication and delusions and a significant positive relationship between insight and attitudes to medication. Bajaj et al (2009) found that insight and compliance were positively related to each other and both of these were negatively

patients describe themselves as having been 'outgoing with plenty of friends', which should be checked against other information given during history-taking. The patient may have been ill for a very long time²⁹ or have had multiple recurrences. Depressed people may describe themselves in a bad light. There are two chief sources of information about how the patient functioned before the onset of illness: the patient himself and *collateral (corollary)* information.³⁰ A physical examination³¹ may be necessary, especially if the patient is being admitted, (Byrne, 2007) if there are new/acute/suggestive complaints or signs, the patient belongs to a high risk category (e.g. substance use), for medico-legal purposes, and so on.³² The nervous system is often poorly assessed or even ignored.³³ (Hughes, 1991; Mitchell ea, 1998; Garden, 2005) The general practitioner (GP) may be telephoned for more facts.³⁴ Blood tests³⁵, X-ray examinations or other ancillary tests may be required.

related to psychopathology scores in a four-week longitudinal study of patients with schizophrenia in India. Supernatural explanations of symptoms are common in the East. (Saravanan ea, 2007)

²⁹ Schizophrenia often causes gradual change over years before presenting 'acutely'.

³⁰ From people who know him well, a home visit, social worker report, previous psychiatric or medical files, and, often forgotten, the general practitioner. The Community Psychiatric Nurse is often a mine of information on the family. (Tyrer ea, 1990)

³¹ See, e.g. Ogilvie and Evans (1997) and Forbes and Jackson. (1997)

Permanent tattoos are more common among psychiatric patients (and other 'marginalised' groups such as prisoners) than in the general population. (Khosla ea, 2010) Adolescents, often impulsively, may seek a tattoo only to regret it later. Requests for removal may reflect poor self-image or to appear more professional in occupational endeavours. Owners of tattoos are at increased risk for impulsiveness/risk-taking, self-harm, alcohol/substance-related problems, and personality disorders. Apart from the usual somatic complications such as keloid and infection, tattoos may be associated with swelling and a feeling of burning during MRI (metallic pigments). Detained patients who lack competence should be protected against being tattooed.

³² Factors that should suggest a somatic disorder include acute onset, abnormal vital signs, physical symptoms or focal neurological signs, youth, older age, no past psychiatric history, hallucinations other than auditory, and disorientation. (Reeves ea, 2000)

Schizophrenic patients are often neglected as far as their significant physical morbidity is concerned. (Meyer & Nasrallah, 2003)

³³ The locomotor system is equally poorly investigated. (Garden, 2005) A **brief neurological assessment** should include: ability to stand, feet together; walk forward/backward heel-to-toe with eyes open; walk on tiptoes and (later) on heels; hold arms outstretched with palms upwards for some seconds; touch nose with tip of index finger with eyes closed; repeat last movement with middle finger; perform piano-playing movements whilst arms are outstretched; pat dorsum of each hand with opposite palm; close eyes tightly; grin; stick out tongue; wiggle tongue; stare at examiner's face while examiner wiggles a finger in each outer quadrant on one side and then the other and then both sides simultaneously (patient points to finger/s); holding head still, follow examiner's finger across midline and up and down; test reflexes with legs dangling from couch; fundoscopy; and anything else that is indicated (e.g. examination of tympanic membranes). Deep tendon reflexes: biceps C5/6; brachioradialis C5/6; triceps C6-8; knee (quadriceps) L2-4; and ankle (gastrocnemius) A1. The finger jerk or reflex (C8) is performed by having the patient gently curve his fingers over your index finger; now raise your hand and then tap briskly on your fingers; the patient's fingers should flex. Tendon reflex reinforcing techniques include the Jendrassik manoeuvre: patient's fingers of both hands grasped together and attempting to pull hands apart with palms facing each other. Remember that muscle rigidity of the clasp-knife variety is associated with upper motor neurone lesions; basal ganglia disease gives rise to cogwheel or lead-pipe (does not vary along whole range of joint movement – can be tested for by asking the patient to mimic screwing in a light bulb by quickly rotating the wrist in alternate directions) rigidity. Asking the standing patient to drop his arms to his sides may screen for EPS: the rigid side will fail to bounce off the side. Asking a person to draw circles in the air with one arm while the opposite elbow is checked for cogwheeling is a useful trick. It should be noted that spasmodic dysphonia, a focal dystonia of the larynx, causes a choking or whispered voice depending on involvement of adductor or abductor muscles respectively. Hemiatrophy may be present in one palm in cases of early brain damage.

A rough examination of the **cranial nerves**: I (smell), II (acuity [Snellen chart or Rosenbaum card], fields [confrontation], discs), II + III (pupillary reflexes), III + IV + VI (eye movements – III nerve lesions in diabetes are associated with intact pupillary reflexes because the pupillomotor fibres are unaffected), V (jaw strength, sensation in face), VII (movement of face), VII (hearing), IX + X (palate), XI (shrug shoulder, rotate head), and XII (move tongue). Poor visual acuity may be implicated in visual illusions or hallucinations. *Gaze-evoked nystagmus* is the presence of nystagmus when the eyes are held for several seconds at the extreme of movement in one direction; it can be caused in both directions by ethanol, sedative-tranquillisers, and anticonvulsant drugs. Normal *saccades* are involuntary, rapid, conjugate changes in eye position between fixations: to test saccades the patient stares at the examiner's nose, then quickly looks at your finger, and then back at the doctor's nose; repeat this test with your finger in up, down, left, and right. Central facial weakness spares the forehead whereas peripheral (VII nerve or facial nucleus) affects the whole hemi-face. Testing speech sounds: 'pa' = labial (lips), 'ta' = lingual (tongue), and 'ka' = palatal.

Horner's (or Claude Bernard-Horner) syndrome (ptosis, meiosis, anhidrosis, apparent enophthalmos, and loss of spino-ciliary reflex [pinching skin of neck should lead to ipsilateral pupil dilatation; a weak reflex but if present it is against diagnosis of Horner's]) was described by the Swiss ophthalmologist Johann Friedrich Horner in 1869. The cause may be anywhere along the sympathetic pathways (making it a poor localising sign) and can be congenital or acquired (including iatrogenic). The lesion is ipsilateral to the abnormal findings. Among the many causes are multiple sclerosis, lateral medullary syndrome, cavernous sinus thrombosis, syringomyelia, sympathectomy, cervical plexus/stellate ganglion/interscalene block, thoracostomy, neck trauma, goitre, carcinoma of thyroid, cervical rib (pulling on stellate ganglion), Klumpke's paralysis, neurofibromatosis type I, cluster headache (the combination = Horton's headache), middle ear infection, Pancoast tumour of lung apex, carotid artery dissection (Horner's syndrome contralateral to hemiparesis: disrupted carotid sympathetic plexus), and thoracic aortic aneurysm (including dissecting).

³⁴ 'Face-to-face contact or a telephone conversation between two doctors caring for a patient can often do more than an exchange of lengthy, repetitive, albeit academically brilliant summaries.' (Cybulska & Rucinski, 1989)

Psychometric studies (psychologist) may be ordered as appropriate. It is not appropriate to rely on psychological tests to make a psychiatric diagnosis. You cannot, for example, ignore clinical context and diagnose from MMPI results. Medically ill patients tend to score high on Hy (hysteria) and Hs (hypochondriasis) scales. (Wise & Rundell, 2005, p. 225) Nursing observations and old case notes may be available and should be consulted.

Infections of the CNS should be considered in the differential diagnosis.³⁶

Nurcombe (2008, p. 1) points out that a good diagnostician matches the pattern of elicited phenomena to the best-fit 'idealized' disorder (commonality allowing generic therapeutic plan) whilst also seeking reasons why this individual person got and continues to have their problem (uniqueness allowing individual adaptation of treatment).

Finish with a *formulation*, a brief summary of the case, differential diagnosis, prognosis, and plan of management, noting positive points only.

Interviewing

'Most mental disorders affect the young and are chronic, recurring illnesses that last a lifetime'. (Michels & Marzuk, 1993)

(a) General.

The interview is a deliberate, non-haphazard process, demanding an understanding of psychopathology and psychodynamics (*vide infra*). Psychopathology may be more obvious with the patient in a familiar environment rather than in the clinic; there may be an apparent 'remission' in hospital, followed by 'relapse' on discharge. (Naguib, 1991) The interviewer demonstrates sensitivity, skill and tact.

Allow patient reveal private thoughts without feeling demeaned
 Patients vary in the degree and timing of revelation and concealment of factual material
 Some patients will be hostile, perhaps (but not always) because they are of involuntary legal status
 Good rapport imparts a therapeutic feel to the encounter
 Interviewer and interviewee should achieve a shared understanding
 Trainees should stick to a set order of questioning
 Flexibility, although not always desirable during a first session, is an acquired art
 Keep interruption to a minimum, and handle it tactfully when it happens
 Settings will vary: office, high security or general hospital ward, busy clinic, or, all too often, a window-seat or linen-cupboard
 Every effort should be made (comfort, lighting, etc.) to acquire a setting conducive to good interviewing
 Note taking³⁷ should be explained ('Do you mind if I write as we speak?') or re-written from brief pointers later; it should be as unobtrusive as possible and serve the dual purpose of aiding recall and a form of communication with others
 Interviewer should be aware that client may request recorded information
 Some patients may feel neglected whilst you write
 More notes will be necessary early on
 Later, only new information needs recording
 Emotional responses of both parties should be noted
 Manner in which interviewer interjects (grunts, verbal acknowledgements, shifts in body posture) may influence relationship for good or bad

³⁵ E.g. **prolactin** level: hyperprolactinaemia is raised by sleep, sexual intercourse, significant stress, pregnancy, lactation, renal or hepatic failure, hypothyroidism, opiates, oestrogens (including anovulants), dopamine antagonist drugs (e.g. phenothiazines, risperidone, domperidone, metoclopramide – dopamine agonists usually shrink prolactinomas), prolactinoma (very high levels are strongly suggestive, e.g. > 5000 mU/L with macroadenoma and > 2000 mU/L with microadenoma), acromegaly (prolactin co-secretion), compression of pituitary stalk, seizures, polycystic ovarian syndrome, and idiopathic cases. Whilst most antiemetic drugs raise prolactin levels, cyclizine does not. Galactorrhoea is not synonymous with increases in prolactin (e.g. duct ectasia). Extremely high prolactin levels may give a falsely low reading due to the 'hook effect' but dilution of the serum will reveal the hyperprolactinaemia. Macroprolactinaemia refers to high molecular weight complexed prolactin + IgG which is inactive – it does not require intervention but can be misleading: 'apparent hyperprolactinaemia' – after precipitation of IgG with polyethylene glycol the prolactin level can be measured accurately and shown to be normal.

³⁶ CSF findings with such infections include polymorphonuclear cells with bacterial infection and increased lymphocyte counts with viral (incl herpes simplex encephalitis), TB, and syphilitic meningitis; lowered glucose levels with bacterial, TB, and syphilitic meningitis (normal with viral meningitis and herpes simplex encephalitis); and protein levels greater than 150 mg/dL in bacterial and TB meningitis (less than 100 mg/dL in viral and syphilitic meningitis and in herpes simplex encephalitis).

³⁷ Casey et al (2004, p. 6) suggest note taking during the interview whilst Schiffer & Lajara-Nanson (2003, p. 4) condemn this practice! Common sense and context should dictate. Note taking has medico-legal significance.

Interviewer forms understanding of stage of illness being dealt with and any effects of treatment³⁸
 Number of interviews required for proper evaluation should be discussed with the patient
 Depth of material that can be elicited varies, e.g. some patients need many interviews before getting to the kernel of the problem, or before the therapist can formulate the problem and decide on management

The interviewer should ask himself many questions: How much encouragement, reassurance, advice, interpretation, indulgence, limit setting, or questions (even if these amount to subtle suggestions) should he direct toward the client? How long should this interview last? Is the setting private (e.g. office) or public (e.g. clinic)? There will be many variables to contend with, such as lateness, privacy, and seating arrangements. Questions should follow appropriately, e.g. do not enquire about intimate sexual details or pastimes just after discussing a recent bereavement. Remind the patient that you must know more about him if you are to be helpful.

Some clients demand immediate gratification, e.g. tablets, extra time, greater attention. The interviewer must choose the correct time for gratifying or interpreting (e.g. an infantile need). If you are asked a personal question use your intuition. This will often reveal much about a client's motivation. You might say: 'Why do you ask that question?'.

Resistances

May interfere with progress, even in the most motivated patient
 He may go silent, intellectualise, stick to symptoms or some other aspect of the history, or get annoyed
 He may continue talking or asking questions of you
 He may be seductive or resort to lateness³⁹

Do not take over the interview for the patient. Encourage spontaneity. Explain to him how matters are progressing from your viewpoint rather than interpreting in an analytical sense.

Try to understand the patient's socio-cultural background, how it differs from one's own, and also know your own personality. Experience, especially under supervision, with a wide range of patients is important. You can learn from your own conscious reactions to a patient⁴⁰. Deal with his emotions openly and honestly.

Defence Mechanisms

We all use defence mechanisms ('mental' mechanisms). Defence mechanisms are unconscious psychic activities used to reduce anxiety and eliminate conflict⁴¹. They are deemed abnormal if used too often, if they are used inappropriately (avoidance of reality testing⁴²), or if they fail to work. *Theory of mind*⁴³ is the ability to attribute mental states (e.g. desires) to oneself or others as a means of understanding and predicting behaviour. Simply knowing that one's delusion is not shared by others does not lead to insight.(McCabe ea, 2004) Examples of defences include:

³⁸ Treatment is a very broad canvas, ranging from counselling to drugs (licit and illicit, prescribed drugs, over-the-counter drugs, vitamin supplements, and herbal drugs – see Dunne, 2009).

³⁹ Freud divided up resistances depending on the assumed part of the psyche they originated from: conscious ego (e.g. the client is ashamed to reveal certain facts), ego (divisible into repression, transference, and secondary gain [elicitation of nurturance]), id [despite repeated interpretation the client repeatedly brings up the same material], and superego (e.g. will not relinquish symptoms because they serve as a punishment of the self).

⁴⁰ Are these reactions he evokes in most people. What are your personal reactions? Do they stem from the subconscious (countertransference)? Do you need his approval? Are you being consistent? Do you overidentify with him? Do you feel angry? Is there a power struggle? Are you intellectualising, and avoiding emotional aspects of the interview? Martindale (1987) discussed the excessive use of defence mechanisms within the families of patients with Huntington's disease and amongst those professionals caring for them. He argued that genetic counselling was not offered to these people and that this might help to spread the condition through to the next generation.

⁴¹ There are many **conscious** ways in which people attempt to deal with stress, e.g. humour (including 'gallows humour' – forbidden wish is verbally expressed but not enacted), stoicism, spiritual solace, seeking help from others, seeing it as a challenge and opportunity for psychological growth, employing relevant personal past experience, relaxation techniques, exercise, sports, and avoidance by withdrawal or distraction.

⁴² **Reality testing** is the objective evaluation of the world outside the self, including the capacity to see the self and others realistically. The ability to objectively test reality is a continuous variable, e.g. a severe case of paranoid personality might be more impaired in this regard at one point in time than, say, a person with schizophrenia of mild severity.

⁴³ **Theory of mind:** Psychologists have divided this into 3 orders: first, what one thinks is going on in one's own mind; second, what you think is going on in another person's mind; and third, what you imagine the other person thinks that you are thinking.(Brüne & Brüne-Cohrs, 2006) Connectivity between insula and anterior cingulate cortex may be an important determinant of ability to correctly sense what other people are thinking or what they believe.(Di Martino ea, 2009)

Reaction formation - person reacts to an impulse⁴⁴ (e.g. to kill) with the opposite behaviour or attitude (e.g. by sending Christmas presents). Mothers who smother their offspring with love may in fact harbour hateful feelings for them at an unconscious level.

Repression - vide supra - important to all unconscious defences - unbearable ideas and impulses are relegated to the unconscious mind (not the same as suppression which is conscious 'forgetting'); the concept of repression has been attacked by Merskey (1995) as (a) been used unethically to produce 'memories' of abuse in infancy, and (b) something for which real evidence is lacking.

Overcompensation - exaggerated correction, e.g. feel inferior so acts the bully

Identification – the unconscious counterpart of imitation; important in personality development (various subterms used like internalisation, introjection, and incorporation) - behaviour and attitudes modelled after another person. For example, in introjection (another's qualities taken as part of self) a person might assume aspects of the deceased in order to mitigate loss.

Regression - vide supra - reversion to earlier developmental level of functioning; common during admission to hospital.

Counterphobic behaviour - approaches fear instead of avoiding it - the claustrophobic (fear of enclosed spaces) becomes an elevator mechanic.

Intellectualisation - avoids facing up to feelings by hiding behind logic; unpleasant thoughts remain conscious whilst associated feelings remain unconscious, a derivative of *isolation of affect*.

Rationalisation – the giving of apparently logical reasons for beliefs or actions when really attempting to conceal true motives; the person who hits his wife avoids the painful reality that it was wrong to do so by deciding that she deserved it because of nagging!

Substitution - replacement of a seriously dangerous impulse with something impersonal and less dangerous, e.g. saw up wood instead of the mother-in-law!

Displacement of affect - the office boy who is annoyed by and hence hostile towards his boss beats his own wife up instead of the boss - not socially acceptable - also the basis of transference reactions.

Sublimation - aggressive and sexual desires diverted into socially and personally more acceptable channels, e.g. kicking a football instead of the boss!

Conversion - unconscious conflicts are given external expression in the form of physical ailments, such as hysterical paresis (hysterical conversion symptoms work via the voluntary nervous system, whereas the somatic symptoms of anxiety - such as palpitations - work via the autonomic nerves). A lack of concern, or *la belle indifférence*, may or may not be present in cases of conversion; anyway, it can also be found with general medical disorders, e.g. multiple sclerosis with frontal lobe involvement. (Raskin ea, 1966; Stone ea, 2006) Conversion disorder may, in fact, be accompanied by depression or anxiety. Cases of hysterical stupor tend to look toward the floor if turned on one side. Patients who appear to have a paralysed limb may have normal deep tendon reflexes.

Dissociation - occurs in hysterical amnesias, sleepwalking, loss of memory with running away (= fugue), and multiple personality - mental function(s) are split off from the rest of the personality.

Retroflexion - either sexual feelings are turned inward leading to excessive love of self (narcissism after Narcissus) or hostility is turned inwards leading to depression or a poor self-image.

Acting out - expressing unconscious conflicts in a manner not consciously recognised as such, e.g. prostitution or delinquency.

Isolation and undoing - compulsive rituals of the obsessive-compulsive neurotic consist of impulses which have become separated from unacceptable impulses, e.g. hand-washing instead of murder or rape (= isolation); atonement for guilt (= undoing), e.g. hand-washing because of past masturbation. Such rituals offer no pleasure. Macbeth tried to wash away Duncan's blood!

Projection - unacceptable wishes or impulses in the self are attributed to others⁴⁵; these wishes or impulses may be experienced as being directed back at the self.

Projective identification – described by Melanie Klein and extended by Wilfred Bion; (Meissner, 1999) good and bad aspects of self are split off and projected into someone or something (e.g. a doll) else; these aspects later become representative of and identified with these split-off parts; the person then tries to gain

⁴⁴ An **impulse** is a maladaptive behaviour that the subject is attracted to or feels obliged to carry out. It is associated with release of tension or with gratification/satisfaction/pleasure.

⁴⁵ 'Accusation is so often confession' (Browne, 2008, p. 32)

control over these parts by asserting control over the person (or thing) into whom they were projected; the person identifies with the object or tries to elicit a response in the object corresponding to the qualities of the projection; common in borderline personality disorder.

Denial - can accept at intellectual level that something has happened, such as a loss through death, but this is rejected emotionally; in delusional states intellectual acceptance is also forfeited so that the dead person is believed to still live, despite irrefutable evidence.⁴⁶

Splitting – strict separation of good and bad aspects of self or others in order to avoid having to cope with ambivalent feelings such as love and hatred.

Why does the patient want to see a particular doctor? Discuss this with the patient. Did he see other doctors before and how did he get on, and why did he stop seeing them? Learn about the patient this way, and try to give him insight indirectly. What does the patient expect from you: a listening ear, tablets, or rejection?

Telephone the GP⁴⁷ for further information. Contact relatives as required, being careful not to contravene the trust placed in the relationship between doctor and patient. Read previous notes and the referral letter. Does the information being collected constitute a true reflection of the client, and, if not, why not? Question any nurses who have dealings with the client.

What was the patient doing while waiting for you? Who accompanied him? How long did he set aside for the interview?

The presenting complaint may be dealt with at the start or end of history- taking as seems appropriate. The patient may wish to take the lead here, or it may be necessary to get early information on his background in order to put the problem in perspective. He should have some time at the start to ventilate. He should know that it is from him that you want to hear the story, not just from the referring letter. The latter vary in quality.

Avoid expressions of boredom/horror

Evasiveness may stem from shame

Guilt may lead to a confession

Help patient to confide and express feelings

Ask how he feels and what he finds difficult to communicate

Remind him of confidentiality⁴⁸

In manipulative cases⁴⁹ the true reason for consultation may only emerge if you bring up the subject, or the patient may reveal it as he leaves

Ask for examples rather than accepting bald statements

Seek patient's actual reactions to circumstances

Do not argue

Find out how symptoms affect patient's/other's lives

Move smoothly between topics

Try to get an idea of his personality. How does he spend his average day, get on with other people, respond to adversity, seem to other people, see his role in life, and feel about his status? Inconsistencies should be pointed out gently, e.g. 'I'm somewhat confused'. You may feed back statements verbatim. Most questions are best left open-ended, although clarification may sometimes necessitate the use of direct questioning. Direct questions can give misleading answers, especially in suggestible clients. Sensitive topics⁵⁰ require tact. You may need to wait for leads from the patients or ask indirect questions. A twenty year-old loss may be easier to talk about than a recent one. Sometimes it may be necessary to put *mild* pressure on the client to elicit his feelings. Extreme pressure might prove problematic, e.g. a catastrophic reaction (*katastrophenreaktion*) in the early dement as described by Kurt Goldstein (1942). Be as gentle as possible, providing reassurance and explanation. Estimate how much stress the patient can tolerate by close observation, and allow him to recover his composure before leaving.

⁴⁶ 'What an asset his optimism is! It keeps out the facts': Lord Moran (Sir Charles Wilson) on Winston Churchill, November 10, 1953, in Moran.(1966) A famous example of denial is that of Anton Chekhov (1860-1904, Russian physician and writer) who persisted in writing that he did not have tuberculosis despite his chronic cough and regular haemoptysis.

⁴⁷ Letters from GPs tend to be deficient in several areas, e.g. prescribed medications and medical and social background.(Pullen & Yellowlees, 1985; Smith ea, 1994) A study of why Dublin GPs referred patients(Maguire ea, 1995) found that 30% were for specialist treatments, 20% due to failed treatment, 14% in order to share 'chronic care', and 13% to hand over care completely.

⁴⁸ In murder cases you should ask to see files, Book of Evidence, etc. With the move of psychiatry into the community and the consequent dispersal of paper-based information the need for electronic information sharing is becoming more relevant, particularly regarding potential for self-harm, alerts (e.g. allergies), and medication.(Feeney & Moran, 2007)

⁴⁹ E.g. a request for a letter for the local housing department initially disguised as 'depression'.

⁵⁰ E.g. salary, sexual habits, or past imprisonment.

He may have questions to ask which have not come up during the interview. These may reveal much about resistances, personality, expectations, attendance, and compliance. Discussions of treatment, diagnosis, prognosis or family diatheses should be tempered with hope and a promise to help in the future. A plan of treatment may be outlined and discussed. It is often best to avoid giving labels (e.g. paranoid personality disorder) to the patient unless they are accurate and adequate preparation has been made.

Second and subsequent interviews allow for a longitudinal study of the client, the monitoring of progress, checks on the effects of drugs, psychotherapy, and so on.⁵¹

Interviewing relatives is a matter of some skill and practice. The confidences of the client need to be upheld. The law allows us to violate confidentiality in some cases; where possible you should discuss the importance of these issues with the patient. You should discover what understanding of the client's problem(s) the relatives have. Do not take sides. You may advise the relatives on how to help constructively. One might see the patient first, then a relative, then both together. A common problem arises when various relatives (including in-laws) call at different times. This requires expert handling.

(b) Psychiatric history

'In spite of the pace of study in the biological aspects of psychiatry, it remains almost exclusively a clinical specialty.' (Casey & Craven, 1999)

Examination of the mental state is going on all of the time but is examined formally later.

The objective is to elicit as much information⁵² as possible about the client, to help us to understand his development as a person and the forces acting upon him as well as his influence on others, to understand his presenting problems against this background, and to act as a record to which we or authorised others can refer back to later.

Special problems encountered are language, interpreters, diminished consciousness, mutism, hostility, the hospitalised patient, and minors.

Allow the patient to state his reasons for consulting and his chief complaints in his own words for a reasonable period of time. Interrupt only in certain circumstances, e.g. obsessional rambling. Verbatim quotes are superior to jargon.

Record the source(s) of information, such as a relative in the case of dementia, and a description of the confidant. Think in terms of *predisposing*, *precipitating*, and *maintaining* factors. Give a description of the patient which would enable a listener/reader to feel that the patient was there in front of him: setting, appearance, behaviour, etc.

Why are you seeing him now, as distinct from any other time? When did his problem(s) begin and how was he functioning prior to that? What were his circumstances then? How has it/they affected his activities/personal relationships?

Get details of past episode of emotional/mental disturbance - symptoms, course, management, and outcome. Due to internal conflict, people often seek out situations that frustrate. Look for evidence of this recurrent theme in people's lives.

Get some idea of his home of origin, the nature of his birth, the attitude of his family to his arrival and its effect on others (e.g. unwanted pregnancy, sibling rivalry), problems during the pregnancy and neonatal period, and the presence of any feeding problems. Was there any head banging, body rocking, febrile convulsions, etc? Who reared him? How did he get on with members of the household, and how did he respond to strangers or separation? Were there any so-called 'neurotic traits' (e.g. nail biting, nightmares, and enuresis)? Did he experience problems in toilet training, which may reflect *temperament*⁵³ and/or parental attitudes? Were there any deaths in the family? Did bereavement reduce parental ability to give emotionally to the child? Was their lack of support made up for by others? Was there role-reversal - having to take over the parental role? What was he like in the early years? What games did he play and how did he get on with others? Could he tolerate frustration? Was he able to entertain himself or did he have frustration, boredom, tantrums, whining, silences, imaginary friends, etc?

Go through his childhood chronologically.

Childhood⁵⁴

Who was the disciplinarian at home?

Home and school atmosphere?

Early school experiences and relationship with peers and teachers?

How did he learn to read, speak, write, calculate, walk and run, and their timing?

⁵¹ Assessment for diagnosis or suitability for certain treatments, such as deep psychotherapy, may require a number of interviews. Psychotherapists often speak of the '55-min. hour', each session lasting 55 minutes. Information received at a first interview may require clarification and reactions to the interview may need to be discussed. More intimate details may be offered with time.

⁵² *Anamnesis*: developmental history of patient and his illness. *Ontogenetic*: pertaining to development of the individual. Piaget championed the idea that *ontogeny* recapitulates *phylogeny*, i.e. individual development reflects species development.

⁵³ Constitutional tendency to react to stimuli in a particular way; component of personality that is heritable, developmentally stable, based on emotion, and immune to social/cultural influence.

⁵⁴ Under Irish law a child is anyone < 18 years of age unless they are or were married.

Cruelty or phobias?
 Heroes?
 Fear of the dark?
 Truanting?
 Alcohol or drug abuse, tobacco, fire setting, problems with weight, or difficulties with assertion?
 Subtle hints of physical or sexual-abuse?
 Puberty: feelings, preparedness, and reactions?
 Masturbation and associated fantasies (tactfully)?
 Embarrassment re secondary sexual characteristics and attempts at concealment?
 Attitudes toward opposite sex and dating?
 Role, if any, of religion in the family?

Occupational history

Jobs: nature, responsibilities, dates?
 Periods of unemployment?
 Relations with bosses/workmates?
 Reasons for leaving/changing jobs?
 Feelings about current job?
 Occupational goals?

Ask about his social activities - loner, hobbies, pastimes, feelings experienced when in company, and sports.
 Has he any sexual difficulties - premature ejaculation, vaginismus, non-consummation. Is she pregnant?
 Ask about marriage, including number of marriages and type of marriage. Enquire about courtship, the early, middle and late years of marriage, co-operation, sex, budgeting, finances, etc. How does he get on with in-laws? How many children does he have and what is his attitude toward them? Has he had any affairs (be diplomatic)? Ask about parenting, separations, family planning, contraception, abortion, and other forms of foetal and perinatal loss. What are his living arrangements? Is hospitalisation likely to injure his career? Will he lose his accommodation or will it jeopardise his relationships? Who is looking after the children (anyone under age of 18 years according to the Child Care Act 1991)? Who visits him in hospital?⁵⁵
 Has he, or increasingly she, any military experience in the armed forces (combat, injuries, discharge, indiscipline, or symptoms)?
 What does he dream about? Does he daydream or fantasise? What are his main values? Does he, or an informant, know of any 'nervous' problems (get details) among relatives? How has his family and others responded to his present and past episodes? How do they normally react to him?

Mental state examination

'... it is probable that no clinician of the near future will have diagnostic tests for functional psychiatric disorders that are more sensitive than the evidence of his own eyes and ears'. (Fraser, 1990)

Here we are interested in general appearance and behaviour, psychopathology, and *cognition* (processes whereby we identify, understand, retain, and utilise information from outside and within ourselves.).

Organic symptoms and signs

Agnosia: inability to recognise and interpret the significance of sensory perceptions, perception without meaning⁵⁶; can take many forms – *anosognosia*⁵⁷, denial of illness (a form of hemi-inattention; a left hemiparesis is not acknowledged due to a non-dominant parietal lobe lesion⁵⁸; this causes management problems because the patient does not see why he needs assistance; also some such cases are also depressed, which itself may be denied by the patient) – the term *disconnection syndrome*⁵⁹ suggests an interruption of communication between brain regions in sensory inattention and neglect following a stroke⁶⁰; *autotopagnosia*, denial of (failure to recognise/name/point out) body part (one's own or that of

⁵⁵ Contact with relatives may occur for the first time when a discharge date is set, or when the patient is referred from a psychiatric to a general hospital.

⁵⁶ *Gnosis*: ability to recognise objects, faces, sounds, or body parts.

⁵⁷ Gk. *a*, not; *nosos*, knowledge. The term was coined by Babinski in 1914.

⁵⁸ Other authorities point to the right frontal cortex.

⁵⁹ Term coined by Norman Geschwind in 1965.

⁶⁰ Neglect can be **visual**, wherein a clock is drawn with figures bunched to one side or the start of a line or word is not read, or **motor**, as when only one hand is used to carry out a task without any neurological finding by way of explanation. Whilst visual inattention

another person), e.g. finger⁶¹ or own face (as in a mirror: hence the ‘mirror sign’ in Alzheimer’s disease where the patient converses with or is frightened by a ‘stranger’, i.e. his own reflection), despite a retained ability to recognise other objects; *asomatagnosia*, denial of ownership of a paretic limb, sometimes attributing ownership to another person⁶², with a right-sided lesion⁶³; *visual agnosia*, inability to recognise objects visually⁶⁴, mostly attributable to bilateral (less often right-sided only) medial occipitotemporal lesions (ventral stream of visual processing); *auditory agnosia*, inability to recognise sounds, everything from a telephone ringing to speech – all is simply noise (usually bitemporal lesions)⁶⁵; *astereognosis*, inability to recognise objects by touch; *topognosis*, inability to recognise an object placed on the skin; *agraphagnosia* (*agraphaesthesia*), inability to recognise numbers or letters written on skin; *prosopagnosia*, inability to recognise familiar faces⁶⁶ (in the extreme case this includes failure to recognise the self in the mirror); *simultagnosia*: inability to recognise more than one element at a time of a visual scene (right temporo-occipital lesion); and, more controversially from the definitional viewpoint, *topographagnosia*, where patients cannot recognise items like buildings⁶⁷.

Alternating sequences: draw a short sequence of alternating squares and triangles and ask patient with frontal lobe pathology to copy the sequence and then continue the pattern⁶⁸; the patient will repeat shapes instead of alternating them.

Attention: the ability to focus in a sustained way on the matter in hand. *Concentration* is the ability to hold that focus. *Latent inhibition* refers to the situation wherein a person becomes used to ignoring a stimulus because of its irrelevance, but when its once again becomes relevant the subject finds it difficult to learn its significance⁶⁹. Terminology around the subject of attention varies somewhat. Krabbendam and Jolles(2002) define attention as a multifactorial construct that includes the capacity to remain alert, orient to new stimuli, to filter what is relevant, and to rapidly discriminate stimuli; sustained attention allows one to be ready to respond to small environmental changes; and sustained attention allows one to focus on the relevant, ignoring the irrelevant. *Sustained attention* (*vigilance* or *continuous performance*) is often measured with the *Continuous Performance Test*⁷⁰ (CPT). The *Stroop*⁷¹ *Colour-Word Test* (reading words, naming colours, and an interference condition of names printed in conflicting colours, e.g. ‘BLUE’ written in red)

may be dramatic following an acute cerebral insult the severity of neglect often declines with the passage of time to more subtle levels; the latter may be more obvious during the application of complex stimuli or when a stimulus is simultaneously applied to the unaffected side. The negation of hemi-neglect by the application of transcranial magnetic stimulation to the intact hemisphere (Oliveri et al, 1999) suggests that it is interhemispheric imbalance rather than damage to the other hemisphere that leads to hemi-neglect.

⁶¹ Tests for finger agnosia: recognise/name individual fingers; name finger being touched whilst patient keeps eyes closed. Autotopagnosia is very rare in its full-fledged form. Milder forms may take the form of misidentification of body parts. Most cases involve failure to recognise body parts bilaterally but unilateral cases may accompany unilateral neglect or anosognosia. The pathology in autotopagnosia is usually diffuse. Damage to the left parieto-occipito-temporal is a less common association.

⁶² The term *somatoparaphrenia* is applied to such bizarre beliefs toward a paralysed limb (too many [*pseudopolymelia*], misshapen, not alive, severed, belonging to a named other person [*somatophrenia*], etc). Whether one uses these terms or not depends on whether a psychiatrist is looking for somatic delusions or a neurologist prefers anosognosia. During the 1960s, Sir Aubrey Lewis suggested that lack of insight in schizophrenia was reminiscent of frontal lobe dysfunction and later authors have suggested that there is a parallel with anosognosia.

⁶³ Usually parietal but can be internal capsule, striatum, or thalamus. *Hemisomatognosia* is where there is loss of body image on one side and is found during an epileptic aura or migraine; the person may ignore this part of the body, acting as if it does not exist.

⁶⁴ One may divide **visual agnosias** into *apperceptive* (specific impairments of colour, movement, and form) and *associative* (cannot recognise faces or objects although the patient is sometimes able to copy or match them) subtypes. In contrast to visual agnosia, *deep dyslexia* refers to an ability to read the sense of a word but a word with similar meaning is substituted consciously, e.g. ‘terminal’ for ‘ending’ – a form of adaptation to neural damage.

⁶⁵ **Pure word deafness** is very rare and has been variably classified as an example of aphasia or agnosia. The sufferer hears words as sounds but not as words so that he/she cannot repeat overheard words or write down words that are heard. The lesion is in the dominant temporal lobe near the primary receptive area for hearing.

⁶⁶ Same areas are affected as in visual object agnosia (with which it sometimes occurs); may occur as part of simple partial seizure, when it is of brief duration.

⁶⁷ Alternatively defined as a loss of sense of direction – see ‘geographical disorientation’.

⁶⁸ Alternatively one could ask the patient to connect numbers and letters in the sequence A-1-B-2-C-3-D-4 etc on a page containing randomly situated letters A to G and numbers 1 to 7.

⁶⁹ This phenomenon is lacking to a significant extent in people with schizophrenia. The latter may be less influenced by prior experience, a phenomenon that might have some relevance for the genesis of hallucinations.

⁷⁰ Letters or digits are presented singly in random order and subject must respond when a designated target stimulus appears, although there are variations in practice.

⁷¹ Called after John Ridley Stroop (1897-1973), American psychologist, who described the test during the 1930s.

is often used to assess selective attention. People with left frontal lobe damage perform particularly badly on the Stroop Test.

The related concept of *alertness* has been divided into phasic (a warning stimulus raises the level of attention), divided (ability to attend to more than one stimulus simultaneously and to react to whatever is relevant), and sustained or vigilant (maintaining attention on a task over a long period of time). Whilst focal brain damage may selectively impair one of these subtypes, mixed patterns of different degrees of severity are common.

Buccofacial (oral) apraxia: patient unable to execute the normal facial, lip, and tongue movements, and the problem is not simply due to paresis; severe cases may be almost mute (*aphemia*⁷²). Broca's aphasia may occur with oral apraxia.

Consciousness: awake and aware; a state of mind which refers to the nature of a person's mental experience at a given moment in time; to be conscious is to be aware of oneself and one's environment; consciousness may be clouded, that is incomplete or diminished; preoccupation may narrow consciousness so that elements foreign to the preoccupation are excluded from consideration; the lay use of consciousness refers to an awareness, e.g. 'I was conscious of your dilemma'. From a biological viewpoint, consciousness is a product of tegmental nuclei of the brainstem reticular activating system; diffuse projections go to the forebrain and diencephalon.

*Dysarthria*⁷³: speech disorder caused by mechanical problems with anatomical structures necessary for articulation of speech. Ask the patient to say 'West Register Street'. Cerebellar speech involves fluctuations in rate, volume and tone, giving the false impression of intoxication. *Anarthria* is the complete absence of speech due to articulation problems.

Dyspraxia (apraxia): absence of praxis without it being explained by diminished motivation, arousal, attention, comprehension of language, or sensorimotor function; *motor dyspraxia* (lesion of dominant premotor frontal cortex or anterior corpus callosum, or diffuse cortical disease) – ask patient to mime simple tasks such as brushing teeth or copy unusual hand postures demonstrated by examiner; *constructional dyspraxia* (especially lesions of non-dominant hemisphere) – inability to construct shapes, by drawing or other means, either on request or when asked to copy a particular design such as a three-dimensional cube, a clock face⁷⁴, or a bicycle; ask patient to light a match (a complex task) to test for ideomotor/ideational dyspraxia (Q.V.). In dressing dyspraxia, the patient has difficulty putting on clothing (e.g. puts on garments backwards or puts arm in wrong sleeve – a good test is to ask a patient to don clothing that has been turned inside-out). Lower limb apraxia is demonstrated by asking a patient to trace specified patterns with the feet on the ground.

Euphoria: unjustified non-infectious happiness, contentment and unconcern; associated with frontal lobe damage or other organic states.

Hypergraphia: uncontrolled excess writing that is correct from a linguistic viewpoint but is nevertheless semantically loose. Causes include CVA, epilepsy, brain tumours, and CJD.

Ideomotor dyspraxia: the patient cannot mime an action (e.g. hair combing, using scissors, or lighting a cigarette) but can carry out the action when given the actual implements (like a comb); in *ideational dyspraxia*, on the other hand, there is defective carrying out of both actions (miming and real).

Logoclonia: spastic repetition of terminal syllable: 'I'm going to the circus, cus, cus, cus.' Found in Parkinson's disease.

*Palilalia*⁷⁵ and *palalolia*: repetition of sounds or words respectively, as distinct from *echolalia*, the repetition of whatever is heard, and *coprolalia*, the uttering of obscenities. See also perseveration.

⁷² *Aphemia* (or *aphemia*) is also used as a synonym for the very rare **pure word dumbness** (the patient, with a sub-insular lesion, cannot speak normally when he wants to or repeat words overheard or read aloud; he can write; he understands what others say and can understand written material; speech is slurred and poorly articulated). Pure word dumbness is apraxia for spoken speech production.

⁷³ Dysarthria and dysphagia often coexist because of shared neuromuscular control.

⁷⁴ **Clock Drawing Test**: Draw a clock-face with hands indicating a specified time (say 10 past 10 on the 12-hour clock): tests construction, planning and organisation. If spontaneous clock drawing is not satisfactory as the patient to copy one you have drawn – this helps to overcome executive problems such as planning but will be of little assistance to a person with visuoconstruction difficulties.

⁷⁵ However, palilalia is often used to mean repetition of the last uttered word or phrase uttered by *others*. (Sanchez-Ramos, 2004, p. 296) It is also used to mean repetition of *one's own* thoughts or sounds. (Ursano et al., 2008, p. 901) This is a good example of the loose use of terminology in the literature.

Perseveration: same answer is repeatedly given to different questions, or same non-verbal response is given for different stimuli; common in dementia and frontal lobe syndrome; includes palilalia and logoclonia. A patient may never get dressed because he keeps opening buttons each time he closes them or if told to copy an examiner who claps (say a few times) the patient may continue clapping. In perseveration the word or phrase used is initially appropriate but continues to be used though no longer relevant whereas a spontaneous and frequent use of a word or phrase that bears no connection with the circumstances amounts to *verbal stereotypy*.

Reduplicative paramnesia (environmental reduplication): a (variously defined) delusional belief that one is somewhere other than where one objectively is or, whilst incorrectly describing their true locality, patients hold that a familiar place has many copies in different localities, or knows where they are (e.g. hospital) but acts as if they are elsewhere (e.g. home); the actual place where the person is may be novel to that person; described by Pick in 1903; often associated with neurological deficit, e.g. head injury or stroke, especially involving both (or right) frontal lobes. Three subtypes have been described:

(a) **Place reduplication** – 2 identical places exist to which the patient gives the same name, but the places are situated at a distance from one another

(b) **Chimeric assimilation** – 2 places become one, as when a patient believes that home and hospital are one

(c) **Extravagant spatial localisation** – belief that one is in another place⁷⁶, often a place that one is very familiar with

Torpor: state of abnormal drowsiness – patient is sleepy, everything is slowed down⁷⁷, perception is diminished in range, concentration requires great effort, and, unlike in functional stupor, amnesia often occurs following resolution of torpor.

Wada test: inject sodium amytal directly into each carotid artery: when dominant hemisphere is perfused the patient becomes briefly aphasic.

Witzelsucht: silly, loud humour, pranks and punning; indicates organic cause, e.g. frontal lobe disease; *moria* is childish excitement or silliness in frontal lobe disease.

Describe the patient's appearance, including state of dress, posture, and body language. Describe his behaviour, e.g. unable to sit still, aggressiveness, fidgeting, and tics. How does he get on with you? Is he attractive, co-operative, docile, combative, hostile, agitated? Is his speech impaired (stuttering, aphasia, dysarthria), monotonous, fast, absent? Is there any abnormality of content e.g. neologisms? Does he tell you how he feels or does he deny certain feelings without conviction? How deep and sincere are his feelings? Is he calm, euphoric, angry, or frightened? Is his mood constant or fluctuating? Does his culture permit the expression of certain affects?⁷⁸ Does he show a variety of affects or is his affective range constricted? Is his affective expression severely reduced in intensity: blunting - 'flat' if no responses at all? How is the fit between subject matter and affect? Is it appropriate? Does he experience depersonalisation? Does he hallucinate and, if so, in what modality? What are the contents of his hallucinatory experiences, their timing, the 'person' in auditory hallucinations, and is there a temporal relationship with substance use?

Thinking

Slow, hesitant, rapid, full of ideas, bereft of ideas, etc?

Perseveration, loosening of associations,⁷⁹ tangentiality, circumstantiality, evasiveness, rambling?

Distracted by irrelevancies?

Thought block?

Incomprehensible?

Preoccupied?

⁷⁶ Carson et al (2007, p. 341) give as an example the patient who believed that he was being treated in a cruise liner and when he saw hospital porters delivering supplies through his (hospital) window came to the conclusion that the ship was in dry dock!

⁷⁷ Incl. thinking.

⁷⁸ A person's minority culture may lead to misinterpretation of normal distress as psychopathology. **Anger/irritability** may be entirely explicable on the basis of circumstances or it may be abnormal/morbid (out of proportion, pervasive, impulsive, uncontrollable, or occurring with high frequency), e.g. personality disorder, catastrophic reaction in dementia, paranoid disorders, mania (e.g. when thwarted), intoxication, and withdrawal states.

⁷⁹ *Asyndesis*: lack of adequate connection between consecutive thoughts.

Excessively abstract (categorical) or concrete (interprets common metaphors⁸⁰, spot differences⁸¹, or note similarities⁸²)? Recognition of similarities, differences, understand a subtle joke, or recognise an absurd question (e.g. 'Which is the bigger, a square or a circle?')?

Ideas of reference, delusions of persecution, etc.? What are the details, when did they start, what effect have they had, did he act on them or does he plan to do so?

Effect of current treatment on thinking, behaviour, mood?

Is his general information in keeping with his job, pastimes, education, background?

Concentration may be tested throughout the interview and tested formally at this stage, e.g. serial 7's (starting with 100, subtract 7 from each answer⁸³).

What is his level of consciousness (lucid, drowsy, stuporous, and comatose)? Dissociative fugue states, retarded depression, and mute schizophrenia may closely simulate a lowered level of consciousness⁸⁴. Disorientation may be a product of a lack of interest or stimulation (e.g. in institutions), physical treatments, or organic mental disorders; *topographical disorientation*, difficulty in finding ones way even in familiar surroundings, may herald organic brain disease. Approximates are sufficient e.g. the date. In organic disorders the first to go is 'time', then 'place', then 'person' - they improve in the reverse order. How long has he been in hospital, how did he arrive here today, why are you both meeting here, and who or what am I? Inability to name oneself occurs in dissociative states and in advanced dementia, or it can be that the patient is deluded into thinking that he is someone else. Confusion (implying organicity) shows up most in the dark: enquire about its timing/worsening from a relative or nurse.

Memory

Tested throughout the interview

Direct questions better if related to matters with meaning for the patient, e.g. what happened a few minutes ago, what did he do on his last birthday, who did he marry (maiden name), rather than formal tests such as repeating digits forwards and backwards (e.g. 46932614)

How does he cope with/hide a poor memory, e.g. notes, diaries, circles on calendar dates?

Judgement may be assessed during the interview or by direct questions, e.g. "If you found a lady's handbag on the street, what would you do?" Alternatively, "If you discovered a stamped, addressed envelope beside a post-box what would you do?"

Does he deny being ill, on has he some strange explanation for his state, e.g. concrete blocking his bowels or a neighbour poisoning him.

How reliable do you think the patient and other informants are in supplying the information you seek, and how motivated is the patient to get better?

Life charts (Sharpe, 1990)

Depict relevant information as it happens chronologically (relapse, remission, life events, treatment)

Renders correlations immediately appreciable

Best if prospective

Ending an interview requires that you signal this in plenty of time, e.g. "Since we are nearing the end of the consultation I would like to cover a few areas we may not have touched on." It helps to summarise the main points of the consultation for the patient. This allows him/her to modify emphasis or correct any mistakes. The interviewer then sets out the plan: tests, homework, contacts to be made (and permission given), next appointment, etc.

Formulation/summary

Short version: This is a very brief summary of your knowledge of the case to date, e.g. Mr. J B, a 64-year-old farmer with recurrent memory black-outs over a period of 18 months related to his excessive drinking.

⁸⁰ E.g. 'A rolling stone gathers no moss'. The value of this type of test in detecting organic disease has been questioned because poor abstract thinking is not confined to this group of disorders. Psychotic patients may give revealing interpretations of proverbs.

⁸¹ E.g. 'What is the difference between a mistake and a lie?'

⁸² E.g. 'What have a lake and a bathtub in common?'

⁸³ If the patient finds this to be too difficult they can be asked to subtract 3 serially from 20 (17, 14, etc) or to count backwards from 20 (19, 18, 17, etc).

⁸⁴ **Psychogenic 'coma'** is suggested by normal vital signs (including pupil, corneal, gag, swallow, and oculovestibular reflexes), eyes that stare (rather than wander), and resistance to movement of eyelids/limbs. The EEG may be normal. IV barbiturate may render the patient verbose, unlike the deterioration in attentiveness to be expected with neurological disease.

Long version: This is much shorter than a full history, mental state, diagnosis or differential diagnosis, and plan of action, and contains positive points only, e.g. Mrs. A.H., a 32-year-old housewife from a working-class area in South Treeville presented with a 4-week history of panic attacks, agoraphobia and feelings of depression. Her husband is unemployed, with a history of violence toward Alice whilst he is intoxicated. Reared by elderly parents in rural setting, left school with no exams at 14 years, and went to the city for work. Lost 6 good jobs (range 12 years - 6 days) because of drink problem/absenteeism/poor discipline. Lives on social welfare payments. Outings to pubs only; brings home a bottle of cider. Married age 25 years, first drink age 24 years (with husband). Husband imprisoned twice for assault (6 months, 1.5 years). 3 children (in care - confirmed abuse, non-sexual). Drinks 6 small whiskies and one large bottle of cider daily. Smokes 60 cigarettes per day. Past psychiatric history: in hospital for one day ('drunk'); took own discharge. Past medical history: gastroscopy (normal) last year. Legal: awaiting court proceedings against husband re violation of barring order and non-payment of maintenance. Mental State: actively denies excess alcohol intake, blames problems on marriage. Diagnoses: alcohol - related problems; social problems; ? underlying personality problem. Plan: detoxification, bloods, urinalysis, chest X-ray (?TB), alcoholism counsellor, Alcoholics Anonymous, interview parents (husband unreliable), check with social services re children, discuss case with GP, and ask social worker to interview

A biopsychosocial framework for formulating cases

The doctor considers predisposing (e.g. family history, neglect in childhood), precipitating (e.g. physical injury, divorce), perpetuating (e.g. avoidance, inactivity, long-term unemployment, insomnia, unresolved financial compensation) and protective (e.g. confiding relationship or a hobby) factors under the headings of biology (e.g. genes), psychology (e.g. self-esteem, ability to trust, locus of control) and sociology (e.g. marital status, finances, neighbourhood, legal entanglements), completing the table for the index case.

	Biological	Psychological	Social
Predisposing	-	-	-
Precipitating	-	-	-
Perpetuating	-	-	-
Protective	-	-	-

Symptomatology

'Phenomenology is like a photographic still whilst psychodynamics can be likened to a motion picture.' (Nemiah, 1989)

'No individual symptom is confined uniquely to a single disease...' (Liddle, 2001)

'So many of the terms used in psychiatry are not precise....with different names may partly overlap and coalesce.' (Sims, 2003, p. 221)

For something to be remembered it must be registered (attention, hearing), retained (often unable to do so in early dementia or in Korsakoff's psychosis), and recalled (goes late in dementia - such as maiden name or place of birth).

Amnesia

Amnesia is abnormal forgetting

Common in affective (mood) and organic brain disorders

Recent memory lost first in dementia (*Ribot's law of memory regression*)

Dissociative (may not know own name or address but can learn new information and selectively recall past events; often follows stressful experience) and manipulative 'amnesias' are generally highly selective⁸⁵

Screen memory: consciously tolerable memory serving as cover for an associated memory too emotionally painful to recall – recalls part of true memory⁸⁶ making it difficult for the observer to distinguish what is true – Freud held that memories, particularly those relating to events that happened many years earlier, may be constructed like dreams with elements of self-deception and wish fulfilment

Anterograde amnesia - loss of memory for events following an insult (e.g. cranial trauma)

Retrograde amnesia - not remembering events leading up to the insult

Posttraumatic amnesia - extends from time of injury to restoration of normal continuous memory

Insult may be psychological (e.g. bereavement) or physical (e.g. boxing)

⁸⁵ However, the reader should realise that isolated inability to recall significant personal events (e.g. wedding date) can sometimes be organic in origin and due to brainstem, fronto-basal, or anterior temporal lesions. (Kopelman, 2002) Of course, similar losses may occur as part of dense anterograde memory loss.

⁸⁶ E.g. 'I was attacked by my school mate', when in actuality I was attacked by my mother. Screen memories may be relevant in the debate around 'recovered memories' and the so-called 'false memory syndrome'.

Whilst pure anterograde amnesia is common, retrograde amnesia is almost always accompanied by anterograde amnesia. (Goldstein et al., 2002) Definitions vary between authors. (Kopelman, 1987; Gelder et al., 1996; O'Shea & Condren, 1996)

Retrospective falsification

Patient is unaware that of remembering things in a manner coloured by unconscious factors, e.g. bleak views of the past in depressives (e.g. 'I was always a burden' - mood colours thinking), or wish fulfilment in the jilted ('He didn't say exactly that he would never come back to me!')

Anxiety states may also be accompanied by an enhanced tendency to recall negative or threatening data (Nitschke & Heller, 2002)

In Korsakoff's psychosis, but also sometimes in other organic brain conditions and in schizophrenia (Lorente-Rovira et al., 2007), the patient may *confabulate*, i.e. unconsciously fills in gaps in memory with events that never happened (or, some of these memories may be real but displaced in time). These two distortions of recall come under the heading of *paramnesias*. Some authors divide confabulation into two types: the form occurring when asked about something that one is unable to remember, which might constitute a normal reaction to either a basically poor memory or to a failing memory; and spontaneous confabulation where the patient confabulates freely, a pathological symptom, i.e. a manifestation of an illness process rather than an attempt to cope with a problem. Other paramnesias include *déjà vu*, a subjective feeling of strong intensity that a novel experience was previously experienced, *jamaïs vu*, a subjective feeling that a previously experienced event is novel, and *déjà entendu*, something which you hear for the first time seems extremely familiar. The last three phenomena are not uncommon in temporal lobe epilepsy (TLE) and are sometimes referred to as *illusions of memory*. *Déjà vu* that lacks the vivid and often clearly repetitive nature of a temporal lobe aura is usually due to anxiety. (Trimble, 1997) *Déjà pense* is a novel thought felt to have occurred previously.

Panoramic recall

The feeling that one is quickly re-enacting long stretches of one's life

Described in TLE

Levels of consciousness may reach extremes of excitation after imbibing LSD25 or an amphetamine. Extreme lowering of consciousness (*coma*) is associated with lack of voluntary movement, absent reflexes, and non-responsiveness to even painful stimuli. Coma due to brain stem lesions may produce alpha or theta coma patterns in the EEG whereas bi-hemispheric disease may produce a delta coma pattern. The term *confusion*⁸⁷, to all intents, is synonymous with disorientation.

In *stupor*⁸⁸, the patient is immobile, mute and unresponsive, but appears to be fully conscious (in neurology the term stupor infers lowered consciousness); he may follow objects with his eyes; if his eyes are closed

⁸⁷ However, it is more complicated than this. Thinking is muddled and disorientation may initially be transient or a patient may be orientated on examination but later be unable to recall the interview. (David, 2009, p. 12)

⁸⁸ The **differential diagnosis of stupor** includes: depression, schizophrenia (one of Bateman's [1990] patients believed that every time he spoke it shortened his life), rarely dissociative states or mania, intra-cerebral (posterior diencephalic and superior midbrain focal lesions such as craniopharyngioma, infarction, meningitis, epilepsy) and extra-cerebral (e.g. uraemia, hypoglycaemia, electrolyte and fluid imbalance, endocrinopathies, alcohol and drug-induced) causes. The EEG may help distinguish organic from psychogenic causes. Disorientation for time is usually an early sign of organic insult (e.g. delirium). The usual site of a lesion in organic cases is upper brain stem or midbrain but it can be in anteromedial frontal lobe or nearby septal area. Cases of hysterical stupor tend to look toward the floor if turned on their side. Stupor from lesions of brainstem is usually accompanied by apathy and sleepiness, and often there is weakness of the extraocular muscles. The patient with stupor due to a frontal lobe lesion - which may involve the anterior cingulate with its subcortical connections) is more often alert and may demonstrate *hyperpathic akinetic mutism* (appearance of vigilant gaze).

Idiopathic recurrent stupor consists of episodes every 1 to 6 weeks during which stupor attacks last 2-120 hours. The patient is only briefly rousable from such a state. Endozepine-4 levels are very high in plasma and CSF. IV flumazenil rapidly normalises the clinical state and the EEG.

he resists attempts to open them; the reflexes are normal; and he can maintain his posture even if he appears to do so clumsily.

Aphasia (Gk. *a*, not; *phasis*, speech): Broca's area⁸⁹ is just below the motor area for the right hand and face. Wernicke's area is in the posterior part of the dominant superior temporal gyrus. The two areas (in most people in the left hemisphere) are joined by the arcuate fasciculus that passes through the angular gyrus. Cerebral dominance⁹⁰ is not well established in very young children. *Dysphasia*⁹¹ (the complete form being *aphasia*) is an organic impairment of language and communication. Broca's aphasia is usually accompanied by contralateral hemiparesis, Wernicke's less commonly so. Wernicke's aphasia is commonly associated with a visual defect, this being rare with Broca's aphasia.

Aphasia

- (a) **Receptive (sensory, fluent, jargon) aphasia** - patient hears but *cannot understand* (lesion in Wernicke's area; speech is fluid and spontaneous but incoherent and nonsensical) and is unaware of the problem (may become annoyed or unduly suspicious when not understood); may be mistaken for thought disorder (neologisms, paraphasic errors, and, by way of compensation for communication problems, exaggerated affect); also, impaired naming, repetition, reading, and writing
- (b) **Expressive (motor, non-fluent) aphasia** (lesion in Broca's area) - patient understands others but cannot express himself normally: speech is halting, laborious, inaccurate, telegraphic⁹², or even absent - in the lesser, *dysphasic* form the appropriate words cannot be found despite knowing what it is one wants to say (patient may communicate through simple 'yes' or 'no' questions or via facial expression)
- (c) **Global (total) aphasia** - combination of (a) and (b) - speech is non-fluent and the patient shows by his emotional reaction that he is unaware that there is a problem
- (d) **Conduction aphasia** - similar to sensory/fluent aphasia but with understanding and awareness of deficits, the latter leading to frustration
- (e) **Nominal dysphasia (anomia, amnesic aphasia)** - inability to find words or name objects that patient should know (e.g. a pen or a watch) - tested for in detail by asking the patient to (a) name 12 familiar (e.g. a cup) and unfamiliar (e.g. examination couch; teeth of a comb⁹³) objects while he handles each in turn, and (b) name as many members of stated categories (e.g. flowers or animals) as can be recalled

Patients with Broca's dysphasia are frustrated: *emotional speech* is found in such patients: they may utter words or sentences when experiencing great emotion that they would otherwise be unable to produce. The acute onset of abnormal speech in a middle-aged person is almost always diagnostic of a fluent aphasia. (Geschwind, 1971) *Fluent dysphasia* may be misdiagnosed because many doctors are unaware of the frequency of aphasia without a hemiplegia. The patient may be mislabelled as 'psychotic' or 'confused', especially when there is a rapid outpouring of abnormal speech. In practice, the differential diagnosis is not always straightforward.

Nominal dysphasia, unlike primary motor aphasia, may be commoner in diffuse rather than focal brain dysfunction (e.g. Alzheimer's disease), and it is often accompanied by *acalculia* (inability to do simple arithmetical calculations; tested for by 'serial 7s' - this, or *dyscalculia* (*dysarithmetria*: a lesser form, may be acquired or developmental). People with nominal dysphasia are aware of the deficit. A temporary inability to remember a proper noun or name, a universal experience, is called *lethologica*.

Word salad, a mixture of words and phrases lacking comprehensive meaning or logical coherence (lacking grammatical rules; no logical link between adjacent words), is found in schizophrenia.

⁸⁹ Posterior part of inferior frontal gyrus of dominant hemisphere, i.e. Brodmann's (after the German neuroanatomist Korbinus **Brodmann**) areas 44 and 45. Brodmann worked on one brain and since there is great interindividual anatomic variability his 'areas' act only as a rough guide. The contralateral (usually right) area to Broca's area is important in giving emotion to speech in the form of prosody and gestures.

⁹⁰ By this is meant (usually) left-sided dominance for speech. *Cerebral hemispheric asymmetry* is a better term since each hemisphere is dominant/ specialised for/in different functions, e.g. the right side for music.

⁹¹ '...a patient who cannot carry on a simple conversation but who can prepare a full meal likely has an aphasia not a dementia'. (Kelsey et al., 2007, p. 293)

⁹² Sentences shorn to their minimum, e.g. 'Read paper' instead of 'Please read the newspaper for me'.

⁹³ The best words to test for are probably ones that most of us know but use infrequently, e.g. the buckle of a belt, the knuckle of a finger, the dial of a watch, or the sole or heel of a shoe.

A lesion of the angular gyrus leads to loss of ability to read and write (speech, both in terms of production and understanding, is normal), the two kinds of visually mediated language. *Alexia*⁹⁴ is loss of ability to grasp the meaning of written or printed words or sentences. Dyslexia includes word blindness⁹⁵ and a tendency to reverse read or written letters and words. Various acquired alexias⁹⁶ have been described. *Developmental dyslexia* (specific reading retardation) is an isolated problem with learning to read and write. It is not explicable on the basis of IQ or educational opportunity. However, in practice, inadequate schooling and difficult home circumstances may play apart, as may genetic vulnerability⁹⁷. *Agraphia*⁹⁸ is the inability to write and may accompany aphasia or apraxia.

There may be associated neurological deficits in dysphasic patients, e.g. right hemiplegia (Broca's aphasia), hemianaesthesia and hemianopsia (Wernicke's), or all of these (global).

Formal assessment of intelligence in the aphasic is difficult and reliance is placed on non-verbal measures⁹⁹ to obtain an estimate.

Definitions

Praxis (Gk. action) : ability to manipulate body parts correctly in space, i.e. perform a planned complex or skilled motor task.

Engram: a memory trace.

Co-morbidity (dual diagnosis): simultaneous occurrence of two or more psychiatric diagnoses in the same individual. (Kim ea, 2003) There are a number of possible reasons for this common¹⁰⁰ phenomenon: adherence to diagnosis according to operational criteria¹⁰¹; co-occurrence of more than one discrete disorder; one primary disorder with additional secondary disorders; addition of personality disorders to Axis I disorders; intellectual disability; (Timms, 2005) sharing a common biological abnormality; and mental disorders are simply reaction patterns rather than discrete entities, thus allowing for considerable interindividual variability and little consistency. (Van Praag, 1996) Comorbid axes I and II disorders carry a relatively poor prognosis. (Crawford ea, 2008) The term 'dual' diagnosis is often confined to the (common) combination of substance misuse plus a mental illness. (Weaver ea, 2003; MacGabhann ea, 2004)

Formal thought disorder: disorder of the *form* (versus content) of speech; disorganised speech; sometimes divided into positive (extreme incoherence, derailment, tangentiality, illogicality) (Andreasen & Black, 1991) and negative (poverty of production or content of speech) types. Thomas (1995) prefers the term 'communication disorder' to thought disorder. Examples are loosening of associations, flight of ideas, and circumstantiality. Speech which is impoverished of content is spontaneous and of normal quantity, whereas in poverty of (quantity) of speech there is little said.

Incoherence: speech pattern is incomprehensible (synonymous with *word salad*).

Illogicality: speech pattern in which conclusions are reached which do not follow logically.

Effort after meaning: ill person tends to recall events that he imagines caused the disorder rather than giving an objective account of all pertinent details.

Derailment: shifts from one train of thought to another with connection; ideas slip off track onto ideas obliquely related or unrelated to the original ones; seen by some as synonymous with loosening of associations. (Ninan ea, 1998)

⁹⁴ The lesser form is called *dyslexia*.

⁹⁵ In **pure word blindness** (*alexia without agraphia*, the lesion being in left visual cortex plus splenium of corpus callosum) the patient can understand the speech of others but cannot comprehend the written word. Letters can be described and copied but cannot be recognised. Writing, spontaneous or to dictation, is not a problem, but the writer cannot read what he/she has written. Colours are perceived but cannot be named. There is usually a right homonymous hemianopia. In **alexia with agraphia** (*visual asymbolia*) the patient cannot read or write but can use and understand speech; the lesion involves the dominant angular and supramarginal gyri.

⁹⁶ In *deep dyslexia* (vascular lesion centring on right perisylvian region) the patient makes semantic errors, i.e. he misreads words but shows some understanding of the meaning of those words, e.g. 'dog' is read as 'animal'. *Phonological dyslexia* (anterior perisylvian lesion) is an inability to read non-words. In *surface dyslexia* (left insula/putamen lesion) the patient makes regularisation errors, e.g. 'comb' instead of 'come'.

⁹⁷ Loci on chromosomes 6 and 18. (Francks ea, 2002)

⁹⁸ **Pure agraphia** (*agraphia without alexia*) is an inability to write spontaneously or to dictation. The classical lesion is in the second frontal gyrus in front of the hand area but it can be in the parietal lobe.

⁹⁹ E.g. Test of Non-verbal Intelligence -2 (TONI-2). (Sherman ea, 2008, p. 112)

¹⁰⁰ 'Epidemic' according to Escobar. (2005, p. 26)

¹⁰¹ Comorbidity by default. (Van Praag, 1996; Clarkin, 2005) See Tyrer and Silk (2008, p. 6): extensive comorbidity decreases the value of a diagnosis and Comorbidity is more acceptable if it follows from what is known about the index (primary) disorder, e.g. substance misuse secondary to borderline personality disorder.

Miserable mania: elderly manic expresses depressive content in jocular fashion.

Recurrence: new episode of illness after a period of complete recovery; preventive (prophylactic) therapy is indicated.

Relapse: worsening of symptoms after initial improvement in the index episode; continuation treatment is indicated.

Relapse signature: the symptoms shown recurrently by an individual patient in the early stages of relapse.

State dependent learning: relative difficulty in retrieving information or behavioural learning during a different mental state, e.g. something learned when intoxicated can only be recalled when again inebriated, but not when sober.

Talking past the point: patient answers question with inappropriate remark that is obviously incorrect but indicates that he understands the question (Unfortunately, the term is sometimes used to refer to *tangentiality* and *Vorbeireden* is then used as a synonym for talking past the point instead of the approximate answers-type of definition just given).

Transitional object: possession that acts as a comfort in absence of the mother (blanket, doll, etc); associated with Donald Winnicott.

Coprophagia: display of rude gestures.

Ecstasy: rare; extreme well being, usually kept private, without overactivity; may feel in communion with God; found in epilepsy, mania, and schizophrenia.

Elation: increased mood that is infectious to others, as in many cases of mania: 'infectious jollity'.

Diurnal variation of mood: any variation in mood with a consistent 24 hour cycle (such as worse in the morning and improving as the day progresses) that is independent of environmental events and is the same on all days of the week (e.g. does not change if working or on annual leave).

Pleiotropy: a single cause can lead to a wide range of behaviours; a gene can manifest different phenotypes, as in Marfan's syndrome.

The rare *foreign accent syndrome* may occur in patients with lesions of the left frontal cortex. A patient, whose speech is otherwise normal, starts to speak with an accent associated with a country to which he or she has no connection.(see, e.g., Seliger ea, 1992) However, *stilted speech*, which may take the form of adoption of a foreign accent, may occur in schizophrenia.

Perception

Mechanism whereby one organises, identifies and confers meaning on ones sensory input (sensation), i.e the bringing of sensory stimuli into awareness

Process of becoming aware of what is presented via sense organs

Perception is modified by cognitive organisation processes and may be attended to or ignored

Body image

Ones sense of the self or body

One definition of an *hallucination* is a that it is a false sensory perception, involving any of the senses, in the absence of a external stimulation of the relevant sensory organ¹⁰². It occurs at the same time as normal perceptions and patients can often distinguish between the two¹⁰³. It has substantiality, is vivid and realistic, appears localised in external space (outside the head, as distinct from the 'mind' – an exclusion criterion that this author and many others [e.g. Ninan ea, 1998; Nurcombe & Ebert, 2008, p. 49] do not subscribe to),(Black & Andreasen, 1996) and it arises independently and cannot be conjured up or dismissed.

¹⁰² There is no totally satisfactory definition of a **hallucination**. If pressure is placed on the eyeball and lights are seen there are no lights in the external environment and the relevant sensory organ is being stimulated! Perhaps a better definition refers to the absence of 'corresponding external stimulus' or absence of an 'external source' (e.g. hearing a voice in the absence of a speaker). Definitions that state 'in the absence of a(ny) stimulus' cannot be correct.

¹⁰³ E.g. a person may be able to carry out a conversation with another person despite on-going auditory hallucinations. However, complaints of seeing visions of other people who speak (especially if they converse with the patient) are not likely to reflect hallucinations; rather they are most likely due to lying (malingered or factitious) or a conversion state.(Mullen, 2008, p. 7)

Sims(2003, p. 99) adds that the hallucinator often does not believe that other people can share his experience and a 'delusional explanation may be given for this'. Patients often do not seem to care if they cannot explain whence or from whom hallucinations arise. One patient with borderline personality disorder claimed to be able to see 'little green men' outside in the garden every time she raised the window blind! Hallucinations would be expected to be present no matter whether the blind was raised or lowered. Likewise, if a patient destroyed his tympanic membranes it should not eliminate auditory hallucinations. Cocainism is often associated with *haptic* (tactile) sensations of insects crawling beneath the skin ('cocaine bug'). *Somatic hallucinations* are sometimes divided into *superficial* (haptic: touching, tickling; kinaesthetic: movement, joint position; thermic: hot or cold; hygric: wetness) and *deep* (visceral changes, sexual stimulation, electricity passing through the body) subtypes. *Visual hallucinations* (incl. autoscopic) are due to organic pathology or drugs until proven otherwise. However, they may also be found in schizophrenia, severe affective disorder, following torture (Rasmussen, 1990) and, in 12% of cases in one series, in 'hysteria', (Perley & Guze, 1962) which today would be called dissociative disorder. They may also occur in people with eye disease (Charles Bonnet syndrome). Anticholinergic drugs may be associated with visions of bugs crawling on the skin. Olfactory hallucinations may, for example, herald an attack of TLE, the ictus commencing in the uncus ('uncinate fit'). Gustatory (taste) hallucinations should not be confused with the various tastes produced by drugs.

Pseudohallucinations, an imprecise and controversial term that would be better discarded according to some authors,(Taylor, 1981) involve the reporting of hallucination-like experiences but without an identifiable percept: he may saw he sees things that are not there but is unable to describe an actual specific perception; they are less vivid and realistic than hallucinations, are often located inside the head (internal space), and often coincide with true hallucinations¹⁰⁴. These 'as if' experiences are not necessarily abnormal. However, the present author agrees with Owens ea (2004, p. 234) when they say that hallucination arising from within the head are true hallucinations, there being nothing 'pseudo' about them. Schweitzer and Parker (2007, p. 179) point out that auditory hallucinations in psychotic depression are 'located inside the head' but then weaken the argument somewhat by adding that they may be interpreted as 'voices of conscience'. In addition, Kapur and Mamo (2004, p. 119) state that, depending on the salience attributed to the internal perception, a person might experience an auditory hallucination varying from hearing his own thoughts within his head 'all the way through' numerous external voices commenting on the hearer's activities. Mullen (2008, p. 9) states that pseudohallucinations are as real (and abnormal) as hallucinations.

Far more common in psychiatric practice are *illusions* (distortion or false judgement of a perception of a real object; 'the food tastes queer' - may progress to a delusion of poisoning) of taste. It should be remembered that visual hallucinations due to disease of the central pathways of the visual apparatus are rare. *Hypnagogic* (going to sleep¹⁰⁵) and *hypnopompic* hallucinations (on waking) occur when the level of consciousness is between waking and sleep, and they are often normal.

Lilliputian or microptic hallucination

Bright, funny, everything is much reduced in size

Aetiology:

Alcohol

Anaesthetics

Enteric fever

Scarlatina

Delirium tremens - small, obscene and abusive creatures (Sims, 2003, p. 45)

Micropsia and macropsia

Seeing things as smaller or larger than they should be

¹⁰⁴ Philpott (1997, p. 294) says that patients recognise these pseudohallucinations as imaginary and he includes seeing/hearing/feeling a lost loved one in the definition.

¹⁰⁵ Many people have a problem remembering which of these two phenomena occur when going to sleep versus on waking from sleep: the clue is in hypn**og**ic, i.e. the go = **g**oing (to sleep).

Aetiology:

Some cases of panic disorder (Coyle & Stermann, 1986)

Schizophrenia - demonic or religious visions, small people, or distorted facial features (Salo & Robertson, 2003, pp. 493-5)

Micropsia, macropsia, and *dysmegalopsia*¹⁰⁶ can also occur with organic states or epilepsy

*Alice in Wonderland syndrome*¹⁰⁷ is associated with migraine, hallucinogen use, seizures, viral encephalitis (espc. Epstein-Barr virus) and lesions of the non-dominant parietal area

A *reflex* hallucination occurs when one sensory modality is excited and the cause is irritation in another, e.g. dental caries causing a noise to be heard. As such it is a synaesthetic phenomenon.

A *functional* hallucination is provoked by a stimulus and occurs in the same sensory modality as the stimulus; both the stimulus and hallucination are perceived at the same time and are also perceived as being distinct. A classical example would be when a person turns on a tap and only hears a hallucinatory voice whilst the water is running, but he also hears the water running.

Unfortunately, some authors (e.g. Cutting, 2003, p. 16) view reflex and functional hallucinations as being synonymous and define it as per the above definition of functional hallucination.

Auditory hallucinations, like those in other sensory spheres, need not be well formed. *Crude* hallucinations include buzzing noises and spots of light.

Auditory hallucinations are commonest in schizophrenia and in alcoholic hallucinosis. (Cutting, 1989) They sometimes occur in depression, mania, or after damage to one of the temporal lobes, and, very rarely, they are a manipulative or hysterical symptom. They may occur as a transient phenomenon in normal people.

Just over 50% of schizophrenic patients hear voices¹⁰⁸ at sometime. In alcoholic hallucinosis the voices respond poorly to neuroleptics but they clear if the patient remains abstinent. Normal people may hear noises or voices when dropping off to sleep, on waking, when tired, when exposed to extreme sensory or social isolation, or at the height of a bereavement - the voice may simply call the person by name, e.g. 'Jack!' Defective hearing aids may account for some cases of auditory hallucinations, or the hearing of additional hallucinations in those who already hallucinate. (King, ea, 1989). There is evidence from fMRI that hallucinating schizophrenic patients activate cortical regions mediating the generation of inner speech before areas implicated in the perception of sounds become engaged. (Shergill ea, 2004) However, the match between inner speech and hallucinatory phenomenology has been challenged by Langdon ea (2009) who also found little difference between the inner speech of hallucinating schizophrenic patients (N = 29) and healthy controls (N = 42); the study involved asking the participants questions about hallucinations and inner speech and the authors pointed out that thought disorder was not a marked feature of the ill group.

Extracampine hallucinations are visual hallucinations seen outside the field of vision, such as behind oneself, or auditory hallucinations reported to be heard from outside the range of unaided hearing (e.g. from another country or town). They may occur in normal people as a hypnagogic phenomenon¹⁰⁹, in schizophrenia, or in organic disorders including epilepsy. (Sims, 2003, p. 112)

Autoscopy (phantom mirror image)

Seeing a vision of oneself outside oneself, usually to the front

Can occur with organic (e.g. simple partial seizures or delirium or migraine) and functional states (e.g. schizophrenia)

¹⁰⁶ Objects seem larger on one side than the other when in fact they are of equal size. *Metamorphosia* means that objects appear irregular in shape when in fact they are not; retinal scars can cause this or macropsia whereas an oedematous retina can be associated with micropsia. *Porropsia* means that objects may seem to retreat into the distance (overlap with micropsia).

¹⁰⁷ Distorted perception of objects, usually microptic or macroptic, distorted time sense, and visual hallucinations.

¹⁰⁸ The word *phoneme* is sometimes used to indicate an hallucinatory voice but it is more often refers to constituent speech sounds.

¹⁰⁹ In a community study covering a wide age range (Ohayon ea, 1996) 37% and 12.5% of people reported experiencing hypnagogic and hypnopompic hallucinations respectively.

Can occur transiently as a normal phenomenon if the person is fearful, tired, intoxicated, suffering from sensory deprivation (out-of-body experience), or as hypnopompic or hypnagogic hallucinations¹¹⁰
 Occasionally it may be encountered in the context of organic brain disease, as in temporal lobe epilepsy
Negative autoscopy is not seeing ones reflection in the mirror
Internal autoscopy is a rare phenomenon where someone sees their own internal organs which they describe in a naive manner
Mirror sign - seen in dementia: non-recognition of ones image in a mirror¹¹¹

Autoscopy is reminiscent of the *doppelganger phenomenon*: a direct encounter with the self is experienced, either in the form of a hallucination or an illusion, and the perceived figure shares the same personality and identity as the self.

Olfactory hallucinations occur in depression¹¹², schizophrenia¹¹³, *olfactory reference syndrome*, and temporal lobe epilepsy¹¹⁴. (Meats, 1988).

Olfactory reference syndrome (ORS - Videbech, 1966)¹¹⁵

Usually a true olfactory hallucination

Believed by patient to arise from the self

No prior depression of mood

Excessive washing of hands, changes of clothing, and avoidance of other people

Associated with delusional disorder

Fish odour syndrome (trimethylaminuria) (Humbert et al, 1970¹¹⁶; Mitchell & Smith, 2001)

Example of a non-hallucinatory disorder – fishy smell from patient leading to social ostracism

Rare (F > M) metabolic disorder, usually autosomal recessive

Mutations of FMO3 gene¹¹⁷ on chromosome 1q with defect in FMO3 production

Unable to break down trimethylamine (TMA) properly leading to its accumulation

TMA appears in body fluids (sweat, urine, breath, vaginal secretions)

Exacerbated premenstrually, by oral contraceptive pill, and around menopause

Diagnosis: urine TMA/TMA oxide ratio

Avoid eggs, legumes, some meats, fish and foods containing choline, carnitine, nitrogen, and sulphur

Olfaction in psychiatry (O'Shea & Haque, 2004; O'Neill & Regan, 2004; Sawa & Cascella, 2009):¹¹⁸ When testing the sense of smell, not that ammonia and alcohol may stimulate the fifth cranial nerve and the resulting reaction may lead to confusion in the examiner! Also, avoid esoteric odours like cloves. Instead, coffee, wintergreen, or peppermint are useful. Olfactory problems may operate in a variety of disorders, such as Alzheimer's disease, Parkinson's disease¹¹⁹, dementia with Lewy bodies, Korsakoff's psychosis,

¹¹⁰ It can also be part of a near-death experience. A rare complication is the Doppelganger phenomenon where the person also believes that they have a double.

¹¹¹ The patient may have a conversation with the reflection or ask it to 'leave' the house! The *TV sign* is when the viewer believes that characters on the television screen are actually present in the room. Perhaps because of non-recognition of family, a person may believe that other people live in his/her house: *phantom boarder syndrome*. Prosopagnosia in its severest form may include failure to recognise ones reflection in the mirror. However, this is most commonly found in dementia with its more global manifestations. Rarely, a patient may look in the mirror and decide that the reflection represents an untrue version of the self (shades of Capgras, although the patient may simply be unsure of the facts).

¹¹² Usually a foul odour; two-thirds believe that they are the source of the odour; seldom associated with other sensory abnormalities; usually an endogenous depression with retardation, depressed mood, and morbid thoughts.

¹¹³ Common but usually subordinate to hallucinations in other modalities; may be dominant in late-onset paranoid cases; believes smells are being forced on him and may take action to stop it, e.g. blocking up the chimneys.

¹¹⁴ Almost always recognised as a subsidiary part of the illness by the patient.

¹¹⁵ See also delusions of bromosis which Munro(1999) views as synonymous with ORS.

¹¹⁶ The condition is probably ancient. Shakespeare's Caliban, an outcast in the *Tempest*, appears to have had this syndrome. It is also known as fish malodour syndrome.

¹¹⁷ The enzyme flavin-containing monooxygenase-3.

¹¹⁸ According to Schiffer and Lajara-Nanson,(2003, p. 16) smoking may be the major cause of impaired olfaction in the Western World.

¹¹⁹ Between 70-90% of Parkinson's disease sufferers may have poor sense of smell and this may precede motor phenomena. It is often not recognised by the patient.(Henderson et al, 2003)

schizophrenia¹²⁰ (close relatives lying between patients and controls: Sawa & Cascella, 2009), Huntington's disease, Down's syndrome, and depression (Harrison and Pearson, 1989; Scalco et al., 2008) as well as PTSD. (Dileo et al., 2008) Compton and Chien (2008) failed to find a correlation between schizotypy based on the *Schizotypal Personality Questionnaire* (Raine, 1991) in healthy first-degree relatives of people with schizophrenia and related disorders and olfactory ability as measured by the *Pennsylvania Smell Identification Test*. (Duty et al., 1984) Turetsky and Moberg (2009) used two fruity/floral odorants (citralva and lylal) that differ in their relative activations of cyclic AMP (which mediates signal transduction in olfactory receptor neurones) and found that schizophrenia patients and their well first-degree relatives, but not comparison subjects, were unable to detect differences between the two odorants. The anterior olfactory nucleus in Alzheimer's disease contains senile plaques, neurofibrillary tangles and reduced cell counts, and the olfactory bulb also shows involvement, as does the nasal sensory epithelium. (Talamo et al., 1989) Odour detection, odour identification, and odour memory/recall are affected differently in different disorders. Omega-3 fatty acids¹²¹, S-adenosylmethionine (S-AMe¹²²), and combinations of inositol and lecithin cause gastrointestinal distress and a fishy odour.

Complexity of hallucinations: Hallucinations can be amorphous, elementary (e.g. simple noises or 'seeing stars') or complex (e.g. hearing voices, or experiencing a panoramic vision).

Pareidolia

Normal phenomenon of conjuring up images when looking at ill-defined impressions like the child who likes to see soldiers on campaign when resting in bed (his flexed knee becomes a mountain, etc) or the adult who 'sees' things in the cooling hearth or a pattern in wallpaper or carpet

Affect illusion

Misinterpretation of vague or ambiguous stimuli during a state of strong emotion as representing a threat, as when a criminal is 'seen' in dimly lit, windblown bushes

Eidetic imagery

Resembles 'visual memory': I see the page before me and can read verbatim' - common in children or with hallucinogen use

After images

Persistence of retinal impressions; stare at a simple design on a white page for a while and then look away – you will still see the design

Palinopsia

A visual image remains, usually for several minutes, after removal of the object because of a non-dominant parieto-occipital lesion (an evolving hemianopic visual defect may be found; there may be distortion of object shape and size)

May occur as a manifestation of simple partial seizures (Muller et al., 1995) or, rarely, trazodone (Good, 2000)

Trailing phenomenon

¹²⁰ Changes in markers indicating abnormal development/differentiation of neurones were reported in olfactory epithelium in schizophrenia. (see Sawa & Cascella, 2009) A report of relatively shallow olfactory sulcus in schizophrenia might indicate early disruption of embryonic development. (Turetsky et al., 2009)

¹²¹ Mainly found in oily fish, e.g. mackerel, salmon, herring, and sardines. They have been shown to help with secondary prevention of cardiovascular disease.

¹²² Popular over-the-counter antidepressant that is involved in transmethylation reactions and may increase 5-HT, noradrenaline and dopamine availability. S-AMe levels depend on B12 and folate levels. S-AMe may cause anxiety/agitation/insomnia, anorexia/dry mouth, bowel problems, palpitations/dizziness, headache, and sweating.

Perceptual abnormality associated with hallucinogens or nefazodone (Good, 2000) wherein moving objects are seen as a series of discrete and discontinuous images

It has been claimed that monaural occlusion using an earplug leads to improvement in hallucinosis in schizophrenia. Hallucinations may occasionally have an hysterical basis. (Andrade & Srinath, 1986) One theory holds that auditory hallucinations represent verbal activity originating in the non-dominant cerebral hemisphere. The dominant hemisphere then views this activity as alien to the self because of a primary dissociation in the functioning of the two cerebral hemispheres in schizophrenia. (Green ea, 1983) In 1897, Parish conjectured that patients who report hallucinations concurrently generate *automatic speech*. Hallucinations may be seen as an expression of brain activity or as products of adaptive behaviour, as when seeking organisation in a chaotic array or motivated by dynamic imperatives. These views are not mutually exclusive. In particular, thought-disordered content could be superimposed on either primary or compensatory brain-based phenomena. During simultaneous occurrence of hallucinations and external stimuli, hallucinations were reported to lower N100 amplitudes and changed topography, suggesting competition between auditory stimuli and hallucinations for physiological resources in the primary auditory cortex; auditory hallucinations may therefore be a consequence of abnormal primary cortex activation. (Hubl ea, 2007) *Subvocalisation* could either accompany hallucinated voices or generate them. Interestingly, subvocalising during reading decreases reading speed but improves comprehension. (Judd, 1927) Lindsley (1963) took the vocalisations of hallucinations to be the patient's response to the hallucination. Bick and Kinsbourne (1987) found that schizophrenic patients reported that the voices they heard went away when they kept their mouths open, so precluding subvocalisation, but not when they merely clenched their fists. They suggested that hallucinations might be projections of the schizophrenic patient's verbal thoughts, subvocalised due to deficient cerebral cortical inhibition. Nevertheless, most patients with schizophrenia can make clear distinctions between auditory verbal hallucinations ('voices') and their everyday thoughts¹²³. (Hoffman ea, 2008) Nevertheless, patients with schizophrenia may be biased in such interpretations toward false positives. (Vercammen ea, 2008)

The box contains important definitions.¹²⁴

Definitions

Lability of affect: variably defined as excessive emotional responsivity or unpredictable changes in affect, such as when the happy person suddenly becomes angry, only to sink into despair a short time later (e.g. in multiple sclerosis and other organic disorders, arteriosclerosis, hypomania, maternal blues); extreme cases reach *involuntary emotional expressive disorder (IEED, pseudobulbar affect, emotional incontinence)*; in pseudobulbar palsy (dysphagia, dysarthria, emotional incontinence, and brisk jaw jerk), bilateral upper motor neurone lesions cause dysfunction of the bulbar musculature, often with emotional lability. Drugs used to treat IEED include amitriptyline, fluoxetine, and levodopa. Winston Churchill told his doctor on July 3, 1953 that 'Since this (stroke) happened I have been very lachrymose. At parts of Phineas Finn I became very tearful, though it is not at all a moving story'. (Moran, 1966)

Incongruity (inappropriateness) of affect (parathymia): common in schizophrenia, e.g. outburst of fatuous giggling or smiling when telling bad news or a strong or weak reaction to unimportant or normally catastrophic news respectively; embarrassment or simple anxiety may mimic this phenomenon and should be outruled before making such a serious observation. In schizophrenia, the emotional reaction may initially be congruous but then not change with altered circumstances, so-called *stiffening of affect*.

Abulia (Gk. *a*, not; *boulē*, will): lack of will or motivation¹²⁵ (often unable to make decisions or set goals); *avolition* is an inability to initiate and sustain goal-directed voluntary activity. The patient with *abulia* has no impulse to action, his mind is blank and empty, and volition is absent. He sits about doing naught. Boredom is not causative. If pushed or supervised he is capable of doing much more. It is classically associated with schizophrenia. However, it has also been described in association with damage to the

¹²³ They do this by examining mainly thought content and sense of control, whereas loudness and clarity are of lesser use.

¹²⁴ In reading these, one should recall Kendell's (1993) words: 'The existence of a number of alternative definitions also helps to emphasise that all definitions are arbitrary, justified only by their usefulness, and liable to be altered or supplanted'. (see also Pawar & Spence, 2003)

¹²⁵ **Motivation** (Latin: *movere*, move): internal (e.g. hunger or curiosity) and/or external (e.g. exams or money) prods to act.

intralaminar thalamic nuclei, the basal frontal cortex, and, as may follow CO poisoning, damage to the basal ganglia. Tumours causing abulia are most often found to affect the frontal lobes.

Apathy with *blunting or flattening of affect* may also occur in schizophrenia; also common in dementia and after stroke. In one study of stroke (Brodaty et al, 2005) apathy was present in 26.7% of cases compared to 4.5% of controls. There is said to be sustained emotional indifference or diminution of emotional response, although a flat affect is quite compatible with subjective emotional arousal. Should only be diagnosed when subject has been observed in a variety of circumstances and when not sedated. Should be distinguished from culturally restricted emotional display. Flattening of affect can accompany frontal lobe lesions as part of an apathetic-akinetic syndrome. Apathy in neuropsychiatric illness has been treated with amphetamine, methylphenidate, selegiline¹²⁶, bromocriptine, rivastigmine, amantadine, and bupropion (bromocriptine and amantadine are most often used for Parkinson's disease rather than for drug-induced EPSE, and they carry a risk of exacerbating psychosis). SSRIs may cause apathy. (Price et al, 2009)

Fear is induced by an obvious threat, e.g. a charging bull.

Anxiety is characterised by apprehensiveness and tension, but the stimulus is ill defined and may be totally intrapsychic, e.g. a fear of harming one's mother may lead to anxiety. *Free-floating anxiety* has no object. When anxiety is attached to an object it is termed a phobia. *Signal anxiety* alerts us to do something that is necessary, e.g. study for exams; it helps us to mobilise defences early on during a traumatic experience, thus attenuating the emotional impact. It has been suggested by many authors that anxiety disorders properly belong with the affective disorders.

Phobias (simple, social, agoraphobic): patient recognises their irrationality; they persist despite rational argument; and they lead to avoidance of what is feared.

Panic: a state of overwhelming anxiety.

Depersonalisation: feelings of weird and inexplicable change in self ('I feel strange, dead, hollow, like a puppet, etc. '); subject may feel as if he is outside his own body looking at himself. *Derealisation*: similar notions about the external environment (things are bigger or smaller, closer or further away, two-dimensional, flat). Both states are common in severe anxiety from any cause and do not of necessity indicate that the patient is ill – it is very difficult for someone to describe an unpleasant state of loss of normal emotional responsiveness; causes include normal emotional upset, tension or fatigue; a symptom of psychiatric or physical illness; and primary cases, the so-called 'depersonalisation disorder'. Depersonalisation and derealisation are common during adolescence.

Ambivalence: mixed feelings or opposing impulses experienced about something or someone experienced simultaneously.

Flight into mania: Freudian idea that mania was a defence against depression - manics do lapse transiently into tears all of a sudden, and there true 'mixed states' (e.g. co-mingled mania and depression). The patient who finds out that he has a month to live and who then goes around with a smile on his face and joins the local football team might be using the defence mechanism called *reaction formation* (doing the opposite to what one might expect like crying, feeling depressed, looking for a second opinion, preoccupied, etc).

Paradoxical reactions are also found in some people on disinhibiting drugs, e.g. rage with diazepam.

*Obsessions*¹²⁷: persistent thoughts (including mental pictures or images) or impulses experienced as unwanted and ridiculous but which the patient is unable to resist; perceived as senseless, or at least as senselessly insistent; obsessions appear to be common in adolescence (Crye et al, 2010) and are not necessarily abnormal at that stage.

Compulsions: acts, such as rituals, resulting from obsessions. *Obsessive-compulsive disorder* (OCD) is characterised by obsessions and compulsions and may occur in the absence of any other psychiatric disorder. *Obsessional thoughts* consist of words, beliefs, ideas or images that the subject recognises as his own but that intrude forcibly into consciousness, are usually distasteful, and the subject tries to exclude them. *Obsessional ruminations* consist of an argument going on in the mind in which the pros and cons are gone over *ad infinitum*. In *obsessional doubting* the subject worries lest he has failed to complete some action, done harm, or told the priest all his sins in the confessional (scrupulosity). *Obsessional impulses* urge the patient to perform acts, often of a violent or socially embarrassing variety. *Obsessional rituals* are either repetitive, meaningless acts or some mental activity like repetitive counting e.g. touching the corners

¹²⁶ Selegiline may cause mania and psychosis, possibly because its metabolites include L-amphetamine and L-methamphetamine.

¹²⁷ L. *obsidere*, to besiege.

of a desk an even number of times. *Obsessional phobia* is a misnomer and not a true phobia; e.g. a subject with an urge to shoot someone avoids firearms. *Obsessional slowness* (uncommon) involves extreme slowness of ordinary activity. It should be noted that obsessional rituals may raise or lower anxiety levels in different instances. While some individuals with OCD have obsessional personalities, the latter are more likely to develop depression.

Psychomotor retardation: slowing or sluggish thinking and movement; common in depression. Agitation and retardation may coexist.

*Automatism*¹²⁸: repetitious, mechanical and seemingly undirected activity seen in, e.g. conversion states or an epileptic fugue.

Negativistic behaviour: associated with naughty children and schizophrenia; patient does the opposite of what is asked for no apparent reason, e.g. he takes his hand away from you when you try to shake it; patient appears to be uncooperative.

Echolalia: automatic repetition of another person's spoken words. *Echopraxia*: automatic repetition of another person's actions. These two phenomena occur in schizophrenia, organic brain damage, and Tourette disorder. Catatonic patients may reply to a question by echoing the content of the question but using different words, so-called *echologia*.

Stereotypy: an action, or group of actions, or words monotonously repeated (see and contrast with perseveration), or a posture maintained long after tiredness would normally have forced the person to quit; non-goal-directed, e.g. rocking, grimacing; *Schnauzkampf* refers to stereotypy seen in catatonia when the lips are thrust forward like an animal's snout (frozen pout).

Mannerisms: repeated, usually odd, goal-directed movements (e.g. eating, flicking dust from the table) or unusual postures; differ from stereotypy by being more in keeping with the personality and by not being repeated so monotonously; found in schizophrenia, intellectual disability, and normals.

Tic: involuntary, sudden, rapid, recurrent, non-rhythmic stereotyped motor movements or vocalisations; can be *simple* like blinking or *complex* such as smelling or jumping.

Verbal mannerisms: Repeated odd use of language short of thought disorder.

Narcoleptic syndrome: narcolepsy, Hypnagogic hallucinations, *sleep paralysis* (frightening - cannot move for a minute or so on waking or going to sleep or coming out of a nap), and *cataplexy* (sudden, transient loss of muscle tone and muscular weakness, often brought on by heightened emotion, e.g. 'my necks gets weak when I laugh').

Catalepsy: increased muscle tone and rigid posture; may occur in schizophrenia, 'hysteria' or organic disorders¹²⁹.

Waxy flexibility (flexibilitas cerea): found in catatonic schizophrenia, stuporose type: resistance to passive limb movement resembling that found on bending candles of olden days; a limb left in any position will remain there despite gravity (as when a patient does not lower the arm after the doctor has finished taking the radial pulse).

Form of thinking may be *concrete* (literal interpretation of everything, including proverbs: found in normal children, organic brain syndromes, schizophrenia, and intellectual disability), *abstract* (ability to formulate concepts and to generalise from the particular, as in normal adults – *categorical attitude* refers to abstract attitude: the ability to shift readily from concrete to abstract as needed), *dereistic* (silly - typically found in schizophrenia), *autistic* (inner fantasies dominate¹³⁰), or *over-inclusive* (full of irrelevancies). Proverb interpretation might be tested thus: 'Tell me how you would explain the saying 'Don't cry over spilled milk' to a young child'. Proverb interpretation is closely related to academic achievement and level of acculturation and a better test is to ask about similarities and differences between objects.

Dysprosody (aprosodia [Gk. *a*, not; *prosodia*, modulation of voice]: *prosody* is that part of speech that conveys mood/shades of feeling): inability to change intonation of speech in order to convey feeling – speech lacks stresses, pauses, accent, cadence, accent, intonation, emotion and melody, being flat, lifeless and monotonous (*expressive aprosodia*). There may be difficulty in appreciation the emotional tone of another person's speech (*receptive aprosodia*). A non-dominant lobe dysfunction – may follow a stroke

¹²⁸ **Legal automatisms** are divided into internal ('insane' – arise from internal factors) and external ('sane'). *R v Burgess* in 1991 created difficulties in relation to classification. It was argued that somnambulism was genetic (internal, arising from a certain sleep stage) and therefore carried a risk of recurrence. However, some countries regard somnambulism as causing external automatisms.

¹²⁹ E.g. encephalitis, vasculopathies, and mid-brain neoplasms.

¹³⁰ *Autism*, from Gk. for 'self'.

affecting right frontal and temporo-parietal regions¹³¹. May mask underlying depression (Dubovsky, 1986) or may simulate depression. To examine prosody stand behind the patient (so he cannot see your face) and say 'I'm going to leave now' in neutral, sad, happy, and angry tones. Ask the patient to identify the emotion (sad, etc) attached to each statement. Then ask the patient to reproduce these four feelings whilst saying the same sentence. One should, of course, normally be on the lookout for disordered prosody during the interview.

Logorrhoea: copious coherent and logical speech.

Apperception: perception modified by emotion, memory or bias; from a cognitive theorist's viewpoint this includes all perception! On the other hand, *syntactic mode* refers to a mode of perception that forms whole, coherent pictures of reality that can be validated by others.

Alogia: from Greek for 'without speech'; impoverished thinking, often seen with schizophrenia; includes poverty of speech or of speech (thought) content, thought blocking, and increased latency (long delay before replying) of speech; coined by Kleist in 1930 (trans. 1987) to indicate failure in the process of thinking.

Amimia: a language disorder in which there is an inability to make gestures or understand their significance, e.g. shoulder shrugging. *Hypomimia* (reduced facial expression, mask-like facies) is associated with Parkinsonism.

Pressure of speech: cannot stop talking; speech is rapid and difficult to interrupt; increased amount of speech; found in mania.

Prolivity: mild (verbosity, rapidity, and difficult to follow) or 'ordered' flight of ideas; found in hypomania; embellished lively speech with some difficulty maintaining thread of thinking.

Distractibility: distracted by nearby stimuli that interrupt flow of speech; relatively unable to inhibit responding to irrelevancies; unable to facilitate goal-directed responses. The Stroop Colour-Word Test assesses distractibility.

Some patients find it very difficult to get to the point: *circumstantiality* - keeps going off the point but gets there eventually - follows a very indirect and delayed path - found in intellectual disability, obsessional people, and, historically, epilepsy; *tangentiality* - never quite makes the point: the patient replies to a question in an oblique or irrelevant manner; in *asyndetic thinking* language retains intact grammar but thoughts appear completely unconnected - this is basically severe tangentiality; if tangentiality is accompanied by pressure of speech we have flight of ideas.

Flight of ideas: found in mania, some excited schizophrenics, and organic disorders such as disease of the hypothalamus - rapid, loosely connected, rhyming, punning, and clang associations; incoherence found in severe cases.

Clanging: sound of a word rather than its meaning determines direction of talk; some connection between sentences remains discernible in mania - all connection may be lost in schizophrenia. E.g. response to 'I'm a conservative' becomes 'Preservatives are important'!

Cluttering: rapid, erratic speech with disturbed fluency that is difficult to comprehend; found in childhood.

Overinclusion: irrelevant thoughts contaminate speech, e.g. in schizophrenia.

Knight's move thinking: a characteristic of schizophrenic thought disorder; essential step omitted in reasoning process.

Neologism: idiosyncratic word that only means something to the speaker and is unintelligible to the listener; frequently a condensation of different words; found especially in schizophrenia¹³² but also seen in Wernicke's (sensory/receptive) aphasia¹³³. When neologisms occur close together, as in the above sample, we speak of *word salad* (mixture of words and phrases lacking comprehensive meaning or logical coherence, i.e. *incoherence*). When all speech is neologistic we might use the old term *schizophasia*.

Verbigeration, again characteristic of schizophrenia, consists of constant repetition of nonsensical words or phrases, or of sensible words and phrases used repetitiously and nonsensically.¹³⁴ *Glossolalia* is gibberish-like speech or 'speaking in tongues'; may be normal if part of accepted religious practice.

¹³¹ Corresponding to speech expression and reception areas of the dominant hemisphere.

¹³² E.g. 'I glabbexed a spurious latyx and poured out a gligbrill!'

¹³³ In receptive aphasia, apart from use of neologisms, words are employed incorrectly, there are paraphasic errors (tendency to use ordinary words in unusual ways), and there are problems with syntax and grammar.

¹³⁴ Terminological use unfortunately varies with source, e.g. there is a modern tendency to use the term word salad to refer to the *most extreme form of senseless speech*.

Paraphasias or *metonyms*: the schizophrenic tendency to use ordinary words in unusual ways. The schizophrenic may repeat certain *stock words* and employ them idiosyncratically. There is obviously overlap in the usage of these various terms. Damage to Broca's area causes *phonemic* paraphasia with a change in the word's sound as, e.g., electricrery for electricity. Perisylvian pathology gives rise to *semantic* paraphasia with substitution of one word for a related word, e.g. orange for apple. In semantic dementia¹³⁵ the patient may give a wide superordinate response, e.g. 'clothes' when shown a hat.

Thought block: schizophrenic patient's speech is suddenly interrupted/comes to a halt; he then goes on talking about something else after so many seconds; patient may complain that his/her mind is empty during discrete periods; unable to recover what has just been said; rare¹³⁶; differentiate from fatigue, preoccupation, anxiety/stress, depression (retarded speech), amphetamine intoxication, interference from auditory hallucinations, the normal experience of one's train of thought being suddenly interrupted by another by asking the patient for detail, and absence in petit mal epilepsy. In other words, thought blocking should only count toward a diagnosis of schizophrenic thought disorder if there is other evidence to back up such a conclusion. (Mullen, 2008, p. 34)

Mutism: nothing is said; found in, e.g., depressed or catatonic schizophrenia; mixed mutism and excitement can occur (e.g. running or dancing whilst mute¹³⁷); *coma vigil* is an alternative term for akinetic mutism¹³⁸.

Elective mutism, e.g. talking only at home and not at school, is due to emotional problems.

Diurnal variation of mood: mood varies with consistent 24-hour cycle that is independent of environment, e.g. in endogenous depression the mood tends to be worst in the morning and to lift as the day progresses.

Waxy flexibility (*flexibilitas cerea*) is found in catatonic schizophrenia (*stuporose* type); there is resistance to passive limb movement resembling that found on bending the candles of yesteryear. In maintenance of imposed postures the limb left in any position will remain there despite gravity.¹³⁹

Fantasy can be normal, even pleasant, unless it interferes with normal functioning. Mental life in schizophrenia is dominated by fantasy. In *Magical thinking* the person's thinking violates the normative understanding of causality, e.g. the belief that simply thinking or doing something will have an extraordinary effect on the environment. This reaches bizarre proportions in schizophrenia, but is normal in children and among those who live in isolated cultures. *Magical undoing* is a psychoanalytically-derived term that attempts to describing the underlying reasons for obsessional behaviour, e.g. a child who avoids cracks in the pavement is trying to avoid some unseen danger, or an obsessional patient performs a ritual in order to avoid harming others.

An *overvalued idea* is, according to Wernicke in 1900, a solitary, abnormal belief that is neither delusional nor obsessional in nature, but which is preoccupying to the extent of dominating the sufferer's life, e.g. the emaciated anorexic thinks she is obese, or the attractive dysmorphophobic thinks she is ugly; it is comprehensible in the light of experience, family or culture; it is often immune to rational argument; and it may denote eccentricity rather than illness. It is not always easy to distinguish overvalued ideas from delusions. (Casey & Kelly, 2007, p. 39; McKenna, 2007, p. 331; Mullen, 2008, p. 24)

The term *zeitgeist* refers to the general intellectual and cultural climate of taste characteristic of an era.

Delusions may be primary or secondary.¹⁴⁰ (Jaspers, 1913/1963) Jaspers listed four primary delusions: *autochthonous* delusion (sometimes used synonymously with primary delusion), delusional perception, delusional atmosphere, and delusional memory. An *autochthonous* ('sprung from the soil') delusion (or

¹³⁵ Semantic dementia is associated with involvement of the left temporal lobe; dysfunction of the right temporal lobe is associated with prosopagnosia.

¹³⁶ 2% of 111 schizophrenic patients in one series. (Andreasen, 1987)

¹³⁷ Some catatonic patients may lie very still and yet sing; but strictly this is not 'mutism'.

¹³⁸ **Akinetic mutism** has a number of causes, e.g. third ventricular tumours or infarction of the cingulate gyri. (Barris & Schuman, 1953) Unlike in catatonic stupor, akinetic mutes will swallow fluids and food placed in the mouth, withdraw from painful stimuli, have not got waxy flexibility, and show no response to parenteral lorazepam. If primates have the anterior cingulate cortex lesioned they will not cry out mother leaves them.

¹³⁹ *Mitmachen* refers to an extreme form of obedience: the therapist is able to place patient's body part in any position without being resisted, the part slowly returning to its resting position. In *gegenhalten* the patient opposes passive movement with the same force used by the examiner. In *mitgehen* the patient moves in the direction of even slight pressure despite being asked to resist, as when an anglepoise lamp lifts with the simplest touch.

¹⁴⁰ Although *delusional explanation* is nowadays often used to describe certain secondary cases, e.g. 'I hear a voice coming from my mastoid bone. This means that there is a transmitter there'.

delusional intuition) arises out of the blue, is fully formed, and is unrelated to prevailing mood or recent events, e.g. 'I was walking down the ramp when I saw that the captain had a red rose in his buttonhole and then I knew that I was here to save the world.' A secondary delusion may arise from a primary delusion, e.g. 'I have the right to all famine-relief funds because I must raise an army of robots to defend the atmosphere against invading Martians.' Alternatively, a delusion may be secondary to a mood disorder, as when the depressive believes that 'I am so bad that I must have been put here to destroy everyone's happiness.' There is evidence from a small study (Colbert et al., 2010) that inflexibility of beliefs and extreme responding may characterise the thinking styles of people with delusions and that such characteristics may not be specific to the delusions themselves.

Delusions

May be *systematised* and/or *encapsulated*

Systemised - Delusion and its ramifications fit into complex, all-encompassing scheme that makes logical sense to the patient, e.g. being persecuted by an organisation, i.e. an elaborated delusion: a basic delusion is added to by other delusions derived from that basic delusion; more common in delusional disorder than in schizophrenia

Encapsulated - Apart from the delusion or its ramifications, the patient generally behaves in a normal manner, or at least is not perceived as especially unusual.

Mood-congruent delusions are in keeping with the prevailing mood, e.g. believing one is the Messiah when manic or damned when depressed; delusions which are *incongruent* with mood might be seen, e.g. in the manic who believes he is the victim of a Martian conspiracy or that his thoughts are being extracted by the FBI; this concept of delusions incongruent with mood has been criticised as leading to overlap with schizoaffective¹⁴¹ disorder. (Kendler, 1991) Hallucinations may (or may not) also be congruous with mood (depressive hears condemnatory voices). In fact, congruity and incongruity of clinical features in psychotic depression may be equally common in clinical practice. (Schweitzer & Parker, 2007, p. 183)

Monosymptomatic delusional states, where only a delusion¹⁴² separates the individual from his normal fellows, may respond to pimozide (Orap) or other antipsychotic drugs; *monosymptomatic hypochondriacal psychosis* has the same meaning as delusional disorder, somatic (sub-) type. (Munro, 1997) Primary delusions¹⁴³ are difficult to identify in clinical practice and might occur in conditions other than schizophrenia, such as epilepsy. The term *paranoid*¹⁴⁴ means 'resembling paranoia'¹⁴⁵, or simply 'deluded' or excessive self-reference but is often used, not very accurately, as a synonym for persecution. Munro (undated) has reviewed the phenomenology, nosology and treatment of 'paranoia'.

Delusions of persecution involve the false belief that people are out to do one harm - they are often quite bizarre in content. Analytically speaking, a delusion of persecution occurs when someone denies hostile feelings in themselves and attributes them to others; he is using denial and projection.

Partition delusion

Belief that a person, animal, object or radiation can pass through normally impenetrable barriers such as walls

Patient, classically suffering from schizophrenia, is usually convinced that the source is the house of a neighbour

¹⁴¹ Described by Jacob Kasanin in 1933.

¹⁴² Such as delusional *parasitosis*, or a delusion of *bromosis* (Gk. to stink – bromine being associated with a foul odour), i.e. that one emitting an offensive odour.

¹⁴³ Some authors dispute their very existence. (Freeman, 1981; Roberts, 1992)

¹⁴⁴ Gk. *para nous*: 'mind beside itself'. Paraphrenia, a relatively redundant term, (Hart, 1990) refers to a state of late onset, paranoid delusions, hallucinations, well preserved personality, and often auditory, or less commonly, visual defects. (Holden, 1987) The familial independence of paranoid psychosis from schizophrenia finds support from a study by Kendler, et al., (1985) who examined the family histories of patients with paranoid psychosis, schizophrenia, and medical illness. It has been argued by others that paranoid psychosis is a variant of schizophrenia (e.g. Schneider, 1959), an affective illness (Specht, 1901), or a separate nosological entity, distinct from both schizophrenia and affective illness (e.g. DSM-III-R, predecessor of DSM-IV).

¹⁴⁵ *Paranoia* = Gk, 'by the mind's side'.

Delusions of worthlessness occur in depressive psychosis. Nihilistic delusions ('my brain is rotten', 'my gut is clogged with cement', 'my liver is riddled with worms') are typical of Cotard's syndrome, (O'Shea, 2006) which may be due to depression, schizophrenia, or an organic brain syndrome. Delusions of grandeur ('I am God', 'I am a billionaire') may be found in organic brain conditions,¹⁴⁶ mania, or schizophrenia.

The belief that some unrelated event or object has special meaning for the individual is called a *delusion of reference*, e.g. the belief that the main evening news bulletin was put on for the patient's sole benefit. With *ideas of reference* (or *ideas of self-reference*) insight is retained but the feeling of being noticed cannot be ignored; the subject knows that he is the origin of the feelings that others are taking undue notice of him or discussing him; anxiety may spawn ideas of reference. *Delusions of control* (or *passivity*) are present if a patient believes that external forces (radio waves, telepathy, etc) can control his thoughts, words, movements or feelings.

There are many different diagnostic criteria for schizophrenia, e.g. Bleuler's 'Four As' (Affect, Associations, Ambivalence, Autism), Feighner's, RDC (research diagnostic criteria; Spitzer, et al, 1975), and Schneider's (1959).

Schneider's first rank symptoms (FRS)¹⁴⁷ are sufficiently often quoted to necessitate reproduction here:

Auditory Hallucinations: voices repeating one's thoughts aloud; voices anticipating one's thoughts; multiple voices discussing one or arguing about one in the third person; and voices commenting on one's thoughts or actions. The phenomenon of hearing one's thoughts spoken aloud may be classified as follows: if heard at the time of thinking them the term used is *Gedankenlautwerden*, and if they are heard just after thinking them they are called *écho de la pensée*. However, the patient may also hear his thoughts spoken aloud just before he thinks them. Sims (2003, p. 165) considers audible thoughts¹⁴⁸ to be an example of auditory hallucination. *Disorders of the possession of thought* include thought insertion, withdrawal and broadcasting. In *thought insertion and withdrawal* some foreign agency puts their thoughts into one's mind or removes one's own thoughts.¹⁴⁹ In *thought broadcasting* (*thought diffusion*) people can hear one think because one's thoughts are broadcast. This is different from the *delusion of mind reading* wherein the patient believes others can read their mind/thoughts, i.e. a subjective experience of others knowing one's thoughts without the belief that they can be heard aloud. Much of these distinctions may be purely semantic. Telepathy refers to the deliberate beaming of thoughts from one person to another.

Delusions of control: 'made' act, feelings, impulses refer to the belief that outside forces can make one feel or do things against one's will. If the temporal lobe is stimulated during surgery, patients may experience similar 'made' thoughts and feelings as are found in both the temporal lobe epileptic aura and in the psychoses. (Penfield & Rasmussen, 1950) According to Frith, (2004, p. 150) a delusion that someone else is moving one's arm is related to lack of attenuation of activity in the parietal cortex.

Delusions of Passivity: one is forced by outsiders to experience bodily sensations. *Delusional perception* is present when a delusional interpretation of a real perception is made; the perception is mundane and logically unconnected, e.g. 'I knew I was God when I saw the cat drink its milk', or a coat hanging in a shop window suggests that one is destined to be the next Pope. The term *delusional mood* (or *atmosphere*; *Wahnstimmung*) refers to the state of *perplexity* (usually unpleasant emotional state akin to bewilderment), foreboding, dread or anxiety occurring early during a psychotic breakdown, consisting of a variety of paranoid delusions which are transient and changing; the patient tries to make sense out of what seem to be unusual changes going on about him; he may recover or develop a stable delusional system¹⁵⁰. During the early formative or recovery stages of a delusion we can speak of a *partial* delusion, when the belief is held with less intensity. *Delusional memory* (retrospective delusion) refers to a delusional interpretation of an apparently real memory or a false memory¹⁵¹ arising in the context of psychosis, e.g. a deluded woman who

¹⁴⁶ E.g. GPI.

¹⁴⁷ Described by Kurt Schneider (1887-1967) in 1959.

¹⁴⁸ The hallucination of hearing one's own thoughts out loud may precede, coincide with, or follow the real thoughts.

¹⁴⁹ Thought withdrawal and thought blocking usually co-exist.

¹⁵⁰ This may be the same as the 'Truman syndrome' of Fusar-Poli et al (2008) who write about impending psychosis being associated with the feeling that the world has changed in some way that others are aware of, that one is the subject of a movie and living on a film set; the ordinary is different; there is a search for meaning; depersonalisation/derealisation; disturbed sense of ownership; fluid sense of self; distorted stream of consciousness; and a sense of disembodiment.

¹⁵¹ *Memory distrust syndrome* is due to *source amnesia* (cannot be sure where the information came from, self or others, so distrusts own memory).

believes someone is trying to kidnap her child recalls a man stopping her for directions some months ago and now 'realises' that he was really getting information that would aid him in the kidnapping. The content of delusions tend to keep up with the times, e.g. satellite TV dishes in the early 1990s (Kidd ea, 1992) and the so-called Truman syndrome (called after *The Truman Show* of 1998 starring Jim Carrey – a patient believes that he is trapped inside a reality show, that every movement is being filmed and that everything is contrived by TV producers).

Feighner's definition of schizophrenia (summary)

Chronic illness with at least 6 months of symptoms prior to index evaluation, without return to premorbid level of psychosocial adjustment

Absence of period of depressive or manic symptoms sufficient to qualify for affective disorder or probable affective disorder

Also, at least one of the following:

- delusions or hallucinations without significant perplexity or disorientation associated with them
- verbal production that makes communication difficult because of a lack of logical or understandable organisation (in the presence of muteness diagnosis must be deferred)
- at least three of the following social factors: single, a relative with schizophrenia, poor premorbid social adjustment or work record, absence of alcoholism or drug abuse within one year of onset of the psychosis, and onset of illness prior to age 40

Somatisation of affect occurs in depressives who complain of somatic symptoms instead of mood disturbance. The term *somatisation* was introduced by Stekel early in the twentieth century; Lipowski (1988) defined it as a tendency to experience and communicate somatic distress in response to psychosocial stress and to seek medical help for it; Murphy (1989) described it as the commonest way in which psychiatric disorder is presented to the GP - bodily symptoms are misattributed by patients to organic disease. Somatisers may be hostile to the idea of emotional dysfunction. (Murphy, 1989) In some cultures the healer shares the patient's explanatory model of somatic causation and diagnoses a physical disorder instead of an emotional one. The rise in popularity of 'somatoform disorders' in the US may reflect direct access to specialists and the easy accumulation of number of symptoms required for the diagnosis. Porter and Gorman (1989) point the finger at doctors' training, which stress the need to search for physical illnesses. Somatization can be a primary personality trait, or secondary and transient when under stress or depressed. *Alexithymia*, or alternatively *somatothymic*, (Yates ea, 1998) refers to a constricted ability to recognise and express feelings or emotional states. (Sifneos, 1973) Somatizers are said to have few dreams and to think in non-symbolical ways; they cannot discriminate between emotional states and bodily symptoms. Alexithymia may be mimicked by certain cultural expression styles and may be a state-dependent phenomenon, e.g. in depression. (Marchesi ea, 2008)

*Astasia abasia*¹⁵² is a hysterical symptom¹⁵³ involving a refusal to stand up or walk for fear of falling. The gait is bizarre and the patient cannot stand without assistance. The patient sways and almost falls.

Hysterical pseudodementia is very rare. Global amnesia has a sudden onset. The patient cannot recall anything. It probably always has an hysterical basis.

A dominant individual within a tight social grouping usually starts *epidemic hysteria*. Hyperventilation may be an important element. A background of tension and apprehension is often found in the group. Treatment involves quick recognition, isolation of affected individuals, psychological explanation and reassurance, use of local traditional healing methods (Skuse, 2007), and the delivery of mental health education programmes to the community. (see Puella, 1986).

Insight: Poor insight in psychiatric patients is associated with non-compliance, social dysfunction, and delayed presentation. Insight into psychiatric disorder is not a uniform phenomenon; and it must be rated on a continuous rather than a dichotomous scale. Rather than saying that insight is present or absent, we should ask if the patient knows that he is acting abnormally, thinking abnormally, or experiencing abnormal

¹⁵² Also called Blocq's syndrome after Paul-Oscar Blocq (1860-96).

¹⁵³ Conversion disorder (DSM-IV) or dissociative motor disorder (ICD-10).

perceptions; if he thinks that the foregoing problems are due to mental disorder or does he blame something else, e.g. somatic disease or poisoning by others; and if he thinks that treatment is necessary?¹⁵⁴

Sophisticated testing suggests that very few acute voluntarily admitted patients can understand the need for neuroleptic drugs. Unawareness of illness in schizophrenia, on MRI evidence, might be related to small intracranial volumes, i.e. brain and CSF combined. Reduced general neuropsychological functioning and grey matter deficits in the posterior cingulate gyrus and right precuneus/cuneus may be important in lack of insight in first-onset psychosis.(Morgan ea, 2010) Factors that influence insight in psychosis are cultural beliefs, IQ, knowledge, the physician-patient relationship, symptomatology (e.g. lack of insight into delusional beliefs, or preserved insight associated with depressed mood), executive function¹⁵⁵ (initiation, selection, and monitoring of activity, and contextual coding) deficits, denial¹⁵⁶ (motivation, preservation of self esteem, stigma avoidance), and personality traits. High IQ scores were associated with better insight in psychosis of recent onset. Descriptions of ‘insight’ should be detailed. The *Insight Scale* (Marková & Berrios, 1992b) is 32-item instrument, can be observer- or patient –rated and purports to measure insight and changes therein.

There are many examples of cases where the patient is hallucinated but *retains insight*. Partial seizures can be associated with visual, auditory, olfactory, or gustatory hallucinations with retention of insight. Tactile hallucinations secondary to cocaine or amphetamines are another example. The same applies to olfactory hallucinations due to migraine or, rarely, damage to the olfactory bulb/nerve. Similarly, auditory hallucinations due to pentoxifylline, deafness (with musical hallucinations – see Miller & Crosby, 1979), and lesions of temporal lobe or pons, can be accompanied by retention of insight. Visual hallucinations can occur during bereavement (visions of a lost one), because of sleep loss, or when falling asleep. Visual hallucinations with insight may also be found with migraine, narcolepsy (hypnagogic), Charles Bonnet syndrome,(Q.V.) lesions of the cortex (including in an hemianopic field), lesions of the cerebral peduncles (*peduncular hallucinations*) or pontine tegmentum (*‘Pick’s visions’* wherein people are seen walking through distorted walls), cocaine, amphetamine, solvents, PCP, other hallucinogens (including flashbacks), quinidine, trazodone, maprotiline, propranolol, L-DOPA, digoxin, and TCAs.

For the patient in psychotherapy, self-observation is insufficient for true insight. What is needed if real change is to occur is emotional¹⁵⁷, as distinct from intellectual, insight.(Donnelly ea, 1970) *Isolation of affect*¹⁵⁸ may be associated with pseudo-insight as when a patient gives an intellectualised account of his dilemma without any associated feeling.

Quality of life

Quality of life is a difficult concept to define and attempts at measuring it have varied from generic (independent of specific disease) to disease-specific instruments.(Katschnig & Krautgartner, 2002) Doctors and patients evaluate this from different perspectives, e.g. bipolar patients in remission have reduced quality of life (Goosens ea, 2008) and the doctor may be happy with the control of delusions whilst the patient may be unhappy with living in a tenement.(Naber, 2003) However, patients with chronic mental disorders may equally set their aspirations at a lower level than might a person not so affected.

One can measure health intervention outcomes in terms of quality (score 1 for perfect health, 0 for no quality, minus scores for ‘better off dead’) and quantity (life expectancy) of life. Quality and quantity are

¹⁵⁴ The majority of patients with schizophrenia in one study (Amador ea, 1994) were unaware of important aspects of their illness and almost one quarter were almost completely unaware of the efficacy of treatment. Those with affective disorders had less severe lack of awareness, although manics more closely resembled schizophrenics in this regard. Schizophrenic patients in remission were just as unaware as were those who remained psychotic. Hence, lack of awareness seemed to be trait that is resistant to treatment. It might relate to prefrontal cortical dysfunction. On the other hand, David ea (1992) found that compliance only weakly related to ability to label psychotic phenomena as abnormal. Murray (2003) points out that delusional beliefs developed during a period of psychosis may persist despite clinical improvement, e.g. ‘the KGB are no longer trying to harm me, but they were doing so!’ Pini ea (2001) found that schizophrenia and bipolar affective disorder were associated with less insight than was the case with schizoaffective disorder and psychotic unipolar depression. David ea (1992) could find little relationship between insight and age, sex, diagnosis or number of hospital admissions.

¹⁵⁵ Neuropsychological dysfunctions, specifically impaired set-shifting and error monitoring, were found to interfere with insight in psychosis in a meta-analysis.(Aleman ea, 2006)

¹⁵⁶ Adaptive or maladaptive depending on engagement with services/treatment.(Cooke ea, 2007)

¹⁵⁷ Capacity to feel and respond to understanding.

¹⁵⁸ A thought or memory is subconsciously divorced from associated emotion.

combined as quality-adjusted life years (QALYs).¹⁵⁹ If, for example, a treatment gives one 5 additional years of life with an average quality of life rated as 0.6 the yield would be $5 \times 0.6 = 3.0$ QALYs.

Classification¹⁶⁰

'Then, we will gradually arrive at the stage where we will be able to separate out individual diseases from the larger categories of our textbooks and sharpen their clinical definition.' (Alzheimer, 1907)

'A classification is a way of seeing the world. It is the reification of an ideological position, of an accepted stand of theory and knowledge ... A classification can remain alive and be improved only if it is constantly re-examined in the light of new knowledge.' (Sartorius, 1989)

'... if a single diagnostic system is allowed to dominate our thinking we limit our nosological options and narrow the chances of finding the cause(s) of the disorder.' (Farmer & McGuffin, 1989)

'... the disorders were created by fiat rather than empirical research.' (McKeon, 1993)

'... theory has its place, but it does not stop things from existing.' (Finger, 2000)

'Multiple diagnoses with simultaneous treatment for each of the diagnoses – as if they are equally important – has been replacing prioritizing diagnoses and treating a primary disorder.' (Scheiber, 2003)

'We do not yet and probably never will possess a diagnostic construct as simply and clearly measured as temperature.' (Kendler, 2009)

Four major types of classification (Jablensky, 1988)

Empirical - based on observed fact, e.g. histology

Inferential - possesses shared hypotheses, e.g. division of depression into reactive v endogenous

Monothetic - units placed in classes according to variations along one dimension, such as IQ

Polythetic - arrange units into classes that share many properties, e.g. the psychoses

The ideal classification is both comprehensive, encompassing the whole range of phenomena, and mutually exclusive (containing no overlap), an almost impossible wish in a soft discipline. (Schatzberg et al, 2005, p. 14) The legal profession is often guilty of referring to 'clinical guidelines and diagnostic manuals' as if they were an exact science. (Simon, 2003, p. 1619) Fonagy and Paris (2008, p. 103) suggest that guidelines (for psychotherapy) cannot replace clinical skill.

Psychiatric nosology is subject to constant review. There are many reasons for this, such as changing patterns¹⁶¹ of mental illness, geographical differences in diagnostic practice, (Cooper et al, 1972; WHO, 1973; Kendell et al, 1974), and the sheer diversity of combinations and permutations of symptoms which are possible in psychological medicine. The symptoms exhibited by a drug dependent person, for example, depend on the type, quality and dose of the drug used and the presence of contaminants; and the previous experience and expectations of both the user and others sharing the experience. Simply deciding if someone is deluded or not may be rendering the world more simple than it actually is. (Kaplan et al, 1994)

Entitlement to care, particularly in the USA, has become to depend on so-called diagnosis-related grouping (DRG). Diagnosis is now much more open to scrutiny than in the past. No longer is it simply a convenient shorthand between clinicians'. (Mace, 1992)

While most psychiatrists see the need for some sort of taxonomy, such a position is not universal.

Taxonomy is useful if it suggests possible causes, says something about likely outcome, and points the way towards rational management. It should serve as a powerful communication role. Rigidly adhered to *operational criteria* (category specified by series of precise inclusion and exclusion statements) carry good reliability (precision) but questionable validity (excessively broad scope). (Farmer & McGuffin, 1989; Farmer et al, 1991; Millon & Davis, 1996) *Operational definitions* are in increasing use. They started in St Louis in 1972 and were adopted by DSM-III in 1980. Rules are laid down for reaching a diagnosis, e.g. how many symptoms from a list have to be present and what must be absent, how long must be the history, and so on; before this approach there existed only thumb-nail sketches of disorders.

Classification may help, via the statistical returns from treatment agencies, in the planning of mental health services and legislation.

¹⁵⁹ Some ethicists believe that the QALY discriminates against old people when it comes to resource allocation (e.g. drugs for Alzheimer's disease) because they have fewer years of life to preserve. (Hoey, 2007)

¹⁶⁰ Classifications are simply 'fictions imposed on a complex world to understand and manage it'. (Marks & Mataix-Cols, 2004)

¹⁶¹ Hare (1998) suggests the nature of mental illness is mutable in the same way as diseases like scarlet fever changed in terms of virulence; he points out (p. 38) that evolution of living creatures were assumed to be immutable during the 18th century and that pre-Darwin physicians and naturalists respectively did not consider that diseases and plants could arise *de novo*.

Sources of variance in diagnosis

The diagnostician

- (a) Different information elicited from patient/other sources
- (b) Using different thresholds of diagnostic significant for what is elicited¹⁶²
- (c) Reliance on different theories of causation, e.g. biology v social (criterion variance)

The patient/subject/client

- (a) Real inter-patient differences
- (b) Similarities/overlap of symptoms/signs between different disorders
- (c) Changes in manifestations over time

Levels of reliability according to diagnostic grouping

High – organic disorders such as amnesic syndrome

Mid-level – functional psychotic disorders, e.g. schizophrenia

Low – neuroses (e.g. generalised anxiety) and disorders of personality

Some disadvantages of current classification

Tells us little about cause, symptoms, treatment, or prognosis

Squeezes people into niches whereas most cases are interforms (low reliability; intersyndromes, not otherwise specified, rag-bag, dustbin or catch-all categories – American insurance may be reluctant to pay for anyone without a ‘hard’ diagnosis!) (Barraclough & Gill, 1996); not elsewhere specified ends up with the majority of cases (Farmer ea, 1992; Widiger & Mullins-Sweatt, 2007, p. 7)

It is pejorative (e.g. ‘schizophrenic’, ‘hysterical’, ‘antisocial’)

Labels give us a false sense of understanding and encourage naïve assumptions about disease entities

Childhood disorders (e.g. separation anxiety) may present to the adult psychiatrist and adult disorders (e.g. depression) to the child psychiatrist (Shear ea, 2006)

There is no quantitative divide in Nature between ADHD and normal children in terms of ability to attend, between dieting and eating disorder in adolescents, and between just enough and too much alcohol intake (e.g. Rey ea, 2007, p. 390)

Spitzer’s (1983) ‘LEAD’ approach to diagnosis is too cumbersome for clinical use: Longitudinal (v cross-sectional), Expert (opinion), All Data (e.g. old case-notes).

Grouping problems

categories e.g. schizophrenia, affective disorders, etc. - good for discrete entities and individual patients

dimensions e.g. euthymic to very depressed¹⁶³ - useful for research¹⁶⁴ (gives more statistical power)

multi-axial form - DSM is the classical example

All current diagnoses are simply working hypotheses and ‘should not be regarded as sacrosanct’. (Tyrer, 1996) Dimensions and categories are not necessarily mutually exclusive and one or both may best suit an individual problem. Attempts are being made to create combined dimensional and categorical diagnoses. (Helzer ea, 2006; Cole ea, 2008; Demjaha ea, 2009)

The influence of culture, a concept that is defined in many diverse ways, (Gaw, 2001, p. 2) is discussed in the box.

¹⁶² However, where does one place the threshold for depression? There is evidence that ‘subthreshold’ depression is (a) on a continuum with ‘clinically significant’ depression, (b) that it interferes with health, (c) that it shares risk factors with more severe cases, and (d) that it occurs worldwide. (Ayuso-Mateos ea, 2010)

¹⁶³ 4 weeks fluoxetine led to more positive affect and increased social facilitation in normal people. (Knutson ea, 1998)

¹⁶⁴ Prisciandaro and Roberts (2009) found that dimensional models had greater predictive validity than did a categorical (DSM major depression) model of unipolar depression.

Culture and psychiatric presentation

Indigenous communities suffered greatly from exploitation, expulsion, slavery, disease, genocide, sexual abuse, loss of tradition and legal redress during the era of colonisation. In some cases their children were forcibly removed and reared by white settlers. In many cases the effects can still be seen today, e.g. in high rates of poverty, indebtedness, illiteracy, unemployment, alcohol-related problems, depression and suicide. It is debatable whether true ('entities') 'culture-bound' syndromes exist or whether these are simply universal phenomena modified by local culture.¹⁶⁵ Bhugra et al (2007) suggest that they be viewed as symptom complexes, modified by culture, occurring in response to stressful circumstances. Race, culture and ethnicity may falsely appear to explain research findings when factors such as economics (poverty, debt, education, etc) are not examined. (Patel & Kleinman, 2003) Studies that look at a sample from a tiny part of a huge country (e.g. China) may wrongly claim to be representative of the country as a whole. One of the points against someone having a delusion is that they share their belief with their culture. Nevertheless, psychopathology causes considerable personal and socio-economic disability across cultures. A discussion of cultural influences on schizophrenia is to be found in the chapter on schizophrenia. Religion influences psychopathological content (Koenig, 2009), e.g. the more orthodox a Jew the more likely is the content of obsessions to have a religious theme. (De Silva & Rachman, 2004, p. 62) Cultures that promote *individualism* (egocentric) may lead to a different mode of expressing distress to those that value *collectivism* (sociocentric), e.g. loneliness and guilt versus shame and unfulfilling interpersonal relationships respectively. Although not universally corroborated, ethnic minorities may tend to express distress through somatic complaints. There are a number of possible reasons for this, e.g. stigma surrounding mental illness, language, and non-recognition of Cartesian dualism, i.e. the mind and body are not distinct from one another.

According to Bhugra (2008) a culture may be:

Pathogenic – causing symptoms

Pathoselective – effecting groups in different ways

Pathoplastic – modifying symptom presentation

Pathoelaborating – reinforced by culture

Pathofacilitative – some cultures are prone to certain disorders

Pathodiscriminating – culture defines what is deviant

Some key terms require definition. *Acculturation* is the assumption of characteristics of the larger or more advanced society. *Assimilation* (a bigger step than acculturation) involves total absorption in the larger society. Examples of maladaptation to a host culture include 'over-identification' (decry old culture in favour of host practices) and 'hyper-identification' (decry host culture in favour of culture of origin). A more comfortable adaptation is represented by 'inside-outside split' (private practice of culture of origin and public practice of host culture). *Emic*¹⁶⁶ refers to a socially unique, intra-cultural perspective, e.g. *susto* or the *fallen fontanel syndrome* of Mexico. *Ethnography*¹⁶⁷ consists of the examination of written records, folk tales, myths, language, key informants, life histories, questionnaire surveys, psychological tests, and participant observation, all aimed at studying cultural forms. The Hmong of Southeast Asia believe that the soul is always in danger from opportunistic spirit thieves called *dabs* and that shamans¹⁶⁸ (*tvix neeb*) who are skilled in spirit rescue oppose such forces; medical interventions break sacred Hmong taboos and the Hmong will only seek medical help as a last resort and with little tolerance for lack of results. (Fadiman, 1997) *Etic*¹⁶⁹ denotes universal, cross-national concepts, e.g. poliomyelitis or Grave's syndrome. An example of a *multiethnic country* would be the USA. However, the values of the white middle class are predominant¹⁷⁰. *Psycholinguistics* is the study of language and its communicative function. The latter must be taken into account for cross-cultural studies to be valid.

¹⁶⁵ E.g. absence of fat phobia in some Chinese anorexia nervosa patients. (Lee et al, 1993)

¹⁶⁶ From 'phonemic'.

¹⁶⁷ Gk *ethnos*, race.

¹⁶⁸ Shamans use verbal and ritual healing methods (as do medicine men) and, in an altered state of consciousness, communicate with ancestors/spirits, and recover the ill person's soul. Diviners read oracles, interpret dreams, and communicate with the spirit world (incl. the dead). Herbalists use plant remedies, active or sham.

¹⁶⁹ From 'phonetic'.

¹⁷⁰ WASP, White Anglo-Saxon Protestant. African Americans with bipolar or psychotic mood disorders are at increased risk of being misdiagnosed as having schizophrenia, i.e. mood symptoms may be discounted and psychotic symptoms given priority by clinicians;

Attempts have been made to match the following syndromes to Western disorders, although this practice has been criticised.(Kay & Tasman, 2006, p. 253) It is more important to grasp the broader issues surrounding culture than to focus on these syndromes. Also, the unthinking global application of Western taxonomies may be mistaken.(Summerfield, 2008) A person could simply be reacting normally to dreadful local circumstances.

Americas

Ataque de nervios (*Puerto Rican syndrome*) is found among Latin American Hispanics, especially older females with relatively little education. It is a socially sanctioned expression of grief or conflict consisting of anxiety and aggressiveness leading on to paresis, loss of consciousness or blanking out of the mind, hyperventilation, shouting and swearing, striking out at others, falling, convulsive movements or lying as if dead, and amnesia. It may be brief and mild, severe and prolonged, and it may be recurrent. Dissociative and somatoform mechanisms have been proposed for this phenomenon.

Billis (*muina, colera*) is considered to be due to disturbed relationships between bodily hot and cold and between spirit and soma as a result of anger or rage in Latinos. Acute tenseness, screams, shakes, headache, and upset stomach are common, whereas some cases appear to lose consciousness. Sufferers may be left bereft of energy for long periods.

Bouffée délirante is found in Haiti and West Africa and may resemble brief psychotic disorder. Sudden onset of agitation, aggression, excitement, and confusion characterise his phenomenon, with some cases experiencing hallucinations and paranoid thinking.

Evil eye (*mal de ojo*), mainly found in Latin America (particularly children), refers to illness induced by the stare of a jealous person. Broken sleep, crying, gastrointestinal upset, and fever may occur. By way of comparison, ancient Ireland had its *Cailleach*, an old hag who was able to transfer mental illness from one person to another. In early Ireland the *madman's wisp* was made from a ball of straw or grass by a Druid and then thrown in someone's face. The unfortunate victim went mad.

Falling out (blacking out, indisposition) is a dissociative state found among excited or fearful black Americans, Bahamians and Haitians in Miami, consists of sudden collapse, paralysis, and an inability to see or speak. Hearing and understanding are, however, intact, and no evidence is uncovered to suggest an epileptic origin.

Ghost sickness among American Indians involves preoccupation with death and the dead. There may be an element of witchcraft. Sufferers may report nightmares, weakness, dread/anxiety/suffocation/futility, confusion, loss of consciousness/faintness/dizziness, anorexia, and hallucinations.

Grisi siknis is seen among the Miskito of Nicaragua. The symptoms include headache, anxiety, irrational anger directed towards nearby people, and aimless running and falling.

Hi-Wa itek in Mohave Indians may follow unwelcome separation from a loved person. Anorexia, depression, suicide, and poor sleep are among its manifestations.

Kayak angst, or anxiety about drowning at sea, is found among the Inuit.

*Locura*¹⁷¹ of Latin America is a chronic, severe psychosis attributed to heredity or life's problems in which there are agitation, visual and auditory hallucinations, incoherent speech, inability to adhere to societal rules, and with the potential for violence.

Piblokto or *pibloktoq* (*running syndrome*) occurs in 'hysterical' Eskimo females who may run away or jump into cold water; she is at risk of killing either herself or others, and she has no memory for the event once it is over; it is viewed as representing a dissociative fugue.

Susto (*chibih, espanto, pasmo, perdida del alma, tripa ida*) occurs in the High Andes and takes the form of a sustained melancholia due to worries that the soul may vacate the body.

Tabanka is found in Trinidad among males who become depressed and suicidal once deserted by their wives.

Windigo is found among the Cree Indians of Canada. A Windigo is a mythical monster. Some tribesmen, during periods of economic hardship, believe that they have become this ghoul, and they have been known to murder and eat their brethren. Trivial symptoms (e.g. nausea or hunger) may lead to great upset lest they suggest imminent transformation.

Africa¹⁷²

Amariko, an Ugandan colouration of post-partum psychosis, involves a wish on the mother's part to eat her baby! Local beliefs about promiscuity and legitimacy may play some role in aetiology.

Brain fag syndrome (*Ori ode* or *Ode ori* in Nigeria) is a prevalent form of somatised anxiety and depression found in association with education in West Africa. It is characterised by a rich variety of somatic symptoms, particularly related to the head (e.g. parasites felt crawling about inside the head when experiencing upset), excess autonomic activity, cognitive symptoms such as poor concentration and retention of new information, and visual symptoms. It has been suggested that the condition may be a response to excessive expectations in, and cost of, education. Another interpretation is that it is panic disorder modified by culture.

Obeah is found among Africans and Asians. The health and wellbeing of a person can be influenced by the actions of a distant other person. It is easily misdiagnosed as a paranoid disorder. Treatment is through the ministrations of a traditional healer (or priest if the victim is Christian) who lifts the curse.

Possession states, e.g. that a ghost occupies one's body, should not automatically lead to a diagnosis of mental disorder. Instead one should discover the personal and communal meaning of the experience; the relatives should be interviewed, using an interpreter as necessary. *Sangue dormido*¹⁷³ among the Portuguese-speaking Cape Verde islanders (or emigrants from these Atlantic islands) consists of numbness, pain, tremor, stroke, blindness, infection, heart attack, and, in pregnant women, miscarriage. *Sar* (or *zar*) is a

African Americans receive higher doses of antipsychotics, are more likely to be on a depot neuroleptic, to be involuntarily hospitalised and to be placed in seclusion, and to be over-sedated (in case of violence – even in the absence of such a history) than are Whites.

¹⁷¹ Derived from adjective *loco* meaning 'crazy'.

¹⁷² Lifetime prevalences were higher in rural than in urban centres for psychoses in adults (4.4% v 1.6%), mental retardation (1.9% v 1.3%), and seizure disorders (4.0% v 1.6%) in a random selection of households in Mozambique.(Patel et al, 2007) Key informants most often attributed psychoses to supernatural origins, followed by seizures. The local traditional healer was the person most often consulted.

¹⁷³ *Sangue* = blood; *dormido* = sleeping (Spanish).

possession state in Somali women; Sar spirits hate men; and outrageous female behaviour may be legitimised by claiming to be possessed! Possession states are universal and are not unknown to Irish psychiatrists. *Ufufunyane*¹⁷⁴ is found among Zulu- and Xhosa-speaking people of southern Africa and is attributed to malicious witchcraft, spirit possession, or poison. Features include pseudolalia¹⁷⁵, paralysis, seizures, nightmares with sexual content, trance, and loss of consciousness.

Asia

*Amok*¹⁷⁶ ('to run amok'), found in Malaysian men (similar to *cafard* or *cathard* in other parts of SE Asia, *iich'aa* among the Navajo, and *mal de peleá* in Puerto Rico and Papua New Guinea), may be a manifestation of hysteria or part of another mental illness. Affected people are usually young or middle-aged living away from home and who have a recent experience of loss (including loss of face) or of being insulted. The victim becomes withdrawn, has outbursts of aggression, may kill or commit suicide, can develop exhaustion, and has amnesia for the episode once it is over.

Latah is found in Malaya with similar conditions being described elsewhere (*amurakh*, *ikota*, *imu*, *irkunii*, *myriachit*, *mali-mali*, *menkeiti*, *olan*, *jumping*, *silok*, etc). People startle easily. There may be echopraxia, echolalia, command obedience, and dissociative/trance-like behaviour. Others may take advantage of affected individuals and subject them to sudden frights in order to elicit startling. The typical victim of *latah* is a woman of low socioeconomic status.

Anthropophobia, described in Japan, mainly affects males who blush easily, show anxiety in face to face contact, and fear rejection. In Japan the self is subordinate to the community and fear of causing offence is socially sanctioned. Western diagnoses that must be considered include social phobia (Ballenger, 2004) and avoidant personality style or disorder. *Taijin kyofusho* (interpersonal fear) is probably the same syndrome (sufferers report that body parts/functions offend other people, e.g. odour, spoken thoughts, blushing, gaze/attention). Shame, which is a symptom of this syndrome, is very important in Japanese culture. It appears to respond to SSRIs. *Dhat* (*jiryán*; also *sukra prameha* in Sri Lanka) is a 'neurotic' disorder common in India. The term derives from the Sanskrit for bodily 'elixir'. The sufferer believes that a white 'discharge' in his urine consists of semen. The notion that semen possesses precious and life-preserving properties is deeply ingrained in Indian culture; therefore, its loss in any manner may be viewed as harmful. The *dhat* syndrome, originally described by Wigg, includes vague physical complaints, such as fatigue, anxiousness, anorexia, and guilt feelings. There may be sexual dysfunction, either impotence or premature ejaculation, which the patient attributes to loss of semen in urine due to excessive masturbation or sexual intercourse. The patient may describe a white discharge that is not confirmed on examination. An overvalued idea may form that the urine is foul smelling and less viscous than normal. *Shenkui* (or *shen-k'uei*) occurs in China and consists of anxiety, panic, and various physical complaints (including tiredness and sexual dysfunction). Again, excessive loss of semen by any means is believed to be causal. The author has certainly seen anxious Irish adolescents who imagined that they have semen in the urine due to 'damage' induced by masturbation, so the syndrome is more widespread than India.(Sumathipala ea, 2004) The importance of alleged falling sperm counts in Western males assumed almost hysterical proportions during the mid-1990s.

Frigophobia, found in East Asia, involves an excessive fear of the cold (wears far too many clothes). The person is concerned with loss of vitality. It may be related to OCD.

Hwa-byung (*wool-hwa-byung*; 'fiery illness' or 'illness of anger') is found in Korea, mainly in women. There are an epigastric mass sensation, anorexia, anxiety, dyspnoea, and epigastric pain. It seems to be reactive to social circumstances (a way to release anger or indignation), although partial improvement with antidepressant therapy has been recorded.

Bebainan is believed to result from sorcery among the Balinese.(Suryani, 1984) Sudden subjective confusion, tearfulness, screaming and shouting, especially in women and generally commencing between 16 and 30 years of age, occur in attacks usually lasting for 15-60 minutes. There is usually awareness of the attack whilst it is happening and it can be recalled later. It may represent a way of expressing feelings without incurring adverse consequences.

Koro (Malaysian for "head of turtle"; *rok-joo* in Thailand; *jinjaia bema* in Assam; also called *suk-yeong* by Cantonese Chinese: shrinking penis) resembles panic in symptomatology. Sims (2003, p. 234) suggests that it's a form of *desomatization*, i.e. depersonalisation localised to one organ. *Koro* occurs in China and down as far as Indonesia. The victim, who usually has no history of psychopathology, believes that the secondary sexual organs (penis, female genitalia, breasts) are retracting (as does a turtle's head) into the trunk. He, or she, may take active steps to maintain the externality of breasts, penis, and so on. There is a tendency toward spontaneous remission. It is probably a non-specific symptom, especially in the West, having been described in both schizophrenia and bipolar affective disorder. It was described also in a patient with a corpus callosum tumour.(Durst & Rosca-Rebaudengo, 1988) This author has seen a few cases in Irish patients. Prognosis is much better in Asia than in the West.(Griffith ea, 2003) Interestingly, in Chinese folklore, ghosts have no genitalia!

Qi-gong reaction is a transient neurotic or psychotic response to practicing *qi-gong*¹⁷⁷ in China.

Shenjing shuairuo (Mandarin Chinese: 'weakness of the nervous syndrome') is known to us as neurasthenia.

Shinkeishitsu, found in Japan, consists of obsessions, perfectionism, ambivalence, social withdrawal, neurasthenia, and hypochondriasis.

Shin-byung is found in Korea where it is attributed to ancestral spirits: initial anxiety and somatic complaints give way to convulsive movements and anorexia. *Hsieh-ping* in Taiwan is somewhat similar: short-lived trance state whilst possessed by ancestral spirit who may be attempting to communicate with the family through the possessed; auditory or visual hallucinations, delirium, and tremulousness.

New Zealand

Whakama (shame) is expressed by Maori people when they break social taboos.(McKendrick & Ryan, 2007, p. 452) Despondency, agitation, anxiety, and unusual thinking may mimic mental disorder. *Whakamomori* consists of low mood, sometimes with damage to

¹⁷⁴ Person or voice that enters and controls a person (Zulu). The same condition is called *saka* in Kenya.

¹⁷⁵ Nonsense speech or babbling, as distinguished from glossolalia (speaking in tongues).

¹⁷⁶ The story of Ajax (in the Sophocles play written 5th century BC) and the sheep is sometimes given as an example of amok. However, the slaughter of the sheep by Ajax was an act of jealousy. Achilles' armour was given to Odysseus instead of to Ajax.

¹⁷⁷ This is a folk health-increasing practice which involves working with *qi* (energy) within the body. It may involve movement, breathing regulation, or focusing on 'energy centres' in or around the body. *Qi* or *qigong* = air, breath (Chinese).

self or others. *Mate Maori* (Maori sickness), which different forms, is due to the spirit world responding to the breaking of rules. Rules may be broken by the patient or by others (alive or deceased) in the *whanau* (extended family). This belief is reminiscent of western beliefs that TB or mental illness could be due to ancestral excesses (alcohol, masturbation, etc).

Early studies of mental disorders shared problems of observer bias, sampling errors, and non-standardised measuring instruments. Initial reports of a lack of depressive guilt in developing countries may not have been entirely accurate, as it has been demonstrated to exist, especially in Uganda. It has been suggested that Afro-Caribbean's are more likely to be detained as offender patients.

Psychologists Li ea (2007) discuss common difficulties in assessing, diagnosing, and treating minorities: flawed approaches to assessment (e.g. norms derived from mainstream culture); culture influences on experience and expression of symptoms (e.g. dissociation or depression); ignorance of norms, behaviours, and values; racial and cultural biases in the clinician; non-realisation that there may be greater differences between individuals from the same minority group than exists between the mainstream and the minority groups; lack of empirically based norms for administering/interpreting psychometric instruments; and inadequate training.

According to Ruiz (2007) the following ethnic considerations apply to prescribing psychotropic medication (relative to Caucasians):

- *Asians* – need less neuroleptics (haloperidol, clozapine), lithium or TCAs to get same results; side-effects are more severe
- *African/Blacks* – need smaller doses of TCAs and SSRIs, higher doses of clozapine and olanzapine, but equal doses of risperidone
- *Hispanics* – need lower doses of typical neuroleptics and some atypical antipsychotics (e.g. risperidone) for schizophrenia, and smaller doses of TCAs (they complain more about TCA side effects)

There are many published papers which report that people from developing nations are more likely to be diagnosed as having schizophrenia, to be admitted as involuntary patients, and to be less often offered psychotherapy.(cf. Bhugra & Bhui, 2001)

Services for ethnic minorities need to be accessible, provide trained interpreters¹⁷⁸, employ members of the minority group, and supply patient advocates. Realisation requires availability and considerable capital funding. Ireland and other countries are experiencing immigration in large numbers and provision remains inadequate.(Kelly, 2004; Skuse, 2008) Access to treatment by the elderly in ethnic minorities may be suboptimal, even in economically advanced countries.(e.g. Medicare in the USA: Virnig ea, 2004)

Provision of mental health services in the poorer nations of the world need to be adressed with more urgency than heretofore.(Jacob ea, 2007) Greater involvement of GPs and nurses may provide part of the answer to manpower shortages.(Ghebrehiwet & Barrett, 2007)

Among the systems of classification used are: ICD - International Classification of Diseases, currently the tenth edition (ICD-10), from the World Health Organisation (WHO, 1992), the official one worldwide¹⁷⁹, and available in many languages and in clinical, research and GP formats; and DSM - The Diagnostic and Statistical Manual of the APA - currently the fourth edition (APA, 1994) with text revision (DSM-IV-TR).(APA, 2000) A national system available in English only¹⁸⁰, the DSM was introduced in 1952 as an alternative to an unpopular ICD-6 and has become less psychoanalytically orientated with progressive editions. Its early editions were much influenced by Karl Menninger and Adolf Meyer. ICD-10 includes psychosocial problems confronting the patient in axis III but does not include social consequences of a disorder among its guidelines and criteria, whereas DSM-IV includes significant impairment in social, occupational and other areas of functioning, concepts derived largely from Kraupl-Taylor.(Kraupl-Taylor, 1971) This clinical significance criterion may be virtually redundant in major depression (Wakefield ea, 2010), i.e. the intended role of the criterion in reducing false positive diagnoses may be small.

¹⁷⁸ Whilst awaiting an interpreter an emergency 'multilingual aid box' may be used. This contains a language identification card, a set of 20 translated phrasebooks and a user manual.

¹⁷⁹ Mental disorders were first specifically included in ICD-6.(Blacker & Tsuang, 1999) DSM-V (www.dsm5.org) and ICD-11 are due in in 2013 and 2014 respectively.

¹⁸⁰ Although there is a 1995 'international version'.

Examples of computerised diagnostic programs are DIAGNO (Spitzer & Endicott, 1968) and CATEGO (Wing, ea, 1974). The French have clung tenaciously to their own idiosyncratic nosology. (Pichot, 1984) The label *functional* refers to 'those conditions which do not have a tangible organic causation'. (Mahendra, 1985) Crow (1986) has argued that there may be a continuum of psychosis¹⁸¹ extending from unipolar, through bipolar affective illness and schizo-affective psychosis, to typical schizophrenia, with increasing degrees of defect; genes predisposing to psychoses have a degree of stability, the form of psychosis tending to remain the same within families, but there is also the possibility of change. As stressed by Cohen (2003, p. 6) 'disorder' is not synonymous with mental illness or disease.

ICD-10 (Chapter V, F)

Theoretical implications are avoided in ICD-10, which is generally an improved version of ICD-9. (Sartorius ea, 1993) Instead of following the neurotic-psychotic dichotomy of its predecessor, disorders are arranged in groups according to major common themes or descriptive likenesses, e.g. cyclothymia is grouped with mood disorders rather than disorders of adult personality and behaviour. The term neurosis is, however, retained. Homosexuality *per se* is omitted. As with DSM, provision is made for the employment of multiple axes.

ICD-10 axes (mirror axis in DSM-IV shown in brackets)

I – psychiatric disorders, mental retardation (intellectual disability), medical disorders (I, II, and III)

II – DAS-S, short disability assessment schedule to assess disability arising from axis I (GAF in V)

III – psychosocial difficulties confronting the patient (IV)

Social deviance or conflict on their own, without personal dysfunction, do not merit inclusion. The term *disorder* refers to 'a clinically recognisable set of symptoms or behaviour associated in most cases with distress and with interference with personal functions'. As many diagnoses may be recorded as are necessary to cover the clinical picture.

Goldberg's (2010) criticisms of DSM/ICD

High rates of comorbidity are products of diagnostic rules

Increasing use of 'not elsewhere classified' by practicing clinicians

Each edition gets bigger and more complicated

The term *hysteria* is dropped, because of its many meanings, and the term *dissociative* covers both dissociative and conversion phenomena. ICD-10 is sceptical about the existence of multiple personality disorder other than as a culture-specific or iatrogenic phenomenon. Many other conditions, such as neurasthenia, are reluctantly included. Disorders of the puerperium are only of use as estimates of workload on services. Simple schizophrenia, although included, is of unresolved status. Borderline personality disorder is hesitantly included and hyperkinetic disorder was broadened. Oppositional defiant disorder appears because of its predictiveness for later conduct disorder.

In *Neurasthenia*, or nervous debility/exhaustion, the sufferer complains of tiredness, depression, irritability, poor concentration, and *anhedonia*¹⁸² (also found in depression and schizophrenia), an inability to derive pleasure from anything. It commonly follows or is associated with exhaustion or an infection like influenza. Beard, an American described this syndrome, once attributed to overwork, in 1869. It has been argued that most cases of neurasthenia are actually cases of anxiety or depression. *Shenjing shuairuo*, in China, and *shinkeishitsu*, in Japan, are related concepts. Freud split off 'anxiety neurosis'¹⁸³ from Beard's neurasthenia in 1894. In 1909, Janet coined the term *psychasthenia* which was used to emphasise that the disorder was

¹⁸¹ Reflecting the 19th century concept of a 'unitary psychosis'.

¹⁸² **Disrupted in schizophrenia 1** (DISC1 at chromosome 1q) SNPs were studied by Tomppa ea (2009): Carriers of the minor allele of marker rs821577 had significantly higher scores on social anhedonia (ability to enjoy social interaction) in a Finnish population cohort study. The opposite applied to carriers of the minor allele of marker rs821633. Disruption in DISC1 in mice causes abnormal migration of neurones in the cerebral cortex.

¹⁸³ *Angstneurose*

psychological, not neurological.¹⁸⁴ *Hedonic tone* refers to the ability to experience pleasure, its absence meriting the label anhedonia¹⁸⁵. (Ribot, 1911; Snaith, 1992)

Personality disorders are deeply ingrained maladaptive patterns of behaviour that are generally recognisable in late childhood or early adulthood and with a not invariable tendency to diminish in intensity in the middle years; patient and/or society suffers as a result of it. Historically, Ernst Kretschmer and William Sheldon tried to associate so-called *somatotypes*, or body builds, with particular psychiatric conditions. There are three basic types, each one with overdevelopment of one of the primary embryonic layers: the endomorph with large visceral cavities and a tendency to bipolar affective disorder, the mesomorph with antisocial proclivities, and the ectomorph who has a tendency to develop schizophrenia. These are only of academic interest today, not having stood the test of time.

DSM-IV

There are five axes in DSM-IV. Kleinman (1988) wondered if its predecessors, DSM-III and –III-R, were guilty of a spurious numericalised specificity. Andreasen (2001, p.182) points out that DSM criteria may ‘limit creativity and flexibility’ in uncovering the pathophysiology of mental disorders. Cultural factors undoubtedly operate in the DSM system, e.g. multiple personality disorder (dissociative identity disorder) is largely an American diagnosis and many children diagnosed with attention deficit disorder in the US would attract a conduct disorder label on this side of the Atlantic.

DSM-IV definitions of psychosis

Delusions or prominent hallucinations without insight into their abnormality

Prominent hallucinations with insight into their hallucinatory nature

Other prominent symptoms of schizophrenia, such as disorganised speech, or grossly disorganised or catatonic behaviour

Impairment causing gross interference with capacity to meet ordinary demands of life

Loss of ego boundaries¹⁸⁶

Gross impairment of reality testing

The above serves to illustrate the lack of an all-embracing definition. This is well illustrated in DSM-IV’s varying use of the above definitions to emphasise different aspects of ‘schizophrenia and other psychotic disorders’.

DSM-IV Axes

Axis I: Clinical disorders and ‘other conditions that may be a focus of clinical attention’.

Axis II: Personality disorders and mental handicap (intellectual disability).

Axis III: Relevant (to understanding or managing mental disorder) general medical conditions – these are classified using ICD-9-CM¹⁸⁷ (clinically modified).

Axis IV: Psychosocial and environmental problems, such as relevant (to first two axes) domestic or economic problems.

Axis V: Global assessment of functioning (GAF) using the scale provided in DSM-IV.

Dress and address

Patients want doctors of both sexes to dress formally, the great majority prefer to address doctors by title, but they like to be called by their own first name or they may be undecided about this (Swift ea, 2000; Gallagher ea, 2008) – when in doubt, ask! In a study by Vinjamuri ea (2009) 91% of adult psychiatric outpatients across all age wished to be greeted with their first name¹⁸⁸; most wanted their hand to be shaken

¹⁸⁴ A French physician described **Briquet’s Syndrome** (St Louis Hysteria; now called somatisation disorder), a term rarely applied in Europe, in 1859. Classically, it occurs in women, starts before their thirtieth birthday, the patient persistently complains of a variety of physical symptoms, she will not accept a psychological explanation - even if one is obvious, and it is said to affect at least one in a hundred females. Sociopathic traits are not uncommonly associated with Briquet’s syndrome.

¹⁸⁵ A term introduced by Ribot in 1897.

¹⁸⁶ In psychoanalysis, the triumph of Id over Ego.

¹⁸⁷ The USA requires ICD-9-CM usage for coding purposes when billing for physical and psychiatric disorders.

¹⁸⁸ First and last names should be used initially for identification purposes.

and the doctor to introduced himself/herself as a doctor with their full name; and almost all patients wanted to know the doctor's role. This approach will require sensitive modification based on context, e.g. some Moslems males may not wish to shake hands with a female.

Management and prognosis

Preparation of a management plan should include investigations, immediate management strategies and long-term interventions; in each instance one should consider social, psychological and biological interventions, and ask who will intervene, when they will do it, and where will it be carried out.

We should consider both short-term (this episode) and long-term (recurrences/maintenance) prognoses; features of both illness and the individual with the disorder should be included in the discussion.(Holden, 1990b)

Case notes/progress notes

Avoid pejorative comments.(RCPsych, 1992) The Irish reader should note that it is UK Department of Health advice to send a copy of all correspondence about a patient between doctors to the patient.

Examples of offensive entries (Crichton ea, 1992)

Patronising
Stigmatising
Flippant
Pejorative lay terms

SOAP stands for subjective (from patient), objective, assessment, plan. This can be useful when highlighting a patient's care and dealing with a specific problem. Psychiatrists are in a very strong position to view clinical cases as a whole because of their commendable tendency to wade through the thickest charts in liaison settings.(Abbey, 1999)

Keeping records

Abbreviated draft MHC guidelines dated December 2007:

A major aim is continuity of care. Records should be completed contemporaneously with note taken of event and recording times on the 24 hour clock. Recording frequency must be sufficient to give an accurate picture of the patient at all times. Late entries should generally be avoided and, if essential, should not be squeezed into the record. Entries should not be predated. All healthcare professionals should be encouraged to read each other's entries when there is a need to know. Emphasis should be placed on a factual record: subjective comments should be avoided - if deemed necessary they should be explained. Do not alter, delete or destroy any original record. The record must provide evidence of care planning and provision. The record must be up to date, accurate and unambiguous. It should be written clearly and legibly. If the notes of others are unclear they should be asked to rewrite the record. Ensure that the record is permanent and capable of being photocopied. Avoid using initials. All entries must be signed off and the writer should be clearly identifiable by name and status.

Entries by students and assistants entries must be counter-signed. Maintain an up to date register of sample signatures. Keep the record in chronological order and explain any variance. Identify names and status of other involved healthcare professionals. Identify when other professionals were contacted and any advice given. Avoid abbreviations. Use only acceptable official grading systems. Record all advice give to the patient and record any decisions made. Be systematic by keeping all patients records together and having the patient's name and record number on every page of the record. Use care plans to assist. Seniors should supervise recording standards. Regularly audit the standards of records.

Writing prescription:

Accuracy, appropriateness, no ambiguity
Document advice including details of foreseeable/unforeseeable adverse events

Abbreviations:

Abbreviations should be kept to a minimum and only used in the context of care
References must be approved locally
Avoid in transfer/discharge contexts

Retrospective Notes:

Record date and time of entry and state date and time entry refers to

Narrative Case Notes:

Identify purpose of the notes and reflect the patient's legal status
Follow best practice – reflect before writing
Use short sentences with no unnecessary abbreviations
Use simple words where possible (quotes/observations are superior to jargon)
Be respectful, simple, direct, and specific
Be legible
Avoid generalisations
Avoid confusion/obscurity – be relevant, clear and objective

Distinguish facts from opinion
 Support ones professional opinions
 Describe treatment plan¹⁸⁹ and give classifiable diagnosis
 Make periodic reviews
 Place a line under the end of each entry

Professional Reports

Put title of case on front page
 Utilise a contents page with page numbers if report > 8 pages
 Identify author and purpose of report
 Give brief summary at beginning
 Clearly define issues being addressed
 Relevant background information/history
 State facts of the case as known to you
 Give information on examination/investigations carried out by you
 Give your professional opinion based on the facts and any published research, standards or guidelines available
 Give conclusions that summarises main points plus your opinion
 Distinguish between facts, information reported to you and your professional opinion
 Do not stray from your area of expertise
 Convey respect for patient
 Use simple, clear, plain language
 Explain any technical or medical terms if report is for layperson – may require a glossary
 Keep report as short as possible but include all relevant information
 Any published material referred to or consulted in preparing report should be included in appendices
 Re-read report and ensure you are satisfied with your conclusions
 Ask a colleague to read the report and comment on it
 Keep a copy on file

Discharge summaries are often deficient in the information required by GPs, especially regarding prognosis, mental state on discharge, management advice, and information given to patient and relatives.(Craddock & Craddock, 1990)

Electronic patient records (EPRs) may replace written records (which are sometimes unintelligible). One London survey (Mistry & Sauer, 2009) found that psychiatrists of various levels of experience (only 56% of consultants responded) experienced technical difficulties, confidentiality issues, extra workload and impact on clinical activity when using this system but that most would not return to using paper. Psychiatrists need administrative support and training if they are to adopt EPR successfully.

Clinical audit

This refers to the regular, systematic study and critical analysis of patient care by clinicians (Garden ea, 1989; Kelly, 2009), e.g. clinical *records* (random selection over a stated time period, e.g. acute admissions/unit time, or a subgroup of such files dealing with a specific problem, e.g. dementia; analysis of data, identification of record-keeping problems, examination of management practices, and recognition of need for further investigation), *incidents* (side-effects of drugs, ECT, admission or readmission rates, use of seclusion, etc), *criteria-based* (e.g. determine diagnostic criteria and standards of care for a particular diagnosis from discussion and the literature), and *outcome* (effectiveness of treatment from various points of view, symptoms, function, quality of life, mortality – use rating scales, interview schedules, etc.). Audit may also be classified as *external* (e.g. a training body determines subject), *department- or practice-based* (e.g. a department in the hospital collects and analyses the data on a subject of its own choosing), and *self-directed* (responsibility of a single clinician).

Clinical governance (quality control)

This continuing process aims to increase quality and reduce risk in clinical work. It should not be so rigid as to stifle practitioners. Essential components include evidence-based practice, good access to clinical information and other necessary knowledge, audit, checks on quality of practice and outcome, research, practice development, and adherence to guidelines.(James ea, 2005)

The *Medical Practitioners Act 2007* provides for competency testing (as distinct from knowledge recall) of doctors and has significant resource and time implications.(Nwachukwu, 2009) All doctors must be registered with a Professional Competence Scheme by May 1 2011. The College of Psychiatry of Ireland is assigned the responsibility of elaborating on the *competencies* required in psychiatry. A doctor must

¹⁸⁹ The *individual care and treatment plan* consists of recorded goals that were developed by the patient and his/her multidisciplinary team. The plan describes the treatment and support to be offered, the resources required, and the hoped-for outcomes.

demonstrate various skills (acquired by learning or practice), aptitudes, and performance levels. Examples of competencies are relating to patients, other interpersonal skills, collaboration and teamwork, management (including self-management), scholarship, professionalism, and clinical skills. Various approaches to assessment are possible, e.g. direct observation of practice, case-based assessment, written tests, audit against guidelines, case note review, and continuing professional development (CPD/CME).

Boundaries

Do not treat people you socialise or work with with (*dual-roling*) and ensure that a patient is formally referred. (RCPsych, 2007) Have a supervisor. It is unethical to engage in any sexual activity with current or former patients. Physical touch must be appropriate and not open to misinterpretation. Chaperones should be used when circumstances dictate that it would be safer to employ them. Family members¹⁹⁰ who speak a patient's language are poor substitutes for a neutral *translator* (see box) who will not interfere with the dynamics of the clinical interaction. Inappropriate self-disclosure must be avoided ('I remember when my husband left me....'). Avoid treating patients in your own home and treat in your workplace and during normal working hours when at all possible. Do not advise on matters that could be misconstrued (e.g. 'You would do well to see my brother who is a very good solicitor'.) or are outside your competence level. Do not break confidences.

Using translators

Avoid non-professional translators when possible¹⁹¹

Ask translator about aspects of patient's culture

Literal translations may be misunderstood

Re-phrasing and summarising of questions are often appropriate

Clinician should face the patient and address him/her instead of the translator

Allow patient to 'read' your body language

Give translator time to translate

Seek clarification if confused about answers or if body language and replies are incongruous

Avoid technical jargon

¹⁹⁰ Family and carers may act as advocates for adult patients but they do not possess any automatic legal authority to make decisions on behalf of mentally ill or intellectually disabled relatives. The graver the decision the wider should the clinician consult and the final decision must always be in the **patient's** best interests and be the least restrictive alternative. Legally, an unwise or unconventional decision made by a patient does not mean that he/she lacks capacity. (see MHC, 2009)

¹⁹¹ **Translators:** Only use a friend/relative/clerical staff if you cannot avoid it. Relatives may talk for the patient instead of facilitating free expression by the patient. Relatives may attempt to change thought disorder into sensible language. Use of close others jeopardises confidentiality and may inhibit disclosure. Use trained interpreters who are fluent in the languages of therapist and patient and who will give literal translations and can with authority inform the therapist about the weight to be attached to beliefs about illness and use of metaphor in the patient's culture.

Legislation & Ethics

Brian O'Shea

'Liberty is always unfinished business'. (American Civil Liberties Union, 1955-6)

Ethical principles governing Medicine and Law:

Ethics are the rules and standards governing conduct. *Ethics committees* provide essential safeguards. They examine the scientific value of proposed research, whether the study design is adequate to answer the hypothesis, and risk-benefit ratios of potential outcomes. They oversee matters such as informed consent¹⁹², adequacy of information given to participants, and subject protection (including insurance). Researchers must inform the committee should study parameters change. The Tuskegee, Alabama study of the 1930s prevented patients with syphilis from receiving treatment long after penicillin was discovered! (Pang, 2007)

*Deontology*¹⁹³ (Gk. *deon*, duty) is an ancient rule-based approach to moral questions: if a patient is in need of care then it should be satisfied by another person. *Teleology* (Gk. *teleon*, purpose), an outcome-based approach, became popular in the nineteenth century. In the former case, action is guided by rights and obligations without heed of outcome¹⁹⁴, whereas in the latter case the outcome¹⁹⁵ is crucial and action is aimed at doing what is best for the majority. In practice, neither of these approaches is of much assistance in daily clinical decision making. Instead, clinicians focus more on issues of respect for the autonomy of the patient (the patient's right to give/ withhold consent), doing good (beneficence: medical obligation to act in the patient's best interests¹⁹⁶) and avoiding doing harm (non-maleficence), and practicing in a just manner. (Gillon, 1994) There may be no single correct answer but rather a number of justifiable approaches to the index dilemma. (Roberts et al, 2008, p. 1608)

Other approaches to ethics include *virtue* (what a virtuous person would do), *relationship/care* (decisions based on commitments to others), *communitarian* (social values/traditions determine what is right), *casuistry* (details of the individual case/similar cases are the main basis for decision-making), and *principle-based* (based on doing good and not harm¹⁹⁷, respecting autonomy, and being just) ethics.

The practitioner must juggle a number of variables in order to act ethically and legally. Profound differences between Medicine and Law can sometimes give rise to poor communication and/or misunderstanding. (see Casey and Craven, 1999) The psychiatrist sees human action and disposition as the summed products of genetic, experiential, affective and cognitive inputs, whereas the lawyer assumes the presence of free will and responsibility. Whilst medical values governing acceptable action include

¹⁹² O'Donnell (2008, p. 12), a surgeon, writes: 'Now pre-operative options had to be fully explored and the acronym BRAT (benefits, risks and alternative treatments) became part of the surgeon's (and patient's) lexicon'.

¹⁹³ Associated with the German philosopher (Königsberg, now Kaliningrad) Immanuel Kant (1724-1804).

¹⁹⁴ *Kantianism* holds that telling the truth is almost always obligatory, regardless of the consequences (i.e. the strict Catholic teaching received by the author during the 1950-60s). In reality, this approach, if not tempered by common sense, could sometimes lead to disaster. Real life is often about striking a balance between competing needs.

¹⁹⁵ *Utilitarianism*, a consequentialist school of thought, is associated with the English jurist, philosopher and social reformer Jeremy Bentham (1748-1832) and the English philosopher, political economist and MP John Stuart Mill (1806-1873). Rigid utilitarian adherence would force some people to take an untried compound in the hope that the outcome might be positive for the majority.

¹⁹⁶ Best interest is difficult to define. Phil Fennell (2009), a law professor in Cardiff, suggests a balance sheet approach, i.e. a weighing up of advantages and disadvantages. We must listen to what the patient says and show unconditional positive regard.

¹⁹⁷ Beneficence and nonmaleficence respectively.

confidentiality, autonomy, and beneficence, the courts generally prefer legal principles, or systems of principles, to medical ethical systems. Exceptions occur when statements of principles have been incorporated into legislation, when Constitutional principles apply, or when the State has adopted international conventions.

The Irish Medical Council places a strict duty of confidentiality on medical practitioners. According to the Irish Medical Council (Medical Council, 2004, p. 29) lists four exceptions to confidentiality: when ordered by a Judge in a Court of Law, or by a tribunal established by an Act of the *Oireachtas*¹⁹⁸; when necessary to protect the interests of the patient, when necessary to protect the welfare of society, and when necessary to safeguard the welfare of another individual or patient. The ascertainment of information from third parties (e.g. relatives) is subject to the same rules of confidentiality: try to get the informed consent of the patient¹⁹⁹; relatives and friends do not have an automatic right to information. (Medical Council, 2004, p. 29) Medical information may be passed to another doctor who is caring for the patient, normally with the patient's knowledge and consent. (Medical Council, 2009) Recourse to the provisions of mental health legislation should be had in the case of psychiatric cases who are incompetent to give consent (a minority). (Medical Council, 2004, p. 30) *Tarasoff v Regents of the University of California*²⁰⁰, 1976, raises the ethical question of an obligation to disclose relevant information to a named potential victim of a patient.²⁰¹ The *Protection for Persons Reporting Child Abuse Act*, 1998, ('Shatter Act')²⁰² imposes an obligation on designated Health Board (now Health Services Executive) officers to report knowledge of any child who might be at risk of abuse.

The Protective Disclosures provisions of the *Health Act 2007* came into effect in March 2009. These provide protection against penalisation and civil liability for health service employees who disclose²⁰³ (in good faith and on reasonable grounds) matters about which they are concerned to an authorised person or regulatory authorities (or, in some circumstances, to other agencies such as the Health Information and Quality Authority [HIQA]).

Principles, Conventions and Protocols: All domestic legal interpretation must conform to the *Irish Constitution (Bunreacht na hEireann)*. Under it, the State's legislation must guarantee respect and defend/vindicate personal rights of the citizen. It must also protect citizens from unjust attack. In the case of injustice done, it must 'vindicate the life, person, good name and property rights of every citizen'. The right to bodily integrity followed from this in *Ryan v Attorney General*, 1963.²⁰⁴ Article 40.4.2 of the *Constitution* holds that one cannot be deprived of liberty except by proper recourse to law.

Principles and Covenant of the United Nations (UN): The *UN Universal Declaration of Human Rights* of 1948 is an influential, if not legally binding, document. Elaboration is provided by the *UN Covenant on Civil and Political Rights*. Everyone has a right to life, liberty and personal security; no one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment; no one shall be subjected without his/her freely given consent to medical/ scientific experimentation; everyone is entitled to a fair, equal, and public hearing by an independent and impartial tribunal, in the determination of his rights and obligations and of any criminal charge against him; no one shall be subjected to arbitrary arrest or

¹⁹⁸ Both houses of the legislature, i.e. Dáil and Senate.

¹⁹⁹ Children should receive as much information as they are likely to understand and their wishes should not be disregarded, but the practitioner 'must never assume that it is safe to ignore the parental/guardian interest'. (Medical Council, 2004, p. 32) Reports to an insurance company concerning a deceased person should only be issued with the permission of the next of kin or the executors to the estate. (Medical Council, 2004, p. 30) Reports of communicable diseases, in the absence of informed consent, should be to the relevant authority 'but should observe the patient's confidentiality in all other respects'. (Medical Council, 2004, p. 31) Likewise, if the patient refuses consent to disclosure of a risk of passing on a communicable disease to others, 'those who might be at risk of infection should be informed of the risk to themselves'. (Medical Council, 2004, p. 31)

²⁰⁰ In 1969 Prosenjit Poddar killed Tatiana Tarasoff. The Supreme Court of California ruled that mental health professionals have a duty to protect people threatened with physical harm by a patient.

²⁰¹ The important British case is *W v Egdell*, 1990: in the case of real risk of physical harm, confidentiality can be breached to those whom it is necessary to tell so as to protect the public interest. The Irish Medical Council guidance of 2009 affirmed its acceptance of the Tarasoff decision when it said that disclosure without a patient's permission could be done if failure to disclose placed others at risk of harm. (medicalcouncil.ie) Otherwise confidentiality should be maintained. In the presence of incapacity the clinician should consider what is in the patient's best interest.

²⁰² This Act raises questions relating to professional confidentiality, especially in an era of the multidisciplinary team.

²⁰³ I.e. whistle blowing.

²⁰⁴ This has been invoked in relation to prison conditions. It also has implications in relation to involuntary hospitalisation. The State has a duty to protect the health of persons held in custody as well as is reasonably possible in the circumstances: *State v Frawley*, 1978.

detention; no one shall be deprived of his liberty except on legal grounds; anyone who is arrested shall be informed at the time of his arrest of the reasons for the arrest and shall be promptly informed of any charges; anyone deprived of liberty by arrest or detention is entitled to take court proceedings so that the court may decide without delay on the lawfulness or otherwise of the detention; and anyone deprived of liberty should be treated with humanity and respect.

The 1991 *UN Principles for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care* states that everyone is entitled to good mental health care based on ethical rather than political/religious/cultural grounds, that they experience no discrimination because of mental illness, that community-based treatment be the standard, that the skills of mental health workers should not be used other than for the good of the patient, that medication is used for treatment purposes rather than to make life easy for deliverers of care, that voluntary patients should normally give informed consent for treatments and involuntary patients be kept informed about their treatment, that restraint/seclusion be governed by official guidelines, that mental health facilities be properly structured and receive appropriate resources, and that involuntary detention be re reviewed impartially in consultation with the responsible clinicians.

The WHO *World Health Report 2001: Mental Health: New Understanding, New Hope* advocated situating (and monitoring) mental health services predominantly in primary care settings/community, increasing availability of psychotropic drugs, educating the community and involving it/service users/families in care delivery, that mental health national policies/programmes/legislation be developed with appropriate resourcing, that links be forged with other services, and that research into mental health/related issues be supported.

The *UN International Convention on the Elimination of all Forms of Racial Discrimination* of 1963 places an obligation on States to prohibit and to eliminate racial discrimination and to guarantee the rights of everyone, without distinction. This Convention includes medical care as a right.

Europe: The *European Convention for the Protection of Human Rights and Fundamental Freedoms* of 1950 precludes the use of torture or degrading treatment or punishment. Everyone has the right to liberty and security of person. No one shall be deprived of his liberty save in stated circumstances.²⁰⁵ In 1987, the Council of Europe established the *European Convention for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment* to allow for inspection of prisoners and psychiatric inpatients. The *Convention on Human Rights and Biomedicine* of 1997 provides that the dignity²⁰⁶ and identity of all persons shall be protected. Everyone is guaranteed equal respect for their integrity and human rights and fundamental freedoms with regard to the application of biology and medicine. Individual interests and welfare predominate over the sole interest of society or science. Appropriate measures must be taken to provide equitable access to appropriate health care. Any intervention in the health field, including research, must be carried out in accordance with relevant professional obligations and standards. Subject to protective conditions prescribed by law, a person who has a serious mental disorder may be subjected, without his or her consent, to an intervention aimed at treating his or her mental disorder only when it would entail serious harm to the person's health not to intervene. Emergency treatment without appropriate consent is allowed in an emergency. Article 9 says that previously expressed wishes shall be taken into account for those persons not (at the moment of the intervention) in a state to express his/her wishes.

The *European Convention on Human Rights Act 2003* applies to Ireland subject to the provisions of the Constitution. It can be traced back to New Zealand's Bill of Rights Act 1990 which states that domestic law must provide those fundamental rights guaranteed by international law. Public bodies must adhere to the relevant fundamental rights unless blocked from doing so by statute law and the latter must be viewed in terms of such fundamental rights when such interpretation can be reached. Courts have this obligation to take 'due account' of the *Convention*.

²⁰⁵ I.e. lawful detention of persons for the prevention of spread of infectious diseases, of persons of unsound mind, alcoholics or drug addicts, or vagrants and in accordance with a procedure prescribed by law; and the lawful arrest or detention of a person for non-compliance with the lawful order of a court or in order to secure the fulfilment of any obligation prescribed by law. Zigmond (2009) is critical of the lumping of psychiatric patients together with vagrants, addicts, and so on.

²⁰⁶ One definition of dignity is the right to be treated with respect as a separate individual.

Domestic legislation: The major piece of legislation in Ireland up to 2006 was the Mental Treatment Act, 1945.²⁰⁷ Mental Health legislation can be confusing and the best way to gain an understanding of it is to read the various Acts in the original. The Mental Health Act, 2001 was introduced in 2006.

The Mental Treatment Act 1945 (Ireland²⁰⁸) covered many aspects of the workings of the psychiatric service and not just those concerned with the welfare of patients. Section 12 in Part II established the post of Inspector of Mental Hospitals, a post with wide ranging powers. He had to inspect all hospitals in the State at least once per year²⁰⁹. He was allowed to examine all aspects of management of these institutions and also interview patients. He reported to the Minister on his findings. The Inspector could examine any hospital at anytime and he also had the power to examine employees on oath (Section 242). It was an offence to obstruct the Inspector of Mental Hospitals in his duties. (Section 279) Part XIV was concerned with 'Reception Orders'. There was the Person of Unsound Mind (PUM) Order, which was very restrictive as regards patients' rights, but it was an Order that had been allowed to fall into abeyance despite the fact that it was the only Order that that could be used to procure a police escort.²¹⁰ Temporary Committal Orders²¹¹ were covered in Part XIV (Sections 184-189). The private temporary order required two doctors' signatures²¹² rather than the one required in the case in the public patient order. Both orders allowed for the compulsory detention of a person suffering from a mental illness or an addiction. Voluntary admissions were covered by Section 190 and the 72-hour notice regulation (giving notice of self-discharge) was covered by Section 194. Section 207 was concerned with the transfer of detained patients to the Central Mental Hospital²¹³. This provision was deemed unconstitutional and had been replaced in practice by Section 208 which basically involved procuring agreement between the Clinical Directors of both the referring service and the Central Mental Hospital.

*The Mental Health Act, 2001*²¹⁴ is a product of concern over civil liberties (Mills, 2001) and resources. (Cassidy, 2003; Ní Mhaoláin & Kelly, 2009) (Before the 2001 Act a patient had no automatic right to review of his/her detention and the single route of challenge was an application to the High Court (*habeas corpus*) under Article 40.4 of the Irish Constitution.) A Mental Health Commission (to oversee the Act), Tribunals²¹⁵ (to check on involuntary admissions) and an Inspector of Mental Services²¹⁶ are provided for. Tribunals are composed of one practising barrister or solicitor (in the Chair), one consultant psychiatrist, and a person other than from the foregoing categories (not a registered doctor or nurse).

Mental Health Act, 2001

Concerned with involuntary admissions (O'Shea, 2002a; Kelly, 2007)
 Definition of 'mental disorder' (S.3) is paraphrased in next box
 Best interests of the patient must be upheld

²⁰⁷ *The Health (Mental Services) Act, 1981* was passed by all the Houses of the Oireachtas but was not signed into law. One criticism of the Act is that it proposed that all committal orders to hospital would require two General Practitioners' signatures. Information concerning the names of patients in a hospital and also copies of their reception orders could be made available to 'any person' who 'may apply to a Health Board for information' and Section 34 required that the Medical Officer provide copies of the various documents to the detained patient! Psychiatric review boards were to be established.

²⁰⁸ 19 Parts and 284 Sections. S 260 stated that the patient could not bring a case challenging committal to Court without the leave of the High Court – the latter had to be satisfied that there were substantial grounds for contending that the defendants acted in bad faith or without reasonable care. S 260 was found to be unconstitutional on December 7 2004 (in the *Louis Belenheim v St John of God Hospital* case) by the High Court (see articles 6 and 34 of the Constitution). On appeal, the Supreme Court upheld the decision of the High Court: (2008) IESC 40.

²⁰⁹ Twice a year for private institutions.

²¹⁰ The Order stated that the patient was unlikely to improve in less than 6 months. The Clinical Director could ask a PUM patient to sign a Voluntary Form, so negating the PUM.

²¹¹ Private and public; patient likely to improve in less than 6 months.

²¹² Originally meant to protect private patients who may have some wealth.

²¹³ Evidence had to be given to a Justice of the District Court that the patient has committed an indictable offence; the Justice had to be satisfied that the person would be unfit to plead if he were to stand trial and he makes an order for the transfer; the Inspector of Mental Hospitals then made a report to the Minister who, in turn, could complete the order for the transfer.

²¹⁴ 6 Parts & 75 Sections.

²¹⁵ Prof Terry Carney (2009), a law professor, provided some interesting contrasts between Irish and Australian (respectively) mental health tribunals (MHTs): time before hearing 3 v 8 weeks; duration hours v 20 minutes; revocations 10% v about 2%. Australian patients complain that MHTs are trial-like, disempowering and tend to exclude the 'consumer' (patient) and the setting may be off-putting (a round table is superior to 'sides' ranged either side of a long table). He feels that a case conference model should be adopted with the patient fully involved and that the medical (rational treatment) and social (e.g. concerns over property, rent payment, etc) domains should be seen as more important than the legal domain.

²¹⁶ Formerly Inspector of Mental Hospitals; must visit mental health services on a yearly basis and can take evidence under oath.

Admission under S.3.1.a is because of a danger posed by the patient (because of an abnormal mental state) to self and/or others

Admission under S.3.1.b must be likely to alleviate or benefit the patient 'to a material extent'

Patient must be kept reasonably informed of what is going on (admission, treatment)

Personality disorder, social deviance, and substance abuse not grounds for involuntary admission *per se*²¹⁷

Gardaí²¹⁸ can enter premises by force to make contact with a patient they have serious concerns about

Gardaí can be requested to provide an escort in order to get (detainable) patient to an approved centre

Certain officers of health boards, among others, are authorised to act as applicants²¹⁹

'Spouse' does not include someone living apart from the patient or on who is the subject of an application under the *Domestic Violence Act, 1996*

A registered medical practitioner makes a 'recommendation' for involuntary admission of the patient

There is no provision under the Act to transfer an involuntary patient abroad

A Mental Health Tribunal can 'cure' minor irregularities (e.g. minor mistake in date) in the paperwork under S 18(1) as long as it is in the patient's best interests to do so and as long as no injustice was done as a result of the irregularity but the Tribunal cannot bend the law to the degree that 'violence' is done 'to the words of the Act itself'

Where the patient's legal representative is unable to get the patient's competent permission to read his file such permission may be granted by the sitting Tribunal or by 'the hospital or treating psychiatrist therein' (EJW case, Peart J, November 2008)²²⁰

What is a voluntary patient? In the EH case²²¹ (Supreme Court, May 2009) he/she was defined as someone who is receiving care and treatment in an approved centre who is *not the subject of an admission order or a renewal order*. He/she is **not** defined as a person who freely and willingly gives consent to an admission order. (Madden, 2009)

Standard of proof required at Mental Health Tribunal

'...to a standard of a high level of likelihood as distinct from simply being more likely to be true'. (MR, High Court, 2007)

This falls short of 'beyond a reasonable doubt'.

Likelihood of physical and/or mental harm occurring must be regarded as 'immediate'.

A minor injury to the self does not qualify as being 'serious' whereas the same injury to a third party would qualify.

The Commission must be informed of all involuntary admissions. Patients must be given a written statement of their rights (S.16(2)). The Commission will refer the case to a Tribunal who will review the case and either affirm or revoke the admission order. The tribunal can discharge the patient, allow the

²¹⁷ 14% of involuntary admissions in 2002 had personality disorder, alcohol disorders, or drug dependence, all of which are excluded *as such* as grounds for detention under the 2001 Act.

²¹⁸ **Garda** (police) involvement under the 2001 Act: as an applicant in the involuntary admission process (s. 9), taking a person into custody because there is a serious likelihood of immediate and serious harm to self/others (s. 12), assisting in removal of patient to approved centre (s. 13), and returning an involuntary patient to approved centre (s. 27). From a police perspective the major gap in services is the lack of a facility to which a Gard can take a person in crisis regardless of diagnosis without being asked to take the person away again. Such a centre would help the person to calm down and prevent escalation of the crisis. A number of models of police-mental health service crisis intervention cooperation have been reported such as the Specialised Police Crisis Intervention Team in Memphis Tennessee. (MHC & An Gardaí Síochána, 2009) Whatever model is adopted it should be modified according to local needs and resources and adequate training and consultation are mandatory requirements. Selection of Gardaí as crisis intervention personnel should be based on personal attributes such as a calm disposition and a flexible approach to problems. Court diversion schemes to prevent unnecessary criminalisation of mentally ill people who commit petty crimes are another area worthy development.

²¹⁹ There were 1,503 applications for involuntary admission of adults reported to the MHC in 2007. Applications were made by spouse/relative (69%), Gardaí (15%), 'any other person' (9%), and authorised officer (7%).

²²⁰ This makes practical and ethical sense. The author's practice under the 1945 Act was that he gave permission to a legal representative **of the patient** to his in-patient client and any documentation that was relevant. If the patient lacked capacity and there was any reason to suggest that the legal representative represented other interested parties and if I had any doubt in my mind I would firstly refer the matter to the legal advisors of my employer and/or the Medical Protection Society.

²²¹ In the same case the Supreme Court stated that appeals to the Courts based on a defect in an earlier period of detention should only occur when there was a gross abuse of power or where fundamental requirements were not met.

admission order to run its course, or extend the order by periods of 14 days.²²² A patient (or solicitor²²³) can appeal the findings of a Tribunal to the Circuit Court. This must be in writing and within 14 days of receipt of the findings/decision. A medical or nursing member of staff can hold a voluntary patient for up to 24 hours if deemed necessary (S.23), at which case the responsible consultant psychiatrist (RCP: one who is involved in the care and treatment of the patient²²⁴) can either discharge the patient or arrange for a second consultant opinion (S.24)²²⁵. The fact that a patient must indicate a wish to leave the approved centre before S. 23 can be used makes little clinical sense²²⁶. The Health Services Executive (HSE) can apply to the District Court²²⁷ for authorisation to detain a child.(MHC, 2006)

Admission orders last initially last for 21 days and can be renewed for up to 3 months; they can then be renewed for up to 6 months and thereafter for periods of up to 12 months²²⁸ at a time.

The time that the Renewal Order commences was addressed by the High Court and thereafter by the Supreme Court case of *MD -v- St. Brendan's Hospital, MHC, MHT* of 27 July 2007. That decision confirmed that a Renewal Order takes effect on the expiration of the previous Order and not the date on which the Order is signed. A Tribunal's decision concerning an admission must be made within 21 days²²⁹. If a defect in an Order is not complained of at the relevant Tribunal it cannot subsequently be used in argument at a later Tribunal. Under the Act, an involuntary person suffering from a mental disorder who has been admitted to an approved centre shall *not* be a participant in a clinical trial. Bodily restraint and seclusion are subject to rules made by the Commission.

The treating psychiatrist should normally ensure that his/her patients give free and informed consent to treatment. However, treatment can be given without consent if the patient is incapable of giving consent. Psychosurgery²³⁰ requires written consent from the patient and authorisation from a Tribunal. ECT requires written consent from the patient and the agreement of two consultant psychiatrists, one being the treating consultant. Following 3 consecutive months of drug therapy, written consent from the patient for further such treatment is required, or such treatment can be authorised by 2 consultant psychiatrists, one being the treating consultant (3-monthly renewal thereafter).

Mental Health Act, 2001

(a) *Definition of 'mental disorder'*: mental illness (abnormal thinking, perceiving, emotions, or judgement seriously impair mental function and necessitating intervention for sake of self and/or others), severe dementia (intellectual, psychotic, and behavioural manifestations) or significant intellectual disability where²³¹ –

1. Person very likely to cause immediate and serious harm to self or others
2. Judgement is so impaired that without admission significant deterioration is likely or appropriate treatment would not be possible
3. Admission would materially help the patient or alleviate the disorder

²²² Such an adjournment extends the review of the existing Order **but not the life of the Order**: the responsible consultant must still complete an Extension Order in order to hold the patient in the approved centre.

²²³ Interestingly, the independent psychiatrist (S. 17) may read the patient's medical file but the legal representative requires the patient's permission! Where the latter is not forthcoming permission has to be sought from the Tribunal.

²²⁴ Sometimes this can mean that there is more than one RCP and any of these can make a renewal order. (JB(2) 2007, unreported) A locum consultant can be the RCP. The important issues at tribunals are (a) the RCP knows the patient and his/her history and (b) is involved in the care and treatment of the patient, i.e. the psychiatrist has more than a 'peripheral' involvement in the case. If a consultant takes over from the usual RCP 'once his shift has started he was the person to whom those working under him would refer matters on which they needed advice or consultation' (JH case): i.e. the Courts are aware that RCPs get sick, have rotas, take holidays, etc. WQ case: a psychiatrist not attached to the approved centre and not involved in the care and treatment of the patient cannot make a renewal order.

²²⁵ S.24 cannot proceed unless S.23 has first been applied to the voluntary in-patient.

²²⁶ What happens to the patient with catatonic mutism who will not eat or the psychotic patient who lies in bed and will not take treatment but who nonetheless do not indicate a wish to/try to abscond?

²²⁷ In late 2009 the Law Reform Commission suggested that persons admitted and treated under the 2001 Act should have access to an independent advocate and a mental health tribunal (rather than the District Court) should review their admission and treatment.

²²⁸ The exact date of termination of this renewal order must be stated on the relevant form.

²²⁹ The first 'legal day' is not necessarily 24 hours long as it end at midnight on the first day of completion of a detention order.

²³⁰ In the *Mental Health Act, 2001* (s. 58) **psychosurgery** is any 'surgical operation that destroys brain tissue or the functioning of brain tissue and which is performed for the purposes of ameliorating a mental disorder'.

²³¹ Any number of these 3 can be used according to a High Court decision, not simply either or as initially stated.

(b) *Time limits under the Act*–

1. Applicant must have seen subject not more than 48 hours before applying
2. Doctor making recommendation must examine patient within 24 hours of receiving application
3. Recommendation remains valid for 7 days
4. Decision to detain at approved centre to be made within 24 hours (was 72 hours in the 1945 Act)

*The Mental Health Act, 2008*²³² was rushed through the Dáil at the end of October 2008 because extensions of detention as stated on Form 7 (renewals) were deemed to be too imprecise (e.g. a full 12 months might not be required to treat the patient). Henceforth precise periods with termination dates are required.

Mental health tribunals during 2008

Cost for tribunals €9,755,433 (per notification €2,922)

2,004 involuntary admissions, 2,096 hearings (241 revocations at hearings)

1,324 renewal orders

1,290 orders revoked by psychiatrists before tribunal hearings

Findings of a postal survey of 238 consultant psychiatrists in Republic of Ireland (O'Donoghue & Moran, 2009)

Subject: experiences and attitudes post-Mental Health Act 2001 introduction

70% response rate

48% felt care of voluntary patients deteriorated

32% felt care of involuntary patients improved

69% stated involuntary patient status was being changed to avoid a tribunal

14% re-admit patients involuntarily just after a tribunal revocation

57% of placements saw reduced training of junior doctors

87% report increase in on-call service workload

23% report increase in service consultant complement

A majority worry about not admitting patients with personality disorders or substance abuse *per se* as involuntary patients

Waterford Mental Health Services November 2006-October 2009 (Umedi ea, 2010)

2,254 admissions (130 or 5.8% involuntary from outset)

66 (51%) of involuntary admission orders revoked by treating consultant

64 (49%) of involuntary admission orders reviewed by mental health tribunal (MHT)

Of those reviewed by MHT: 87.5% affirmed and 8 (12.5%) revoked

Revocations were all on grounds other than absence of a mental disorder, e.g. recommendation preceded application

National survey of 735 MRCPsych holders²³³ in Ireland (Jabbar ea, 2010)

Examined views 1 year after full implementation of the Act

Respondents views (only 43.7% response rate):

Satisfied with training – 84%

Increase in workload – 69.1%

Reduced time with service users – 26.8%

Changed relationship with service users – 40.7%²³⁴

Did not believe Act could be implemented – 27.4%

Other issues: adversarial tribunals, effects on doctor-patient relationship, and issues regarding minors

The Criminal Law (Insanity) Act 2006, (Cassidy, 2003; Wrigley, 2003; Barry, 2006; Kennedy, 2007) became law in 2006. If a judge finds the defendant unfit to plead he may issue a hospital & treatment order

²³² A woman (SM) who had been admitted to St Patrick's Hospital in Dublin challenged her detention in the High Court stating that she was being detained because of lack of suitable accommodation outside hospital. Her legal team stated that the period of renewal was too imprecise: 'not in excess of 12 months'. The judge found that she was not well enough to leave hospital. In response, a new Form 7 was created by the MHC. Cummings and O'Connor (2009) suggest that the direct costs of the case (€993,377) could have provided supported accommodation for SM for 37 years!

²³³ This group includes senior and junior psychiatrists. Consultants were most likely to report negative views.

²³⁴ Some said they were more empathic but others that legalism had crept into the relationship with resultant conflict.

(with independent reviews) or a community order. The Act introduced diminished responsibility and (re-)introduced the verdict of 'not guilty by reason of insanity' into Irish law. The Minister designates psychiatric centres to receive persons diverted from the courts. Lack of secure facilities in non-forensic settings is worrisome. (O'Shea, 2002; Brophy, 2003) Interaction between the *Criminal Law (Insanity) Act 2006* and the *Mental Health Act, 2001* requires further consideration in order to avoid disrupting care of patients. (MHC, 2008, p. 83)

Part II of the Irish *Powers of Attorney Act 1996* allows a person to make an enduring power of attorney. The donor gives an attorney power to make personal welfare decisions on his/her behalf: such power has to be in a form prescribed by the Minister for Justice, the attorney must apply for the power to be registered with the Office of Wards of Court when the donor is/is becoming mentally incapable, certain people must be notified of the intention to register such power, and there are certain grounds for upholding objections to registration.

UK:

Mental Health Act 2007 (Zigmond, 2008) for England and Wales²³⁵, as of November 2008²³⁶ introduced community treatment orders (CTO)²³⁷. Children cannot be put on adult wards²³⁸. Non-medical

²³⁵²³⁶²³⁷ The **Mental Health Act 2007** amends the the *Mental Health Act, 1983* and the *Mental Capacity Act 2005*.

Mental Capacity Act 2005 in England and Wales, (Jones, 2005; Church & Watts, 2007; Church & Jones, 2008; Nicholson ea, 2008) states that a person lacks capacity if at a relevant time he is unable to decide in relation to a particular matter due to an impairment/disturbance of mind/brain. The Act applies to carers and professionals. People with capacity can appoint others to make decisions for them if/when capacity is lost (lasting power of attorney). They can also state what treatments they would wish to refuse should they become incapacitated in the future (advance directives). Should a person lose capacity without having appointed a lasting power of attorney, the Court of Protection may be involved in deciding on capacity and in handling financial/health/welfare decisions. Doctors are able to make decisions based on the Act and will not have to rely on common law.

Principles of Mental Capacity Act 2005, England and Wales (Bartlett, 2006)

- A person is presumed to have capacity if there is no evidence to the contrary
- A person does not lack capacity just because of an unwise decision
- Decisions made on a person's behalf must be made in his/her best interests
- Such decisions should intrude as little as possible into rights/freedom of action
- A person must be helped to make a decision before he/she can be treated as lacking capacity

The Mental Health Act, 1983 (England & Wales) replaced the *Mental Health Act 1959* and was itself amended in 2008. 10 Parts in the Act and 149 Sections. Many experts felt that it erred too much on the side of rights to freedom as distinct from rights to treatment ('Rotting with your rights on'). It attempted to continue the philosophy of community psychiatry. Nevertheless, it was followed by almost doubling of the numbers of compulsory admissions during first 12 years of its existence (Wall ea, 1999)

Part I dealt with definitions of mental disorder, severe mental impairment, mental impairment and psychopathic disorders. There was no definition of mental illness! Promiscuity, sexual deviancy and dependence on drugs or alcohol excluded as categories for compulsory detention in hospital

Part II concerned with compulsory admissions to hospital and also guardianship. Guardianship is not commonly used in practice, perhaps because of resource implications. (Taylor & Estroff, 2003, p. 607) Provision for admission for assessment (S2) admission for treatment (S3) and emergency admissions (S4) S. 5 (2) allowed detention of an inpatient (incl. in a general hospital) for up to 72 hours – this allowed a fuller section to be completed

S. 5 (4) allowed a nurse to detain a patient for up to 6 hours for a detention process to begin

S. 12 described requirements for 'approved doctors'

S. 114 lays down regulations for 'approved social workers' - approved social workers central to workings of Act and provide the vast majority of the 'applications'

Part III concerned with the mentally abnormal offender: courts can make orders for treatment and assessment of people on remand S. 37 was a Hospital Order - allowed court to commit person to hospital for treatment instead of sentencing

S. 41 concerned with Restriction Orders - here a higher court could put a restriction on discharge of a patient who is committed to hospital on a Hospital Order - patient cannot be discharged without the permission of the Home Secretary. Court must hear oral evidence from a psychiatrist before making a Restriction Order

Part IV provided regulations concerning a patient's consent to treatment. If a detained patient does not want treatment, including medications, after 3 months one must arrange for a second opinion. Special treatments such as ECT and psychosurgery have greater restrictions

Part V concerned with mental health review tribunals that review detained patients annually if requested to do so by the patient. They must review detained patients every 3 years. They have various powers depending on the category of detention.

S. 136 concerned powers of police who encounter a mentally disordered person in a public place. They could take the person to a 'place of safety'

Section 136 facilities are inadequately developed so that many patients are detained in police custody. (Anonymous, 2008)

²³⁷ Such orders only apply to patients detained in hospital for treatment. The responsible clinician may discharge such a patient under a renewable supervised CTO which may specify conditions, including treatment compliance. Discharge from a CTO is only via the responsible clinician or a mental health tribunal. The patient can be recalled to hospital if deterioration occurs or certain conditions are not kept. Medication can only be given forcibly within hospital.

professionals may take overall charge of patients' care and treatment²³⁹ and provide the report required to renew detention orders.²⁴⁰

Mental Health Act 2007 – main provisions

Single definition of 'mental disorder'²⁴¹

Statutory advocates for detained patients

Under-18s must be accommodated in age-appropriate setting

'Appropriate medical treatment test' applies to all longer term detention powers

Medical treatment must be available and appropriate

'Treatability test' abolished

Broadens group of practitioners²⁴² who taken on functions formerly held by Approved Social Workers and Responsible Medical Officers

Patient can apply to have nearest relative displaced²⁴³; nearest relative can now include civil partners

Single Mental Health Review Tribunal and shorter period before cases are referred to it by hospital managers

New safeguards for electroconvulsive therapy²⁴⁴

Supervised community treatment following detention

'Bournewood safeguards' for non-detained persons who lack capacity²⁴⁵ – legal safeguards, no arbitrary decisions, powers of challenge

Mental Health Act 2007 – important sections

2 – Assessment & treatment (lasts 28 days): signed by 2 doctors or 'approved clinicians' + nearest relative or approved mental health worker

3 – Treatment (6 months): signed by same as s2

4 – Emergency admission (72 hours): signed by 1 doctor or 'approved clinician' + relative or approved mental health worker

5(2) – Emergency detention of inpatient (72 hours): signed by doctor in charge of case or nominee or approved clinician

5(4) – as for 5(2) (6 hours): signed by registered mental nurse

136 – Police bring patient to hospital because person in public place thought to have mental illness + need place of safety (72 hours): signed by police officer

²³⁸ In mid-2009 the MHC, in response to continued admission of children to adult approved units issued an **Amendment to: Code of Practice Relating to the Admission of Children under the Mental Health Act 2001**: MHC will review the number of admissions of children to approved centres for adults from time to time. In respect of the admission of a child to an approved centre for adults, the following applies: no child under 16 years is to be admitted to an adult unit in an approved centre from 1st July 2009; no child under 17 years is to be admitted to an adult unit in an approved centre from 1st December 2010; and no child under 18 years is to be admitted to an adult unit in an approved centre from 1st December 2011.

If, in exceptional circumstances, the admission of a child to an adult unit in an approved centre occurs in contravention of the above, the approved centre is obliged to submit a detailed report to the MHC outlining why the admission has taken place. This report should be in the form specified by the MHC as per Section B of the *Notification to the Mental Health Commission of the admission of a child to an adult unit in an approved centre*. **Section 2.5m** is amended to read as follows: MHC should be notified of all children admitted to an approved centre for adults within 72 hours of admission and also notified of the discharge of all children from an approved centre for adults within 72 hours of discharge using the associated clinical practice forms. Procedures should be in place to identify the person responsible for notifying the MHC.

²³⁹ Hence one doesn't have to be a psychiatrist to be the 'responsible clinician'.

²⁴⁰ A large majority of Irish patients who had been the subject of involuntary detention in a private psychiatric hospital were interested in having the option of an *advance directive*. (O'Donoghue et al, 2010)

²⁴¹ Replaces the 1983 four definitions of mental disorder, severe mental impairment, mental impairment and psychopathic disorders.

²⁴² 'Approved Mental Health Practitioners' (social workers, mental health or learning disability nurses, occupational therapists, and chartered psychologists) and 'Responsible Clinicians' (registered medical practitioners and Approved Mental Health Practitioners). When a patient on a **Community Treatment Order** (CTO) is returned to hospital, the Responsible Clinician has 3 days in which to decide whether to send the patient out on a CTO or to revoke the Order, i.e. to keep the patient in hospital, but the Responsible Clinician must have the agreement of an Approved Mental Health Practitioner. Hall and Ali (2009) expressed concerns about the changes in the Responsible Clinician role and about the effect this might have on relationships between professions as well as on the role of the psychiatrist.

²⁴³ A relative can be displaced by County Courts if reasonable to do so.

²⁴⁴ ECT cannot be given to a person who has capacity unless in an emergency, i.e. to save the person's life or to prevent serious deterioration in his/her condition. A 'Second Opinion Doctor' has to examine the patient. Parental permission does not override the decision of patients aged 16-17 who have capacity.

²⁴⁵ See 'Bournewood gap'.

*Mental Health (Care and Treatment)(Scotland) Act 2003*²⁴⁶ was passed in early 2003, replacing the *Mental Health (Scotland) Act 1984*. Whilst treatment cannot be forced on a person in his/her own home, that person may be removed to a specified place for 6 hours so that treatment may be administered. (Lyons, 2008) 'Advance statements' are written statements setting out how the patients wants to be treated for psychiatric illness should mental disorder impair their decision-making ability. (Foy ea, 2007) A study of psychiatrists' views and experiences (76% response rate) showed that 12% believed it improved patient care but most respondents believed that informal patient care had suffered, that tribunals were no better than the previous court system, and that out-of-hours work had increased. (Carswell ea, 2007) However, satisfaction with the Act among psychiatrists may have improved with time. (Donaldson ea, 2008)

According to Owen ea (2008), mental capacity to make treatment decisions is usual in detained patients and common in voluntary in-patients. Owen ea (2009a) examined consecutive admissions²⁴⁷ to a London psychiatric hospital (Maudsley) and found that psychotic disorders and the manic phase of bipolar affective disorder were most strongly associated with lack of capacity; in non-psychotic cases, unlike in psychosis, depressed mood was associated with capacity status; insight was the best discriminator of capacity status in psychosis and mania but is less discriminating in non-psychotic cases; and cognitive performance did not predict capacity status in cases with psychosis. In a further publication, Owen ea (2009b) examined 200 psychiatric inpatients using the *MacArthur Competence Assessment Tool for Treatment*: a quarter were informal (voluntary) but lacked capacity and these people felt more coerced and were more likely to refuse treatment than voluntary patients with capacity; a small number of detained (involuntary) cases had capacity and were difficult to characterise.

Adults with Incapacity (Scotland) Act 2000 establishes statutory authority to treat adults who are not able to consent for themselves. A proposed treatment must be for the patient's benefit; it must be the least restrictive intervention; account must be taken of known/present wishes (if available); consultation should take place with family/carers/appointed proxy; and the patient should be helped to exercise any remaining capacity.

Incapacity in Northern Ireland

Covered by *Mental Health (Northern Ireland) Order 1986* Part VIII and *Enduring Powers of Attorney (Northern Ireland) Order 1987*

Management of the patient's affairs are controlled by High Court via Office of Care and Protection – a controller is appointed to manage patient's finances

Northern Ireland intends to introduce an Act that covers both capacity and mental health

Fitzpatrick & Anor v K. & Anor (2008) IEHC 104 (Irish High Court)

A female Jehovah's Witness (K) booked into Coombe Hospital Dublin as a Catholic

She bore a baby boy in September 2006

She suffered a postpartum haemorrhage but refused blood transfusion

An emergency High Court order allowed the hospital to give the transfusion

The hospital sought (at the court's behest) a declaration that it was entitled to seek the order

Principles involved in determining capacity re-stated by court:

Adults have capacity to refuse treatment, but this is a rebuttable presumption

Cognitive ability has to be so impaired that patient doesn't sufficiently understand the nature, purpose and effect of the treatment and the consequences of accepting/rejecting it in light of all available choices

Cognitive ability is so impaired that patient is incapable of making the decision to refuse because he/she does not understand and retain²⁴⁸ the information about the treatment and consequences likely to follow refusal; does not believe the information given (especially that death is a likely outcome); has not weighed the information, alternative choices and likely outcomes 'in the balance' in arriving at his/her decision

The doctor must tell the patient about the appropriate treatment, its risks/consequences, and available choices

²⁴⁶ The *Mental Health (Northern Ireland) Order, 2004* applies in Northern Ireland.

²⁴⁷ 200 patients participated but 150 did not participate. Dysfunction on the GAF was similar in both groups. Decision making was measured with the *McArthur Competence Assessment Tool for Treatment*. (Grisso ea, 1997)

²⁴⁸ Retention of information need only be brief. (Lush, 2008, p. 770)

The doctor must recognise/note if misunderstanding/misperception of the information might represent lack of capacity

Irrational decision or decision made for irrational reasons is NOT relevant to the assessment

Regard must be had to the gravity of the decision and the likely consequences

Incapacity in the Republic of Ireland

Wardship (Ward of Court): Wardship is a practice of uncertain antiquity. It was originally exercised by the Court of Exchequer, later passing to the Lord Chancellor, and now lies with the President of the High Court under *Lunacy Regulation (Ireland) Act 1871*. (see Agyapong & Wrigley, 2009) Application (usually by a relative with two supporting medical affidavits) may be made to have the court appoint a representative to manage the affairs and provide for the welfare of a mentally incapacitated person²⁴⁹ (e.g. dementia). It is important to note that wards of court are not subject to the 'reception, detention and treatment regime' of mental health legislation. (O'Neill, 2004, p. 119) It is also important to note that medical interventions in such cases require the permission of the High Court. However, emergency interventions are allowed, permission being retrospectively sought (via The Office of Wards of Court²⁵⁰) as soon as is feasible. The Irish Medical Council (medicalcouncil.ie) states that if a patient with disability lacks capacity the clinician should consult parents/guardians/carers and, when relevant, consider getting a second opinion.

Irish Mental Capacity Bill 2008²⁵¹

Designed to replace Wards of Court

Only applies to adults

Evidence level – balance of probabilities

Capacity is the ability to understand nature/consequences of a decision in context of available choices at time decision has to be made

Lack of capacity signified by inability to understand/retain/weigh information relevant to the decision or to communicate decision – must be tested for in relation to the decision in question

Doctor's overriding duty – act in patient's best interests

Must presume capacity is present (even if person makes unwise decisions); intervene only if necessary in particular circumstances; must make all practical steps to help patient decide first (supported decision-making is a right); use least restrictive intervention; respect dignity, privacy, and autonomy; take account of known past/present wishes and views of interested (in patient's welfare) others (no hierarchy of relationships/authority given)

A patient's decision can be transmitted to the treating clinician in any manner that suits the patient (gestures, sign language, written, verbal, a third party)

If a person cannot be supported to make a decision the High Court or Circuit Courts appoints a personal guardian to act as substitute decision-maker re property/affairs

Certain decisions are reserved to the High Court, e.g. withdrawal of artificial life-support, non-therapeutic sterilisation, organ donation

Independent Office of Public Guardian supervises court-appointed guardians – if no one is able/willing to be a guardian the Office acts as guardian of last resort

The capacity required to make medical decisions depends on the decision to be made²⁵². The decision arrived at is less important than the rationality of the process whereby the individual arrives at the decision.

²⁴⁹ Of unsound mind and unable to handle his/her affairs.

²⁵⁰ 3rd Floor, 15/24 Phoenix Street North, Smithfield, Dublin 7. +353-(0)1-8886189 (tel), 8724063 (fax).

http://www.citizensinformation.ie/categories/justice/courts-system/office_of_wards_of_court/

²⁵¹ Gives effect to *Hague Convention on the International Protection of Adults* and *UN Convention on the Rights of Persons with Disabilities*.

²⁵² Roberts et al (2008, p. 1618-9) make the points that capacity, which must be subjected to a targeted assessment, cannot be assumed only from the diagnosis or from illness severity; capacity may change over time (e.g. mania settles) so that capacity may need to be reassessed; and that whilst a patient might display an understanding of facts he/she may not appreciate that they apply to him/her (e.g. 'I am divine and therefore it will not harm me/therefore I do not need the treatment.').

Should a patient defer completely to the physician's (or other's) judgement he/she should have his/her capacity to make such a waiver assessed and documented.

Testamentary capacity (capacity to make a Will at a particular point in time) is not usually questioned (i.e. they are admitted to probate and put into effect without court involvement), but may be (e.g. a child could apply to the court on the basis that the parent/testator failed in the moral duty to make proper provision for him/her). In reality, most bad decisions are made by people who are deemed competent! It is important for the assessor to record questions, answers and results of their examination in case of future legal involvement. (Posener & Jacoby, 2008) The doctor reporting on an examination for testamentary capacity should read as if addressed to the Court and not gloss over any deficiencies in his/her understanding of the case, e.g. if the testator's estate is unknown to the doctor except from the testator's own account then this fact should appear in the report.

Suffering from dementia does not *per se* invalidate a Will. The amnesic syndrome is very likely to interfere with one's ability to dictate a valid Will because of its effects on recollection and retention. Undue influence, which may be difficult to prove, might invalidate a Will.

The legal requirements for being of 'sound disposing mind' (make a valid Will) date to 1870 in the case of *Banks v Goodfellow*²⁵³ (see box). One can have the capacity to make a certain decision and yet, at the same time, not have capacity to make another decision as in the British *Park v Park* case of 1954 where a man validly married and invalidly made a Will within hours of one another!

A doctor may be asked retrospectively to assess if a person, perhaps deceased, had testamentary capacity at the time of making a Will. Such evidence may be as a witness of fact (the doctor was the testator's physician and is asked to deliver the facts he/or she observed personally) or as an expert witness.

Requirements for Will-making

Set out in Irish *Succession Act 1965*

There is no maximum age

Testator must

- **be at least 18 years of age or have been married**
- **be of 'sound disposing mind', even if this is only during a 'lucid interval'**²⁵⁴
- **must know that one will die and that the Will comes into operation after death, who the executor(s) is(are), that he/she can change the Will anytime before death, who will benefit what from the Will and who would expect to so benefit, what he owns**²⁵⁵ **(this need not be very exact), how a new will differs from a previous one, that some parts of property may not be given to certain people because others (say a spouse's rights to jointly owned family home**²⁵⁶**) have**

²⁵³ The delusions of John Banks did not interfere with his capacity to leave most of his estate to his niece.

²⁵⁴ A Will, once valid, will not become invalid just because the testator/testatrix later loses testamentary capacity as long as the person had such capacity when making the Will and retained this capacity until the Will was executed (drawn up and signed). When dealing with cases that might be contested (e.g. elderly or seriously ill) the solicitor should arrange for a medical examination and assessment of capacity: this is known in England as 'Templeman's golden rule' after the judge in *Re Simpson* of 1977 (see *Solicitors Journal*, 1977:121;224).

²⁵⁵ The solicitor's request to the doctor should state what is required and outline what the proposed testator owns and who might hope to benefit from the Will.

²⁵⁶ The Napoleonic Code (e.g. in France) restricts testamentary freedom by the idea of mandatory heirs.

- rights in this area, and know why he/she is not leaving certain persons things in the Will
- **There must not be a delusion²⁵⁷ that *specifically* interferes with the terms of the Will (e.g. leaving the universe to his wife because of a grandiose delusion)**
 - **Testator may not be able to speak or write but can indicate wishes to his/her executor (not to the beneficiary)**

The National Assistance Act 1948, section 47: A rarely used provision whereby a community physician may apply to a magistrate for an order to remove to hospital a vulnerable person who lives in a state of neglect or squalor.

'*The Bournemouth*²⁵⁸ gap': This referred to the absence of procedural safeguards in UK law for a patient who lacked capacity and where carers and professionals disagreed as to correct management. A similar dilemma exists in Ireland in the case of dementia sufferers who lack capacity who do not qualify (or cease to qualify) for involuntary admission under the *Mental Health Act, 2001* but who cannot be allowed to simply walk out of the hospital. Can they be placed in a nursing home without their consent (as often happens) or kept on as a 'voluntary' patient in a psychiatric facility (as sometimes happens)? Section 4 (best interests) of the *Act* only applies to involuntary patients.

A retrospective study of 115 consecutive psychiatric admissions of people who lacked capacity to make treatment decisions (Owen *et al.*, 2009c) found that 83% of those who regained capacity agreed retrospectively with the decisions made on their behalf.

Should patients be allowed to reject life-saving care? In 2009 the Law Reform Commission (LRC) recommended new legislation which would give patients the power to refuse life-saving treatment. The *advance care directives* (ACD, "living wills") would allow patients to make treatment decisions in advance, in case they suffer an illness or accident that leaves them unable to communicate their wishes directly. The LRC recommends that: an ACD would not change current legislation on euthanasia and assisted suicide; ACDs could include an instruction to refuse life-sustaining treatment but only if it is provided in writing and witnessed; ACDs would allow patients to refuse medical treatment on religious grounds; patients would not be able to refuse basic care (e.g. nutrition, hydration and hygiene); patients would be advised to seek medical advice when making an advance care directive (not mandatory); new legislation would not mean medical professionals would be legally liable if a directive they believe to be valid, later becomes the subject of an investigation; and professional bodies would be able to investigate medical practitioners who failed to honour an ACD. The LRC also believes a statutory code of practice on ACDs should be created to offer guidance for healthcare professionals.

²⁵⁷ Some judges may decide that what psychiatrists term an overvalued idea amounts to 'a disorder of mind' (read 'delusion') despite the fact that such overvalued idea might be best understood to arise from the usual self (personality), as in *Dew v Clark & Clark* of 1926 in which a man had a persistent dislike of his daughter.

²⁵⁸ *R v Bournemouth Community and Mental Health NHS Trust Ex P.L.* (1998) All E.R. 289. An intellectually disabled man was taken into hospital informally (voluntary) against his carrier's wishes. The case eventually ended up in the European Court of Human Rights which ruled that the detention constituted deprivation of liberty under Article 5 of the *European Convention on Human Rights*. It would have been better to have used the mental health legislation if the patient had a mental illness and not to admit as a voluntary patient when the person lacks capacity.

Measures and scales in psychiatry²⁵⁹

Brian O'Shea

'A test is an objective measure in a sea of opinion, but its value depends on the discretion and understanding with which it is used.' (Freeman *et al.*, 1992)

The *criterion instrument* ('gold standard') is one which we accept as being reliable and valid (see box). New measures are tested against the criterion instrument, e.g. the Hamilton Depression Scale. In practice, there is a trade-off between sensitivity and specificity (see box) when it is decided where the cut-off (threshold) lies (dividing 'cases' from 'non-cases').

Reliability²⁶⁰ is concerned with how well an instrument measures what it is being used to measure. It is a measure of the level of agreement between 2 sets of observations, agreement being usually measured by the correlation coefficient (good reliability if high and positive: +0.8 or more) which has a range of -1 to +1; *inter-observer* reliability is the extent to which different raters can agree when assessing the same group of patients with an instrument at the same time; *inter-rater reliability* describes assessments by different raters of the same material on two or more occasions; *split-half* (*split-instrument*) reliability refers to the division of items in a test into 2 halves – if all items measure same characteristic there should be a high correlation between both halves, a measure of *internal* reliability (similar to construct validity); *test-retest reliability* is tested when the test is given to a group on several occasions, allowing sufficient time to overcome memory artefact – useful for stable characteristics but may underestimate reliability for fluctuating variables; *alternative form reliability* describes 2 supposed similar forms of the measurement used to assess the same material simultaneously or immediately consecutively.

Inter-rater reliability tests include the kappa statistic²⁶¹ which assesses agreement between 2 observers and an outcome, and intraclass correlation²⁶² assesses agreement between observers when there are 3 or more observers and with interval data.

Validity: an instrument measures what the authors want it to measure, e.g. the Hamilton Depression Scale has validity because it measures depression and not personality factors; validity of psychiatric diagnoses is concerned with their meaningfulness and usefulness; *content*²⁶³ validity is the extent to which the items of a rating scale are representative of the disorder under investigation; *face* (basically the same as content validity) validity means that the instrument is congruent with clinical experience – it feels or looks right; *predictive* validity means an ability to foretell outcome or response to treatment; *construct* validity is the extent to which a scale's items can be added to give a total score without reduction of the information

²⁵⁹ Many measuring instruments used by psychologists and psychiatrists currently find greater research than clinical application. They should not be interpreted in isolation in individual cases, but rather they should be viewed within the context of the case as a whole, e.g. a very depressed individual will score badly on standard tests of intelligence. Before asking a psychologist to 'perform tests' it is wise to discuss the case with the psychologist, who will be able suggest the more appropriate battery of tests. The main applications of measuring instruments are case identification, standardisation of psychiatric interviews, and serial measurement of symptom severity. They can be helpful in standardising local, national and international reports.

Some important concepts are defined in one box (see, e.g. Tyrer *et al.*, 1993) and a selection of instruments are described in another box.

²⁶⁰ Appropriate statistics for a continuous scale and a categorical measure are the intra-class correlation and Cohen's kappa respectively.

²⁶¹ Kappa ranges from -1 to +1 where -1 = no agreement (e.g. on diagnosis), 0 = agreement no better than chance, and +1 = complete agreement.

²⁶² Intraclass correlation gives estimate from -1 to +1 and the closer it is to +1 the more similar are the ratings for individual patients across observers, i.e. there is low variability.

²⁶³ The term '*descriptive validity*' means the extent to which various manifestations of a disorder/syndrome actually occur together in real life. This tendency to co-occur is measured with *latent class analysis*.

contained in the individual items²⁶⁴; *concurrent validity* describes a comparison of the measure being tested with an external valid yardstick concurrently (e.g. a new rating scale for depression with the HAM-D)²⁶⁵; *criterion validity* is the combination of concurrent and predictive validity; *incremental validity* tells us if the measurement is better than other measurements in approaching true validity; cross-validity describes validation of a measurement that has its criterion validity established for one sample and then is retested on another sample. *Ecological validity* refers to a growing awareness of the need to design tests the better predict real-life behaviour and functioning, e.g. many tests avoid fatiguing the patient or having much ambient noise whereas symptoms may be worst during the normal noise and bustle of a tiring day; an elderly man who performs poorly on mental arithmetic tests may still be able to manage his finances at home by using a pen and paper.

Sensitivity (true positive rate): proportion of true cases (identified using criterion instrument) identified as cases by a novel instrument.

Specificity (true negative rate): proportion of non-cases (identified using criterion instrument) identified as non-cases by a novel instrument.

Psychiatric rating scales can be divided into self-appraisal or self-rating on the one hand and observer-appraisal or observer-rated on the other. (Kugler, 1992) The orientation of rating scales for depression varies from a somatic bias (e.g. HAM-D) to a cognitive (e.g. BDI) bias. (Thompson, 1991) However, both the HAM-D and the BDI contain enough somatic complaints questions to give false positive depression scores. (Novy et al., 1995) Imprecision in psychiatric conceptualisation explains many problems in measurement. (Snaith, 1991)

Intelligence testing is expanded on further in one of the boxes. Projective testing, based on psychodynamic concepts and not used as much today as heretofore, are discussed in the chapter on personality and personality disorders. Personality tests tell us more about differences between groups of people and are relatively non-specific regarding individuals.

Various attempts have been made to measure individual subjective experiences and attitudes. Shapiro (1961) developed the *Personal Questionnaire* to measure symptom intensity and change over time from a patient's perspective. Osgood et al. (1957) advocated what they called the *Semantic Differential*, which measures psychological meaning of concepts. Kelly's (1963) *Role Construct Repertory Test*, and the associated *Repertory Grid Test*, aims to reveal a person's constructs or way of looking at the world. Constructs are presented as bipolar adjectives (big-small, friendly-hostile, etc) and cards are shown to the client naming people (called 'elements') with a significant role in his or her life. The chief use of such tests is in psychodynamic therapy, although they have wider applications.

Interviews

Clinical – conducted by a trained or trainee professional

Structured – (1) fully structured – questions and follow-up probes asked verbatim by trained, non-professional interviewers; and (2) semi-structured – questions asked verbatim by professional but considerable latitude is allowed to follow up on leads (individualised and contextualised approach)

Structured interviews have the advantages of improved reliability (reduced variability) and validity (diagnostic criteria are covered in a full and systematic way) and are useful in training (learning what questions to ask) and as research tools (cheap use of lay interviewers), but they may interfere with rapport, are subject to the validity of the classification system (e.g. DSM-IV-TR), may be poor at assessing severity²⁶⁶ (Jablensky, 2003, p. 206), and are a trade-off of breadth versus depth in that they don't cover all disorders/topics. (Segal & Coolidge, 2007)

²⁶⁴ Extent to which parts address a common construct. For a scale we measure with Cronbach's coefficient alpha (varies 0 to 1; 0.6-0.8 = moderate internal consistency; >0.8 = high internal consistency).

²⁶⁵ If there is no known gold standard for comparison one tests for *known group validity*, i.e. can a measure distinguish members of two groups.

²⁶⁶ Concerns that lay interviewers conducting structured diagnostic interviews have been raised, one criticism being that they inaccurately assess severity of symptoms. (Jablensky, 2003, p. 206) However, Segal and Coolidge (2007, p. 83) believe that structured interviews allow determination of severity and impairment because they incorporate systematic ratings.

Unpublished scales should be viewed with suspicion. For example, Marshall et al (2000) argue that their use in treatment trials in schizophrenia may bias the results in favour of the treatment of interest over the control intervention.

Definitions

Proband (propositus): index case – the original individual under consideration in relation to a stated characteristic, such as his disease.

Morbid risk: lifetime expectancy or lifetime incidence of a disorder – proportion of people who would develop a disorder if followed through entire period of risk; one way of expressing rate of an illness; in order to allow for high risk ages it may be necessary to correct for actual age. Perälä et al (2007: DSM-IV, Finland) estimated the lifetime prevalence of all psychotic disorders to be 3.06% (using register data this rose to 3.48%) and for schizophrenia, 0.87%; schizoaffective disorder, 0.32%; schizophreniform disorder, 0.07%; delusional disorder, 0.18%; bipolar I disorder, 0.24%; psychotic major depression, 0.35%; substance-induced psychosis, 0.42%; and psychosis secondary to a general medical condition, 0.21%.

Stability: the variability of scores when a test is repeated on the same individual; little variation indicates high reliability; tests may possess equivalent forms to counter memorisation in test-retest situations (see split-half reliability).

Standardisation: availability of normative data, such as IQ scores in a suitable population, for the index test, such as IQ, to allow comparison with future test results.

Bottom drawer phenomenon: negative findings less likely to be published, which may bias literature toward positive results. See Cuijpers et al (2010) for publication bias in research on CBT and adult depression.

Response set: a source of error resulting from excessive responses to propositions.

Bias towards the middle: a responder's tendency to rate his responses in a way that avoids excesses.

Hawthorne effect: tendency for patients to fare better in research study than in clinical practice; may be related to selection criteria or increased personal attention. The term was coined in 1955 by Henry A Landsberger who examining earlier research work performed at the Hawthorne (electricity) Works near Chicago: almost any intervention increased workers' productivity by virtue of the attention offered by researchers.

Halo effect: the observer tends to answer in a way that conforms with his initial impressions; if a student has handed up a poorly written exam paper the assessor may fail to detect any good in its content.

Proximity: if two items are placed closely together in a scale the rating given to one may psychologically affect the rating given to the one beside it.

Defensiveness: answers are given in such a way that certain information is not revealed.

Von Domarus error: considering 2 different things as equal because of a single shared property.

Effort after meaning: people with a disorder remember events imagined to be causative rather than giving an objective account of all pertinent details.

*Yerkes-Dodson Law*²⁶⁷: performance increases gradually with increasing arousal until peak performance is reached; as arousal increases further performance declines.

Social desirability: a further cause of error, leading to a reduction in accuracy at the expense of what is deemed to be acceptable.

Reactivity: degree to which behaviour changes as a result of being assessed; potential problem for naturalistic observation studies and self-recording techniques; difficult to overcome, even with unobtrusive measures.

Carry-over effect: drug continues to exert some effect after administration is discontinued; may contaminate results in a crossover trial.

Selected individual instruments, alphabetically listed

Beck Depression Inventory (BDI-II): from A Beck and colleagues; patient (13 years of age or older) chooses one of a number of severity statements from symptom and attitude categories that come nearest to recent experience; does not say why patient is depressed. Both BDI and GHQ were developed as symptom inventories and not as diagnostic instruments. (Ennis et al, 1989) BDI and other self-report depression inventories can give misleadingly high picture of

²⁶⁷ This Law was published in 1908. During WWI, the American psychologist Robert Mearns Yerkes (1876-1956) and John D Dodson devised scales to measure IQ in order to weed out unsuitable recruits and to find suitable 'officer material'.

prevalence of depressive illness in distressed populations (e.g. self-harm admissions or those with chronic pain²⁶⁸) and include many with personality disorders. It has been suggested that the BDI could simply be replaced by an acknowledgement that 'my future seems dark to me'!

Brief Psychiatric Rating Scale (BPRS): short instrument devised by Overall and Gorham in the '60s; 18 symptom constructs, each rated on a 7-point severity scale; presents difficulties in sorting out different 'neurotic' disorders; mainly for psychiatric inpatients, especially psychoses and long-stay, i.e. severe illness; useful when determining effects of drugs on symptoms; symptom profile and a computer used to render a diagnosis. (see Leucht et al, 2005)

Cambridge Mental Disorders of the Elderly Examination (CAMDEX; Roth et al, 1986): standardised instrument for diagnosis of mental disorder in elderly, especially early detection of dementia. Three main sections: structured clinical interview with patient; range of objective cognitive tests; and structured interview with informant. Acceptable to patients; has a high inter-rater reliability; and cognitive section has high sensitivity and specificity. CAMCOG is the computerised version of the CAMDEX.

Clinical Interview Schedule (CIS; Goldberg et al, 1970): partially structured psychiatric interview for community survey work on minor psychiatric problems and requiring training before use.

Combat Exposure Scale (Keane et al, 1989a): subjective, quantitative assessment of wartime stressors, from light (1) to heavy (5) exposure.

Composite International Diagnostic Interview²⁶⁹ (CIDI; Robins et al, 1989) is a standardised interview that can be used by trained lay people or by the patient. Questions have to be asked in a defined way. A computer gives ICD or DSM diagnoses. It may have exaggerated prevalence rates for some disorders.

Eating Attitudes Test (EAT; Garner & Garfinkel, 1979): shortened, 26-item version in use; evaluates behaviours and attitudes found in anorexia nervosa (AN); cut-off point is used to distinguish AN from normal controls; has its limitations because classic eating disorders are uncommon which is said to greatly reduce its positive predictive value, i.e. the proportion of true cases divided by the number scoring positive on the test. (Williams et al, 1982) Using the EAT, Halpin & Fitzgerald (1992) found that 2.8% of Dublin adolescent males scored above the cut-off point, whereas between 6.8% of London schoolgirls score positively and 13% of Dublin schoolgirls score highly.

Edinburgh Postnatal Depression Scale (EPDS; Cox et al, 1987): not for use with 'blues', puerperal psychosis, anxiety disorder, phobias or personality disorder. Useful in primary care. Ten self-report statements looking at how woman felt in the past 7 days, not just today. While it has a cut-off point, the authors suggest an accompanying clinical assessment. Can be repeated after 2 weeks in borderline cases. Underline answer that is closest to how she feels, e.g. 'I have felt sad or miserable': Yes, most of the time; Yes, quite often; Only occasionally; No, never.

General Health Questionnaire (GHQ; Goldberg, 1972): long (60 items) and short (30, 28, 20 and 12 items) versions; self-administered; looks for recent changes, i.e. symptoms; a screening test for non-psychotic illness to be used in community, primary care, (Crossley et al, 1992) or general medical outpatient setting; does not give a diagnosis. In one 3-city British study, (Platt et al, 1991) housing conditions most powerfully predicted GHQ caseness – psychological disturbance was associated with a woman having inadequate housing, having a low income or being personally unemployed, having no co-resident with a job, and bringing up children without a partner's support. A scaled version exists with symptom subscales for somatic symptoms, anxiety and insomnia, depression, and social dysfunction. (Goldberg & Hillier, 1979)

Geriatric Depression Scale (GDS; Brink et al, 1982; Brink, 1984; Yesavage et al, 1983): self-rating; can be read to elderly or answered in writing; minimises purely somatic symptoms (very common in this age group, e.g. constipation) emphasised in the Zung and Hamilton scales; not accurate in the presence of significant dementia; simple yes/no answers; 30 questions; 1 point for each depressive answer; final score: 0-10 normal; 11-20 mildly depressed; 21-30 moderate to severe depression. There are also shorter versions of the GDS: 4, 5, 10, and 12-item versions.

Geriatric Mental State Schedule (GMSS; Copeland et al, 1976): a research instrument taking three quarters of an hour to administer; used to assess psychopathology; AGE-CAT, a computerised algorithm, provides diagnoses.

Glasgow Coma Scale (GCS; Teasdale & Jennett, 1974): assesses initial severity of the event (head injury); measures 3 clinical features, i.e. eye movement (from spontaneous eye opening to never opening), best motor responses (from obeys command via decerebrate state to no response), best verbal response (from orientated to silence); coma is present with a score of less than 8. Minimum score = 3, maximum score = 15 (there is no zero score):-

Eye opening: spontaneous (4), to speech (3), to pain (2), none (1).

Best motor response: obeys commands (6), moves within general locality (5), withdraws (4), abnormal bending & flexing of muscles (3), involuntary straightening and extending of muscles (2), none (1).

Verbal response: orientated (5), confused in conversation (4), use of inappropriate words (3), incomprehensible (2), none (1).

A paralysed and intubated ICU patient can score 3 despite full consciousness!

²⁶⁸ Longson (2007, p. 97) criticised the BDI because inclusion of somatic symptoms over diagnoses depression in physically ill patients.

²⁶⁹ Developed from Robins' earlier *Diagnostic Interview Schedule* (DIS).

Hachinski ischaemic score (HIC: Hachinski, ea, 1975): the higher the score the more likely dementia is due to cerebrovascular disease: abrupt onset (score 2), stepwise deterioration (1), fluctuating course (2), nocturnal confusion (1), relative preservation of personality (1), depression (1), somatic complaints (1), emotional incontinence (1), history of hypertension (1) or strokes (2), evidence of associated atherosclerosis (1), focal neurological symptoms (2) or signs (2) - not very accurate but helpful - score < 4: probable Alzheimer's disease; 4-7: probable mixed Alzheimer's and multi-infarct dementia (MID); > 7: probable MID. The HIC was derived from patients who were relatively young and mildly impaired.

Hamilton Rating Scale (HRS) for Depression (HAM-D or HRSD or HDRS; Hamilton, 1960): standard for other scales (e.g. Carroll's); measures depression but does not diagnose it; used in drug trials; useful during ordinary interviews; not a good test to repeat on the same individual; more sensitive to physical than existential symptoms; may not distinguish clearly between symptom frequency and intensity. (Kugler, 1992) Has a number of items such as anxiety, psychic and somatic (nos. 10, 11), and insomnia (4,5,6) that respond to sedation. (see O'Shea, 1989)

Hamilton Anxiety Scale: same author (Max Hamilton) as HAM-D; picks up both somatic and psychic components of anxiety; includes some depressive symptoms; measures severity of anxiety syndrome rather than of the symptom of anxiety. (contrast with CAS above)

Hopkins Symptom Checklist (HSCL; Derogatis ea, 1974) self-report inventory of current psychiatric symptoms, e.g. somatisation, obsessive-compulsive behaviour, interpersonal sensitivity, depression and anxiety. *Inpatient*

Hopelessness Scale (HS; Beck ea, 1974): self-rating scale; 20 statements of thoughts or feelings about the future that subject rates as true/false. Hopelessness found to be a better discriminator than depression (on BDI) in distinguishing between unemployed, who had scored high on HS, and employed male parasuicides in Edinburgh. (Platt and Dyer, 1987) Aish and Wasserman (2001) wondered if the whole could be replaced simply with 'my future seems dark to me'!

Hospital Anxiety and Depression Scale (HAD; Zigmond & Snaith, 1983): used to detect states of anxiety (A) and depression (D) in hospital medical out-patient departments and in primary care; brief; limited to the 2 most common aspects of mood disorder presenting in hospital practice; has 14 items, 7 for anxiety and 7 for depression. Items representing symptoms of severe mood disorder (e.g. suicidal feelings) or bodily symptoms likely to be found in physical illness have been excluded. Scores of 11 or over on either scale suggest the presence of the relevant disorder and a total score of at least 18 means that the patient is likely to be distressed. Reliably used in primary care settings, e.g. in its Arabic version, (EL-Rufaie & Absood, 1987) and in non-psychiatric inpatient units. (Abiodun, 1994) Barczak ea (1988) used it and found a 31% prevalence of DSM-III psychiatric disorder in a genito-urinary clinic population. Chaturvedi (1991) found total HAD scores to be more clinically meaningful than subscale (A and D) scores.

Mini-Mental State Examination: quantitative test of cognitive functioning. This is covered elsewhere.

Minnesota Multiphasic Personality Inventory²⁷⁰ (MMPI; Hathaway & McKinley, 1943): contained 550 statements grouped into 9 scales (e.g. 'paranoid' scale); results plotted to produce personality profile; not to be used for normal personalities; validated on psychiatric patients; contains a 'lie' scale (assessment of test-taking attitudes)²⁷¹. The current scale (MMPI-2, 1989) contains 567 items with a forced choice yes/no format. The relevance of the MMPI to current psychiatric disorders is complicated by differing underlying theoretical constructs, and the profile may not tally with clinical insights. (Yates ea, 1998) A high score on a given scale does not necessarily mean that the respondent has that psychiatric disorder. (Kaslow & Farber, 1998) The *MMPI-A* is for adolescents (13 years of age onwards) and includes items relating to matters such as family and school difficulties and obsessiveness.

Montgomery-Asberg Depression Rating Scale (MADRS): based on 10 items of the *Comprehensive*

Psychopathological Rating Scale (CPRS) of Asberg ea (1978) - sadness, inner tension, inability to feel, pessimistic thoughts, lassitude, concentration difficulties, reduced appetite, reduced sleep, suicidal thoughts, and apparent sadness on observation - measures psychic but not somatic symptoms; may be more sensitive than HAM-D. (Montgomery & Asberg, 1979).

National Adult Reading Test (NART; Nelson, 1982): a reliable measure of premorbid IQ and educational level, including among patients with schizophrenia; (Crawford ea, 1992; Morrison ea, 2000) 50 short, irregular words to be pronounced, such as 'gauche', i.e. words that do not follow normal pronunciation rules; depends more on prior knowledge of pronunciation²⁷² than current cognitive capacity. An alternative to the NART is the *Wechsler Test of Adult Reading* (WTAR). (The Psychological Corporation, 2001) Both these tests have ceiling effects. The effects of culture and education must be taken into account. Dyslexia may reduce the usefulness of NART and WTAR results.

Neuroticism, Extroversion, and Openness Personality Inventory (NEO-PI; Wiggins & Pincus, 1992) measures 5 central facets of personality. The revised version (NEO-PI-R; Costa & McCrae, 1992) measures the following 5 facets

²⁷⁰ J Chamley McKinley, a psychiatrist, and Starke R Hathaway, a psychologist, compared the responses of patients with those of visitors to university hospitals in Minneapolis. Many years passed before the test was accepted for publication.

²⁷¹ Extremely high scores on this scale were obtained by the present author in Munchausen patients. The **MMPI validity scales** are the **L** (Lie - unsophisticated attempt to deny problems), **F** (Infrequency - excess endorsement of uncommon symptoms in order to appear ill), **K** (Correction - subtle attempts to deny problems), **VRIN** (Variable response inventory - inconsistent answering of similar items), **TRIN** (True response inventory - answering contradictory items as if they were similar), and **F_B** (F back - to test for inaccurate responding as the patient reaches the later items in the MMPI) scales.

²⁷² Relatively resistant to intellectual decline.

of personality: neuroticism, extraversion, openness, agreeableness, and conscientiousness; each facet includes 6 subscales, e.g. 'neuroticism' includes anxiety, anger/hostility, depression, self-consciousness, impulsiveness, and vulnerability.

Nurses' Observation Scale for In-patient Evaluation (NOSIE; Honigfeld & Klett, 1965): originally consisted of 80 items of ward behaviour completed by a pair of nurses using a 0-4 frequency of occurrence format for each item; later refined to a 30 item (NOSIE-30) scale; sensitive to effects of treatment over time; economical and accurate means of systematically assessing patient status and change (Honigfeld, ea, 1966); used with chronic schizophrenia patients.

Present State Examination²⁷³ (PSE): covers symptoms of previous 4 weeks; use probe questions before asking for details; 140 items; groups of items are rated to produce 'syndromes', e.g. situational anxiety; latter are then processed by a computer programme, *CATEGO*, to yield a standard diagnosis; psychiatrists need training before using PSE; poor for some areas, especially organic disorders, alcoholism, personality disorder, and intellectual disability; less reliable for anxiety than for depression; used in international comparisons and in local research, including medication effects in schizophrenia; high inter-rater reliability, with the exception of assessments of behaviour. A screening version is available. The *PSE Index of Definition* (ID; Wing ea, 1978) uses data from either the full or a 40-item version (there is also a 10-item version) of the PSE to give a score of 1 to 8 on the likelihood of having a psychiatric illness, when 5 or more means a 'probable' case; used to identify 'caseness' (having a disorder) in epidemiology. Expanded version of PSE (SCAN) covers episode-specific (current or representative) as well as lifetime diagnosis²⁷⁴.

Scale for Assessment of Negative Symptoms (SANS) and Scale for Assessment of Positive Symptoms (SAPS). Developed by Nancy C Andreasen, Iowa. SANS: comprehensive assessment of negative symptoms in schizophrenia (Andreasen, 1982, 1983, 1989); 5 scales evaluating 5 different aspect of negative symptoms: alogia, affective flattening, avolition - apathy, anhedonia-asociality, and attentional impairment; each symptom can be rated globally; also, detailed observations are made to achieve global rating. SAPS: complements SANS (Andreasen, 1984); allows detailed evaluation and global ratings of hallucinations, delusions, positive formal thought disorder, and bizarre behaviour. SANS and SAPS together provide comprehensive set of rating scales measuring schizophrenic symptoms and assesses change over time. Affective flattening includes unchanging facial expression, decreased spontaneous movements, paucity of expressive gestures, poor eye contact, affective non-responsivity, lack of vocal inflections, and a global score. Alogia includes poverty of speech, poverty of content of speech, blocking, increased latency of response, and a global score. Avolition - apathy involves grooming and hygiene, impersistence at work on school, physical anergia, and a global rating. Anhedonia-Asociality includes recreational interests and activities, sexual interest and activity, ability to feel intimacy and closeness, relationships with friends and peers, and a global score. Attention, apart from a global rating, involves social inattentiveness and inattentiveness during mental status testing. Peralta ea (1992) performed a factor analysis using both the SANS and SAPS and were unable to divide up schizophrenia in this way: the positive-negative dichotomy appeared to be an oversimplification, and the SAPS have low internal consistency.

Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978): structured interview using Research Diagnostic Criteria (RDC); symptoms assessed on 7-point scale; score of 3 or more is clinically significant; each symptom and rating criterion is defined; each symptom separately assessed for maximum severity for current episode and for past week; also assesses past episodes; chiefly for inpatients; not useful for organic disorders or anorexia nervosa, but purports to be useful in making most diagnoses using RDC; 3 versions are SADS, SADS-L or lifetime version which might be used for someone currently well, and SADS-C or change version that can be used for looking at changes in clinical state.

Suicide Intent Scales: Beck ea (1974) used such a scale in the early '70s that consisted of a series of scored questions dealing with circumstances surrounding a suicidal act and self-report of mental state at the time of the act. By adding 2 items dealing with the medical risk of the act and by changing some other components, an Intent Score (IS) Scale was formed. Circumstances score was high in men, older patients and physically ill patients, while self-report scores were high in patients with a past history of psychiatric therapy or previous attempted suicide. Pierce (1981) found that, in a 5-year follow-up, future suicides tended to have high scores on a scale for their original self-injury episodes and had very high scores for the penultimate self-injury before suicide. The fact that suicides had made an average of nearly 3 non-fatal attempts emphasises the importance of repetition along with high intent in predicting at least some suicides. Harriss ea (2005) found that suicide intent scores appeared to have most value in assessing short-term suicide risk.

Tower of London Test²⁷⁵: the test involves moving coloured beads on three upright poles in order to produce a pattern determined by the examiner; the subject must be able to plan moves (break down the task into parts and follow a sequence of moves); worst results are found with left frontal lobe damage; not surprisingly, patients with schizophrenia also perform poorly here.

²⁷³ Associated with John Wing.

²⁷⁴ **Schedule for Clinical Assessment in Neuropsychiatry** (SCAN; Wing ea, 1990) is a semi-structured interview employed by professionals and used with adults. Included are PSE-10, a glossary of symptom definitions, direct rating of symptoms with Item Group Checklist, and ICD-10 and DSM-IV diagnoses via Clinical History Schedule. The diagnosis is made by a computer.

²⁷⁵ This was derived from a puzzle known as the Tower of Hanoi.

Wechsler Adult Intelligence Scale (WAIS-III, ages 16-84): most commonly used IQ²⁷⁶ test (Wechsler, 1997); useful in confirming clinical impression of organic mental deterioration - latter depends on fact that verbal abilities are more resistant to impairment than performance; if there is more than 20-point difference between performance and verbal scores organic impairment is likely (a lesser discrepancy should be treated with caution: Rao & Swanson, 2003, p. 31); WAIS has 12 subtests (6 measure verbal ability [information²⁷⁷, comprehension²⁷⁸, arithmetic²⁷⁹, similarities²⁸⁰, digit span²⁸¹, vocabulary²⁸² - a seventh, optional subtest is called letter-number sequencing²⁸³] and 6 are performance tests [digit symbol²⁸⁴, picture completion²⁸⁵, block design²⁸⁶, picture arrangement²⁸⁷, matrix reasoning²⁸⁸, symbol search²⁸⁹]); standardisation for age and further calculation yield verbal, performance, and full-scale IQs²⁹⁰. Selective impairment of cognitive function may lead to abnormal scattering of scores on the WAIS. In organic cerebral disease those tests reliant on memorisation of recent events and on perceptual motor control will exhibit greater deterioration in scores than tests that depend on vocabulary and general knowledge. Grey areas in clinical certainty usually correspond with shortcomings in psychological reporting. No instrument supplants a comprehensive mental state examination²⁹¹. The *Wechsler Abbreviated Scale of Intelligence* (WASI) was introduced in 1999. The **Wechsler Memory Scale-III (WMS-III)**²⁹² gives a memory quotient (MQ) that allows for age - various aspects of memory are tested, e.g. recall of stories related by the examiner²⁹³; in brain trauma IQ and MQ correspond fairly closely to each other; in dementia the MQ will score inferior to the IQ; when the WAIS Verbal IQ score is greater than the Performance IQ score a lesion of the right side of the cerebrum is probable but it could be bilateral; the opposite situation favours a left-sided lesion. The dominant hemisphere is the left hemisphere in most people, including left-handed (sinistral = left-handed, dextral = right-handed). The *Bender-Gestalt Test for Geometric Designs* and the *Graham-Kendall Memory for Designs* are other useful procedures; the latter, as with the Bender, measures visuo-motor control and it also examines immediate visual memory. The *Halstead Category Test* that addresses conceptual thinking detects damage to the frontal lobes. The *Rey-Osterrieth Test* looks for dysfunction of the dominant frontal and temporal areas. The **Wisconsin Card Sorting Test** (WCST; Berg, 1948) also detects frontal lobe damage. In the WCST, the participant has to sort cards into 4 heaps according to a sorting rule deduced from feedback supplied after each trial; once the rule is deduced, it is changed arbitrarily without any warning and the new sorting rule has to be deduced. Feinberg (1997) disagrees with using the WCST in patients with schizophrenia saying that they score badly because of poor motivation and attention and difficulties with trusting others. Indeed, a meta-analysis²⁹⁴ (Laws, 1999) suggests that really what is being picked up is only part of a general intellectual dysfunction. The *Token Test* is used to detect receptive language disturbance. Parallel versions of tests may allow serial testing, e.g. the use of the Benton Visual Retention Test (patient studies and tries to reproduce 10 designs) to investigate perceptual function. Batteries of tests are useful when assessing dementia, e.g. the *Kendrick Battery* and the *Clifton Assessment Procedures for the Elderly* (CAPE). *Raven's Progressive Matrices*, an assessment of non-verbal visuospatial abilities, attempts to tap 'observation and clear thinking' and employs a set of matrix tests of different age groups, including adults; you are asked to select a pattern piece that is missing from the matrix; the raw score is expanded as a percentile; even poorly educated people can score well; correlates fairly well with IQ scores; may be superior to WAIS for very high intelligence levels. The *Mill Hill Vocabulary Scale*, an

²⁷⁶ Gale et al (2007) suggest that bright children often turn out to be adult vegetarians!

²⁷⁷ Wide variety of information in order of difficulty (N = 19).

²⁷⁸ Meaning of proverbs, next step in defined circumstances, etc (N = 16).

²⁷⁹ Arithmetical problems set in everyday activities (N = 14). *The only timed verbal subtest.*

²⁸⁰ In what way are 2 things alike (N = 14)?

²⁸¹ 3-9 digits repeated forwards and 2-8 backwards. This is a good test of working memory.

²⁸² Patient must give meaning of 35 words of different degrees of difficulty.

²⁸³ The patient must extract separate sequences of letters and numbers from a mixture of both.

²⁸⁴ Quickly follow a code in order to match symbols and digits.

²⁸⁵ Quickly follow a code in order to match symbols and digits.

²⁸⁶ Timed test: 20 pictures (e.g. faces) are presented with a missing part, but which part is missing?

²⁸⁷ Timed test: The patient must reproduce designs using red and white blocks.

²⁸⁸ Cartoon pictures (10 sets) must be arranged sensibly into a story.

²⁸⁹ This is thought of as a non-verbal measure of ('fluid') IQ. Patient must choose the next in a sequence of abstract coloured symbols. This is derived from *Raven's Progressive Matrices* (Q.V.) and replaces 'object assembly' subtest of WAIS-R. *The only non-timed performance subtest.*

²⁹⁰ The patient looks for either of 2 symbols in a sequence.

²⁹¹ All 3 IQ scores have a mean of 100 and SD (standard deviation) of 15: a difference of 15 points between verbal and performance IQs is statistically significant and carries clinical implications. Each of the WAIS subtests have a mean score of 10 and an SD of 3.

²⁹² Some brain-injured subjects can score within the normal range on the WAIS despite being unable to work because of (frontal) apathy, memory problems and are slow at processing information. (Carson et al, 2007, p. 337) An attempt to correlate cognitive tests with white matter lesion density in the elderly revealed that the association was significantly influenced by IQ at age 11. Therefore, what appears to be due to change due to age may actually stem from inherent ability. (Deary et al, 2006)

²⁹³ The WMS-IV is being developed currently.

²⁹⁴ Information, logical memory, faces, verbal paired associates, letter-number sequencing, and spatial span are non-optional components in WMS-III, whereas word lists, visual reproduction, mental control, and digit span are optional.

²⁹⁵ Looking at WCST and, as an index of general intellect, the WAIS.

intelligence test, measures verbal ability. Useful sources of information on this subject are Mittler(1973) and Lishman(1978).

Wechsler Intelligence Scale for Children (WISC-IV): for children aged 7-16 years; verbal and non-verbal abilities tested; the WISC-R-UK and WISC-R-S versions use norms from UK and Scotland respectively.

Wechsler Preschool and Primary Scale of Intelligence (WPPSI): for children aged 3-7 years; the WPPSI-R-UK uses UK norms.

Yale-Brown Obsessive-Compulsive Scale (Y-BOCS; Goodman ea, 1989): specific measure of symptom severity in OCD (during preceding week) uninfluenced by type of obsession or compulsion; 10-item, 40-point semistructured instrument, each item rated by clinician from 0 (no symptom) to 4 (extreme symptom), with a total range of 0-40; separate totals for obsessions and compulsions. A childhood version is available.

Zung Self-Rating Depression Scale: devised by W Zung, 1960s; patient asked to quantitate 20 sentences; poorly correlated with observer ratings; insensitive to change with treatment; fallen into disfavour.(Lee, 1998) The *Zung Observer-Rated Depression Status Inventory* followed nine years later.

Electroencephalogram, neuroimaging²⁹⁵ and sleep Brian O'Shea

'...the hallucination/Broca's area claim is trapped in an unresolvable ambiguity for there is no way of telling whether the subject reports an auditory image or the belief that he is having one'. (Berrios & Marková, 2002)
'The neuroanatomical maps ...used to localize activation may not be identical throughout the literature. Despite anatomical proximity, these areas may have very different connectivity patterns'. (Ebmeier & Kronhaus, 2002)

According to Freud, dreaming employs primary process thinking and may represent discharge instinctual drives repressed by day. The 'non-dreaming' part of the sleep cycle²⁹⁶ may be involved in body tissue restoration. Sleep seems important for memory consolidation and immunity. The dreaming component may entail brain tissue restoration, non-specific casting off of excess neuronal load, or intrusion of events from the previous day (*day residue*) to influence dream content. Young obese people were found to have relatively little REM sleep in one study. (Liu et al, 2008)

Pooled data on over 1.3 million subjects around the world (Cappuccio et al, 2010) suggests that sleeping less than 6 hours/night is associated with a 12% increased chance of premature death compared to sleeping 6 to 8 hours. Excess sleep (> 8 hours/night) is associated with a 30% greater risk of death.

The ascending reticular activating system (RAS²⁹⁷), extending upwards from medulla to thalamus, exerts tonic control on arousal and consciousness.

Brain components of arousal vs sleep promotion

Arousal

Ascending RAS – main arousing system: two main branches are:

1. Thalamo-cortical arousal branch – contains cholinergic neurones from laterodorsal tegmental pedunculopontine tegmental nuclei → thalamus → cortex
2. Hypothalamic-aminergic arousal branch – serotonergic (dorsal raphe), noradrenergic (locus coeruleus) and histaminic (tubero-mammillary) → lateral hypothalamus → basal forebrain

Sleep promotion

Ventrolateral preoptic area (VLPO – 'sleep centre') of anterior hypothalamus – inhibits both branches of ascending RAS – GABA and galanin are main neurotransmitters

REM-non-REM sleep switching

REM-active neurones of extended VLPO

Wake-sleep switching

Lateral hypothalamus peptides orexins A & B (aka hypocretins 1 & 2)

Tubero-mammillary nuclei

VLPO

Suprachiasmatic nucleus²⁹⁸

²⁹⁵ Walter Edward Dandy (1886-1946), neurosurgeon at Johns Hopkins, described the injection of air (as contrast medium) into perispinal space (and thence into the ventricles: air encephalography/ventriculography) in 1918/19.

²⁹⁶ Dreams do occur in this phase, albeit with poorly formed, non-narrative imagery.

²⁹⁷ The RAS includes the brainstem reticular formation (ventral medulla, central pons, and midbrain), posterior hypothalamus, subthalamus, nucleus basalis of Meynert, septal nuclei, diagonal band, and certain thalamic nuclei (ventromedial, intralaminar, and midline). There are two RAS pathways: dorsal (forebrain to thalamus to forebrain cortex) and extra-thalamic (subthalamus, posterior hypothalamus and basal forebrain project straight to whole of cortex).

²⁹⁸ The SCN can function autonomously (without external zeitgebers – free running state) but it can be entrained by zeitgebers (entrained state).

Stimulation of the RAS causes EEG desynchronisation and behavioural arousal. Lesioning of the RAS leads to permanent sleep, although destruction of parts of it, such as the median raphe, causes permanent insomnia. Basal forebrain cholinergic magnocellular neurones project throughout the cortex and appear to play an important part in the maintenance of cortical arousal.

Sleep and chronobiology³⁰⁰

There are two main theories of sleep³⁰¹ energy conservation and energy restoration. As sleep progresses the episodes of non-REM (or n-REM) sleep shorten while those of REM lengthen. The metabolic rate decreases at night, and especially during sleep, by 5-25%. Animals seldom attacked, such as horses, sleep much longer than those in constant danger, like bats. When much growth is required³⁰² slow wave sleep and the overall amount of sleep are increased. When less sleep is needed, as in hypothyroidism, the amount of slow wave sleep is diminished. ATP (adenosine triphosphate) derived from cells is consumed during periods of protein degradation; cell mitosis increases during sleep and ATP concentrations increase in association with protein synthesis.

Deficiency of melatonin³⁰³, which is produced from serotonin by the pineal gland at night and has a role in sleep-wake cycle regulation, or disruption of its rhythms has been suggested as explaining the increased prevalence of sleep disorders with advancing age. Melatonin does not induce sleep in nocturnal rodents. During winter, melatonin indirectly affects the gonads to reduce reproduction potential, a fact that is of particular relevance in season-breeding reptiles, amphibians, and birds. (Tamarkin et al., 1985) Haimov et al. (1994) hypothesise that a lack of exposure to bright light in institutions may deplete 6-sulphatoxymelatonin (6-SMT, major urinary measure of melatonin) excretion in old age. Garfinkel et al. (1995), looking at elderly insomniacs, found reduced or delayed peak nocturnal 6-SMT excretion; 2 mgs. controlled-release melatonin corrected the insomnia. According to Famuyiwa and Adewuya (2008) the effectiveness of melatonin in getting children with neurodevelopmental disorders to sleep is questionable and it has a potential for causing adverse effects; sleep hygiene measures should take precedence in such cases. Anonymous (2009) states that the evidence for the use of melatonin for primary insomnia is limited. Melatonin may stabilise sleep onset time in some blind subjects. (Arendt et al., 1995) In sighted humans melatonin is excreted early in the sleep cycle whereas blind people³⁰⁴ have irregular 24-hour rhythm and

²⁹⁹ The putative *flip-flop switch* consists of mutually inhibitory REM-off and REM-on GABA-ergic mesopontine tegmental areas. The REM-on area has two groups of glutamatergic neurones – one projects to basal forebrain to regulate EEG in REM and the other travels to medulla and spinal cord to regulate REM atonia.

³⁰⁰ Foster and Kreitzman (2004) and Mendlewicz (2008) provide readable introductions to this topic. See also complete issue of *Dialogues in Clinical Neuroscience* 2007; 9(3).

³⁰¹ Which fail to comprehensively explain all that is known about sleep. The *homeostatic model* emphasises need for sleep (stronger with time awake – adenosine, an inhibitory neurotransmitter, plays a role here) while the *circadian model* states that sleep propensity has a circadian (24 hour) pattern for sleepiness and attention. Depending on clock time, circadian issues can attenuate or promote homeostatic drive.

³⁰² Pregnancy, exercise, sleep loss, hyperthyroidism, adolescence, refeeding in anorexia nervosa, etc.

³⁰³ 5-O-methyl-N-acetylserotonin. Drugs capable of changing the *circadian clock*, such as in rodents, are known as chronobiotics. The suprachiasmatic nucleus (SCN) contains highly expressed melatonergic receptors. There seems to be a two-way feedback between melatonin and the SCN. Synthesis and timing of melatonin production depends on afferent signals from the SCN; the SCN projects to the pineal gland via the paraventricular nucleus and the latter projects to the spinal cord; ascending cord fibres synapse in the superior cervical ganglion which projects in turn to the pineal gland (such connections are disrupted in *tetraplegia* [upper cord lesion] and thus rhythmic melatonin production is not possible). Daily injections of melatonin can entrain the activity cycle of rodents kept in perpetual darkness. The antidepressant agomelatine is agonist at melatonin MT1 and MT2 receptors and antagonist at 5-HT2C receptors. Given to depressed patients, agomelatine restores sleep pattern by redistributing slow wave sleep in the first nocturnal cycles but it does not suppress REM sleep.

Fruit flies were important in discovering how circadian clocks (transcriptional regulatory loop wherein each calculates its 24-hour period via an oscillating cycle of transcription and translation), with a similar mechanism throughout much of biology, work. *Drosophila* containing long- and short-day and arrhythmic mutants was used to lead to similar discoveries in other living creatures. A majority of the various implicated genes (e.g. *period*) are found in flies and *Homo sapiens*.

³⁰⁴ Hypneryctohemeral (or non-24-hour-day or free-running) **syndrome resembles normals in time-free environment (non-24 hour circadian rhythm that is not entrained to astronomical time) and occurs in blind people or socially isolated (a similar problem is reported in schizophrenia); sleep-wake cycle delayed by 45 minutes later each day;**

melatonin excretion patterns. Melatonin levels and rhythms have been reported to be normal in both unipolar depression³⁰⁵ and seasonal affective disorder. (Ferrier & Scott, 1998) However, one study (Wehr et al, 2001) found that the duration of the nocturnal period of active secretion of melatonin was longer in winter than in summer in affective disorder patients but no such changes were found in healthy controls. Excess nocturnal melatonin secretion, possibly related to nocturnal hypoglycaemia, has been reported in untreated females with anorexia nervosa. (Arendt et al, 1992) One meta-analysis (Buscemi et al, 2006) found no evidence that melatonin is effective for sleep restriction (incl. jet lag and shiftwork disorder) or secondary sleep disorders.

A higher brain stem level lesion at the mid-collicular level (A: *cerveau isolé*) is associated with EEG and pupil responses characteristic of permanent sleep; a lesion just above the entry of the fifth cranial nerve (B: *mid-pontine preparation*) leaves the brain permanently awake; and a lesion cutting the brain stem off from the cord (C: *encephalé isolé*) prevents sensory inputs from the cord reaching the brain and is associated with a normal sleep-waking cycle. Therefore, between B and C, there may be a lower brain stem sleep-promoting area, and, between A and B, there may also be a rostral arousal area. There is animal experimental evidence for these suggestions. (Steptoe, 1992) Stimulation of the anterior (ventrolateral preoptic nucleus) and posterior (tuberomammillary nucleus) hypothalamus may induce sleep and wakefulness respectively, illustrating an important cortical role in the sleep-wakefulness cycle. Hence, both brain stem and cortex have important, integrated roles. More recently, it has been determined that a small group of neurones in the posterolateral hypothalamus secrete the neuroexcitatory peptides hypocretin 1 and hypocretin 2 (orexins A and B).³⁰⁶ These neurones project widely throughout the brain, including areas associated with arousal, such as the locus coeruleus, the raphe nuclei, and the thalamus. The arousal produced by hypocretin 1 may occur via activation of histamine-1 receptors. Lesion studies in the rat suggests that cholinergic input from the nucleus basalis in the forebrain is important for suppressing slow wave activity during wakefulness. (Buzsáki et al, 1988)

It has been suggested that REM rebound during drug withdrawal is really subclinical delirium tremens (DTs). Prior to the DTs, the sleep EEG record is almost entirely occupied with REM, suggesting that REM spill over constitutes the DTs. (Scheepers, 1997) The EEG shows *increased frequency* during DTs, hyperthermia and PCP poisoning (*hyperactive deliria*) and reduced frequency in all other deliria. (Mulligan & Fairweather, 1997) While the EEG in most deliria shows diffuse slowing, it can, in practice, be normal or fast with alcohol withdrawal delirium. (Bernstein, 2000)

Sleep may have an immune function, e.g. sleep onset is associated with secretion of interleukins 1 (α and β) and 2. (Tattersall et al, 1998) Interleukins (IL) 6, 15 and 18, nerve and other growth factors, brain-derived neurotrophic factor (BDNF), neurotrophins 3 and 4, tumour necrosis factor, interferons α and γ , tumour necrosis factors α and β , oleamide, prostaglandin D2, nitric oxide, nuclear factor kappa B also promote sleep. Sleep is inhibited by interleukins 4, 10 and 13, prostaglandin E2 and a number of other substances. Rats deprived of sleep for two weeks or more die, probably of infection, although short-term sleep loss may sometimes enhance host defences. (Majde & Krueger, 2002)

Chronobiology is the study of the regular biological rhythms of living organisms. Almost all biological functions have some rhythm and the length of the rhythm varies, e.g. daily (circadian). Examples of rhythms include the sleep-wake cycle, hormonal levels, body temperature, and the menstrual cycle. Rhythms may be in or out of phase with each other. Also rhythms may be phase advanced (brought forward in time) or delayed (brought backward in time). Biological rhythms are set by internal and external zeitgebers (time clues). The main endogenous zeitgeber is the suprachiasmatic nucleus (SCN) of the hypothalamus³⁰⁷. Lesions of the mouse (and other animals) SCN lead to sleep fragmentation and lack of a

preservation of melanopsin (a pigment) receptors in specialised retinal ganglion cells which signal the clock in the hypothalamus (project from lateral geniculate body to suprachiasmatic nucleus [retino-hypothalamic tract]) independent of vision, may protect blind people against free-running, as may work and exercise routines; managed with regular routine, morning bright light (if sighted), nocturnal doses of melatonin (if blind), or perhaps B₁₂.

³⁰⁵ **Sleep-related changes in depression** (e.g. earlier REM onset and early morning awakening) suggest possible phase advance of internal circadian control system. (Lamont et al, 2007) Other reported changes are increased amount of REM, longer sleep latency, decreased total sleep time, diminished sleep efficiency, and a reduction in slow wave sleep.

³⁰⁶ Orexins are cleaved from preprohypocretin.

³⁰⁷ Paired structure above optic chiasma containing about ten thousand neurones. These are innervated by 5-HT neurones from midbrain raphe nuclei. The first circadian clock was discovered in mimosa plants that continue to open and close their leaves each day despite being deprived of sunlight: this discovery, in 1729, is attributed to Jean Jacques d'Ortois de Mairan (1678-1771), a French

daily sleep/waking rhythmicity. Examples of exogenous zeitgebers are the normal workday, set mealtimes, sunrise and sunset (The *photoperiod*, daily variations in intensity of light, is the chief zeitgeber for synchronizing circadian clocks.).

If a human is removed from all outside clues, his circadian³⁰⁸ rhythms lengthen to 24.5 hours³⁰⁹. Jet lag is important here: if one goes from E to W one experiences a phase delay which is less of a problem than the phase advance (shortening) associated with travelling from W to E. The latter represents the opposite of the natural tendency to lengthen the biological day. Biological rhythms are disrupted by shift work.³¹⁰

Depression is associated with early morning wakening (EMW³¹¹), reduced REM latency, and neuroendocrine abnormalities, all of which may be due to lack of co-ordination in biological rhythms.

Exposure to artificial light for seasonal affective disorder or changing the sleep-wake cycle (as in sleep deprivation) may ameliorate symptoms. Lithium, tricyclics, and MAOIs delay rhythms in animal studies.

Some depressives might have phase-advance disorders.(Robash & Hall, 1989)

*Clock genes*³¹², mainly found in the SCN, can maintain a circadian rhythm of transcription in constant darkness and can be entrained to a new light/dark cycle when exposure to light occurs. A cycle occurs of protein production which then inhibit transcription, degradation of these proteins, followed by further transcription. The SCN gets information from retinal photoreceptors via the (monosynaptic) retino-hypothalamic tract. It also gets photic and non-photoc information from the lateral geniculate nucleus, as well as non-photoc data from median raphe, ventral subiculum, and infra-limbic cortex. Anticipation of food delivery, arousing activity (running on a wheel), and deprivation of sleep are known *zeitgebers*³¹³ in rodents.(Sinton & McCarley, 2003, p. 371)

Hibernation, a state of internally controlled hypothermia, is not true sleep. Birds sleep, even on one leg.

Cows sleep with their eyes open (as can humans) and meanwhile continue to chew the cud. Different species normally sleep by night (humans) or by day (cats, rats).

While awake, we experience increased adrenaline and corticosteroid output³¹⁴, increased physical activity and relatively poor healing. During sleep there is increased output of testosterone and growth hormone³¹⁵.

Cholinergic activity is at its highest during REM sleep, and the aminergic cells (serotonin and noradrenaline) are at their least active during this time.(Craggs & Carr, 1992) In fact, acetylcholine can promote cortical activation that can accompany the waking state or REM sleep. It also reduces muscle tone via the brainstem. Whilst REM is eliminated by lesioning the cholinergic ponto-mesencephalic neurones

astronomer. The fact that these plants carry out these actions every 22 hours when in constant light was recorded in 1832 by Augustin Pyrame de Candolle (1778-1841), a Swiss botanist and physician.

³⁰⁸ L. *circa*, roughly; *dies*, day, i.e about a day long. Circadian rhythms have a **mean** (level at which the oscillation takes place), a **period** (time to complete a cycle), an **amplitude** (distance between mean and peak of cycle's oscillation), and an **acrophase** (time of the peak of the circadian rhythm's phase). **Masking** or **masking effect** refers to the influence of environmental factors (temperature and light intensity and duration, food, social activities, etc) and internal states (e.g. hunger, sleep, fatigue, movement, etc) on the shape of endogenous rhythms.

³⁰⁹ This period may be genetically determined. Researchers have bred hamsters with different innate circadian rhythms (20-25 hours) – if the suprachiasmatic nucleus is transplanted from one hamster to the other the recipient's rhythm changes to that of the donor.(Ralph ea, 1990)

³¹⁰ Beware the hours worked during internship! Shift workers appear to adapt less well than do people who traverse multiple time zones. Journeying home in daylight (which is much brighter than office lighting) interferes with adaptation.

³¹¹ **EMW** is also associated with mania, alcohol, caffeine, anorexia nervosa, and ankylosing spondylitis (pain).

³¹² E.g. *clock*, *timeless*, and *period (PER)* genes. Polymorphisms of *PER2* and *PER3* were discovered in familial advance sleep phase disorder and in delayed sleep phase disorder respectively. There have been conflicting reports of a *CLOCK* gene polymorphism in people who prefer evenings (owls).(see Lamont ea, 2007) Most cells contain circadian clocks and such clocks are set by endogenous signals. Such signals induce a second messenger cascade leading to altered concentration of clock gene products. The molecular clock then regulates the rhythmic expression of genes or other functions of cells, e.g. hormonal secretion or membrane electrical characteristics.(Roenneberg & Merrow, 2005) The intrinsic oscillations of cells are synchronised by the SCN. An important output target of the SCN (via the paraventricular nucleus) is the pineal gland (source of melatonin).

³¹³ Non-photoc synchronisers. The term 'social zeitgeber' has been used for social factors that entrain biological rhythms, e.g. occupational and interpersonal demands. *Zeitstörers* are events that disturb biological clocks. They include social, chemical, and physical events, e.g. the nocturnal demands of the newborn on its carer, long haul flights, erratic meals/sleep, rotational shift work, working late to meet deadlines, and daylight saving time changes to the clock. The social zeitgeber theory is still some distance from proven fact.(Grandin ea, 2006) In other words, for example, lack of sleep may be an early symptom of mania or may precipitate mania in someone with a genetically unstable suprachiasmatic nucleus as much, or more, as lack of sleep can cause mania.

³¹⁴ Cortisol plasma levels are highest at about 6 a.m. and lowest in late afternoon or evening.

³¹⁵ Growth hormone is released in pulses throughout the day, but pulses are more closely spaced during the first hours of sleep than at other times.

(but with little effect on waking), damage to the cholinergic neurones in the forebrain causes deficits in attention and activation of the cortex during the waking state. Locus coeruleus neurones discharge at their fastest rates during waking³¹⁶, at a slower rate during slow wave sleep, and are quiet during REM sleep; this is very similar to the effects of both histamine and serotonin. Serotonin (5-HT) promotes a quiet, relaxed but waking state that facilitates sleep; damage to the raphe nuclei may lead to complete insomnia with agitation. Dopamine mainly promotes wakefulness, but it is active during sleep during positive (awarding) emotional states. Glutamate is an excitatory neurotransmitter that seems critical for the waking state, and is the transmitter of the ascending reticular activating system.(Jones, 2002) Orexins A and B³¹⁷, from hypothalamic neurones, stimulates feeding and wakefulness.

Substances that promote or permit REM sleep include acetylcholine.³¹⁸ Interestingly, reserpine increases REM in depression, possibly because of a depression-related lack of monoamines. Vasoactive intestinal peptide is often cotransmitted with acetylcholine and also appears to promote REM. Gamma-aminobutyric acid (GABA) may contribute to muscle atony, as may glycine may also contribute to atony.³¹⁹ Noradrenaline, serotonin, and histamine neurones are turned off during REM. Dopamine possibly contributes to some aspects of dreaming: vivid dreams have accompanied hallucinatory states in people taking amphetamines³²⁰ or L-DOPA. Cholinesterase inhibitors can also cause vivid dreams. Glutamate may also be involved in REM sleep.

Slow wave sleep³²¹ (SWS) is promoted by GABA³²², growth hormone-releasing hormone, somatostatin³²³, adenosine³²⁴, and, acting via the tenth cranial nerve when released in association with alimentary activity, insulin, cholecystokinin and bombesin.

After a true epileptic seizure there is an increase in the serum prolactin, which does not occur following a pseudoseizure; there is also a rise in the serum cortisol but this is much less specific. Attacks of bronchial asthma commonly occur at night because of exaggerated bronchial constriction and may cause insomnia; the sole symptom may be a cough; some cases of insomnia are secondary to management with adrenergic agents; fatalities are most likely among those whose peak expiratory flow rate fall the furthest.(Williams ea, 1988; Catterall & Shapiro, 1993)

We live in a world of sleeping tablets. At 65 years of age 50% of females regularly take a sleeping pill.

Neurotransmitter control of REM sleep

Noradrenaline:	↓ REM + increased wakefulness
Acetylcholine:	↑ REM (? depressives supersensitive to ACh)
↓Serotonin (5-HT):	↓ REM (↓1-tryptophan: ↓ REM ³²⁵)

³¹⁶ Especially if something arouses the subject.

³¹⁷ Also called hypocretins 1 and 2 respectively. They are secreted during the day and suppress the ventrolateral preoptic area (VLPO).

³¹⁸ Eserine, which blocks acetylcholine breakdown, normally promotes waking, but it leads to REM if monoamine levels have first been depleted by reserpine. Reserpine depletes transmitters in storage vesicles by blocking transmitter uptake by magnesium-dependent ATPase-linked transport sites on vesicle membrane, so making transmitter available for catabolism.

³¹⁹ Locally applied strychnine reverses the atony of REM by blocking glycine.

³²⁰ Mice deprived of dopamine transporter (knockout) are insensitive to wake-promoting effects of amphetamine.(Staner, 2005)

³²¹ **Stages 3 and 4 of non-REM sleep**, also called delta sleep. The sleeper is pale and peaceful, heart and breathing are slow, and it is difficult to rouse him/her. Sudden waking during SWS is associated with transient confusion (**confusional arousal**) with simple, non-affect laden motor behaviour. Speech may be indistinct, behaviour automatic, and response to the environment is reduced. Memory for the event is very poor. There may be delta waves on the EEG. Confusional arousals may occur during daytime naps. *Sleep drunkenness* (inertia following on final awakening), *sexsomnia* (abnormal sexual behaviour), and *sleep-related violence* may be seen as variants of confusional arousals.

³²² Benzodiazepines act via GABA-A receptors to open chloride channels. Gamma-hydroxybutyric acid (GBH) acts on GABA-B receptors to open potassium channels and promotes SWS and REM.

³²³ And the related peptide cortistatin.

³²⁴ **Adenosine** promotes SWS through direct inhibitory effects on cholinergic basal forebrain neurones; it also stimulates the indirectly.ventro-lateral preoptic nucleus. Adenosine receptors are antagonised by caffeine. Adenosine levels increase during wakefulness and decrease during sleep.

³²⁵ If a rich large neutral amino acid drink without tryptophan is given to someone treated with SSRIs (but not selective noradrenaline reuptake inhibitors) for depression a transient increase in depression follows after a few hours, something that does not happen in untreated cases. This is due to removal of tryptophan from stores as a result of stimulation of protein synthesis, for which tryptophan is required.(Checkley, 1998) Only 1-2% of body tryptophan occurs in brain and, since serotonin does not cross the blood-brain barrier, the brain must make its own 5-HT. Tryptophan competes with other amino acids for transfer across the blood-brain barrier by LNAA (large neutral amino acid) transporter. Male brain makes more 5-HT than female brain under normal circumstances, and this gap

Ancillary tests in psychiatry

Many different tests come under this heading. Examples are blood and urine tests, drug assays³²⁶, radiological examinations (skull, chest, etc.), cerebrospinal fluid (CSF) examinations³²⁷, angiography, myelography, electroencephalography (EEG), visual evoked responses, electromyography, nerve conduction studies, muscle biopsy, computerised axial tomography³²⁸ (CT), positron emission tomography (PET), and nuclear magnetic resonance (NMR – because of the association of ‘nuclear’ with bombs, NMR is now called magnetic resonance imaging, MRI). The clinical application of neuroimaging in psychiatry is still developing.(Sharma & Sheringham, 2002) We are still not certain about the nature of the in vivo competition between endogenous and exogenous ligands,(Liddle, 2001, p. 14) and the use of different exogenous ligands may be partly responsible for the failure of different investigators to produce compatible results. Biopsy is occasionally required in the interface between neurology and psychiatry in order to reach a diagnosis: brain/meninges, pharyngeal tonsil (vCJD), nerve, or muscle. It is important that specimens are seen by an experienced neuropathologist.

The TRH challenge test is performed by giving 500 µg TRH and then measuring TSH at 15, 30, 60, and 90 minutes. A blunted TSH response has been recorded in, amongst others, depression, anxiety, and bulimia nervosa. A blunted growth hormone response to insulin challenge has been reported in depression. The dexamethasone suppression test (DST), first used to assess cases of Cushing’s disease, is discussed with the affective disorders.

Hypoalbuminaemia³²⁹ reduces drug-carrying capacity for protein-bound medications leading to a rise in free drug serum concentrations despite therapeutic range levels for total serum levels. Low serum albumin levels may be of aetiological significance in confused patients.

The term *tomogram* simply means viewing something in layers or planes. Neuroimaging techniques may be structural as with CT or MRI, or functional as with SPECT or PET. All brain-imaging techniques utilise computers to construct a series of 2-dimensional slices from a succession of one-dimensional data.

Regarding imaging, functional segregation of parts of the brain has helped understanding of symptoms, but functional integration is better for understanding fundamental disease mechanisms.(Dolan & Friston, 1997)

There are many potential tests of arousal: paper and pencil tests such as Thayer’s Activation-Deactivation Adjective Checklist, cardiovascular status (pulse rate, blood pressure, skin blood flow, forearm blood flow), electrodermal activity (galvanic skin response), breathing rate, electromyography, electroencephalography (not very useful), pupillary diameter, genital arousal, and biochemistry (e.g. adrenaline at the extreme level of arousal). Such measures must be integrated with the complete clinical picture, mindful of individual idiosyncrasies. Arousal is best gauged using a number of measures.

Skull radiography

The yield of helpful findings is fairly low in psychiatry. A single lateral film is usually adequate unless specific pointers suggest further work. Skull fractures may not have been suspected. Infection (e.g. from mastoid or ear) may destroy bone. Meningiomata may erode bone or cause bony overgrowth, the internal auditory meatus³³⁰ may be eroded by a neuroma, abnormal vascular marking may mean tumour (including vascular tumour), osteolytic lesions may infer multiple myeloma or multiple metastatic deposits, and the skull may appear generally thick or woolly in osteitis deformans. The posterior clinoid processes are eroded by increased intracranial pressure³³¹, and the pituitary³³² fossa (sella turcica: ‘Turkish saddle’) can be

widens with tryptophan depletion.(Svensson & Mathé, 2002) Tryptophan depletion may unmask an underlying serotonin-related trait dysfunction in persons prone to major depressive disorder.(Neumeister et al, 2004)

³²⁶ E.g. the presence of cocaethylene in serum suggests combined use of cocaine and ethanol.

³²⁷ CSF recovered at lumbar puncture (LP) should normally be very clear and not coloured with a (recumbent) pressure of 60-150 mm of CSF; there should be less than 5 cells per cubic millimetre (only mononuclear cells should be present); there should be no oligoclonal bands; blood should be taken at the same time and CSF glucose should be 66-50% of blood glucose; and IgG should make up less than 15% of total protein in CSF.

³²⁸ Gk., *tomos*, cut. CT images can only be viewed in the axial plane, unlike MRI which produces axial, sagittal, and coronal images.

³²⁹ Malnutrition, liver and kidney diseases, chronic diseases, the elderly, etc.

³³⁰ Various neural foramina may be expanded by tumours, e.g. optic.

³³¹ There may be a ‘beaten silver’ appearance to the vault.

³³² The anterior pituitary is derived from an upgrowth of Rathke’s pouch (a depression in the roof of the developing mouth). This meets a pouch of the floor of the third ventricle which becomes the posterior pituitary. The ‘empty sella’ syndrome is usually a result of flattening of a normally functioning pituitary.

enlarged from within or above. Half of all adults have a calcified pineal gland, which may be displaced by a pathological process. Other structures may also show calcification, such as the falx cerebri and the choroid plexuses, and, sometimes, parts of a tumour. Calcification can occur in the walls of an aneurysm or an angioma, in tubers of epiloia, and in the basal ganglia in the case of excessive parathormone levels.

*The electroencephalogram*³³³ (EEG)

The EEG, an indirect measure of brain activity, measures summation of electrical activity. This is recorded as a difference in electrical potential between two active recording electrodes³³⁴. The weak signal requires amplification. In a standard recording, the paper moves at 30 mm/sec and an impulse of 50 μ V causes the pen to deflect by 7 mm (there may be no paper sheet, as in digital EEG). The standard arrangement for EEG electrodes (usually the International 10-20 System) are named for the underlying brain lobe³³⁵. (Reeve, 2003) Cycles per second are synonymous with *Hertz* (Hz). Common EEG rhythms are subdivided according to frequency (see box). Rhythmic changes of potential are seen of about 20-40 millionths of a volt. These are produced by the inhibitory and excitatory postsynaptic potentials on neuronal dendrites close to the surface of the brain. At any moment only 3% these neurones contribute to the detected signal. By convention, EEG recordings are arranged so that negative potentials cause an upward deflection.

EEG rhythms³³⁶

<u>Activity</u> ³³⁷	<u>Hz</u>	<u>Usual location</u>
Alpha (α)	8-13	posterior
Beta (β)	> 13-30	anterior
Theta (θ)	4-7.9	generalised +/- focal
Delta (δ)	0.4-3.9	generalised +/- focal
Gamma (γ)	> 30	

Alpha, best seen over the occiput, is the dominant/background EEG activity in normal people. It is prominent when in a relaxed state with the eyes closed or during hypnosis, (Craggs & Carr, 1992) but disappears with eye opening, concentration, or anxiety. Since its presence accurately monitors freedom from anxiety it is useful in biofeedback, 'alpha-training', and other behaviour modification techniques. Alpha rhythm is also lost during sleep or with psychotropic drugs and it slows in old age and in almost every neurological illness.

Beta rhythm is usually of lower voltage than alpha, is present normally, but increases with concentration, anxiety, or minor tranquillisers; it replaces alpha rhythm during stimulation or when the eyes are opened; best seen over mid-scalp (somatosensory/motor cortex). Tolerance does not occur to benzodiazepine-induced fast beta activity.

Theta & Delta are usually absent in healthy, alert adults, are a normal finding in children, in everyone as they enter deep sleep, and in many people with fairly minor problems, e.g. migraine headache. If diffusely present over the brain, slow activity may indicate a degenerative or metabolic disorder, but, when localised, may indicate a discrete cerebral lesion, but its absence does not exclude such a lesion.

Mu rhythm, found in the precentral region, lies within the alpha range and is reduced by moving (or thinking about moving) the contralateral limbs. *Lambda waves* are caused by small eye movements. They resemble the teeth of a saw and are usually situated over the occiput. *Gamma rhythm* (up to 100 Hz) are thought to represent the coming together of different neuronal networks to allow cognition or movement. Autism has been associated with increased amplitude in this frequency and may represent diminished inhibitory processes whereas schizophrenia may be associated with differences in gamma amplitude and

³³³ Hans Berger of Jena introduced the human EEG in 1929: the Nazis prevented him accepting the Nobel Prize (he hung himself). (Finger, 2000)

³³⁴ One cannot record from a single electrode.

³³⁵ E.g. Fp1 or left frontal pole, P4 or right parietal, C means along a central line between the ears, Fz is frontal along the vertex or a line from nose to occiput, and Pg 1 and 2 are left and right nasopharyngeal, etc.

³³⁶ Exact frequencies vary slightly with reference source. Beta frequency range is sometimes divided into beta 1 (13-20 Hz), beta 2 (21- or 35 Hz) and gamma (> 30 or 35 Hz). The study of the gamma band is relatively new and followed discovery of its functional significance in intracerebral recordings.

³³⁷ In summary, delta = sleep, theta = drowsy/hypoalet, alpha = relaxed wakefulness, and beta = alert and vigilant.

coherence.(e.g. Light et al, 2006) *Coherence* refers to a comparison of the periodicity of a particular frequency between two locations and research using analysis of coherence suggests that circuitry is abnormal in Parkinson's and Alzheimer's diseases.

In most instances EEG recordings are taken via scalp electrodes. Sphenoidal electrodes (less often used today than heretofore) record discharges from the temporal lobes. One reason for this decline in use is the belief that this technique may simply sharpen an already discernible but muffled surface EEG abnormality. Electrodes are pushed through the masseter muscle and up behind the zygomatic arch, whereas in the simpler nasopharyngeal EEG the electrodes are placed via the nose in the pharynx against the floor of the sinus. Nasopharyngeal leads are not thought to add much to scalp recordings and can be very uncomfortable. Although electrodes F7 and F8 are known as anterior temporal leads they lie over frontal areas; nevertheless, they reflect mostly anterior temporal lobe activity. More accurately, anterior temporal activity can be recorded by tracing a line between the external meatus and lateral canthus and putting the electrode one cm above a spot one third of the distance forward from the meatus.(Homan et al, 1988)

Anterior temporal leads as just described are about as sensitive as nasopharyngeal leads and, arguably, a combination of anterior temporal and nasopharyngeal leads may be as sensitive as sphenoidal leads.(Goodin et al, 1990) During surgery it becomes possible to record directly from the surface of the brain (electrocorticography³³⁸). Depth electrodes³³⁹ record activity from specific structures within the brain. During surgery it becomes possible to record directly from the surface of the brain, so-called electrocorticography.

Activating procedures, to detect or enhance abnormalities, include sleep (may be chemically induced³⁴⁰), deprivation of sleep, flashes of light using a stroboscopic light (photic stimulation³⁴¹), hyperventilation³⁴², metrazole³⁴³ (Cardiazol), pentylenetetrazol, chlorpromazine, 24-hour monitoring, cortical electrodes at surgery, and so on. Prolonged monitoring may take the form of videotelemetry (video of patient plus EEG) or ambulatory monitoring (no visual accompaniment).

Spike and wave patterns³⁴⁴ are nearly always pathological, e.g. the classic finding in petit mal epilepsy is 3c./sec. spike and wave discharges. Abnormalities can be focal³⁴⁵, unilateral or generalised. They can be synchronous or asynchronous, depending on whether they appear in corresponding leads. EEGs can be normal in people with abnormalities and vice versa. About 10% of people have EEG 'abnormalities', usually mild. An example is the normal hunger striker with hypoglycaemia. The EEG rarely offers a specific diagnosis. Even the localisation of an abnormal electrical discharge is not a universal indicator of lesion site.

Many 'functional' psychiatric disorders are associated with EEG abnormalities. Hill (1952) found that psychopaths (especially those with a history of impulsive homicide) had evidence of 'delayed' cerebral maturation (bilateral rhythmic theta activity in central and temporal regions, alpha variants, and episodic posterior temporal slow-wave foci). The latter may improve both in terms of EEG tracing and in behaviour, with age. In practice, about half of psychopaths presenting to an acute psychiatric service will have an abnormal EEG, a finding that shows a negative correlation with age and a positive one with the occurrence of epileptic convulsions. Theories about the origin of delays in EEG maturation range from environmental deprivation to epilepsy or various 'organic' diatheses. The finding of slow waves should not be too readily passed off as indicative of 'electrical immaturity'.(Fenwick, 1992)

Decreased slow-wave sleep has been reported to correlate positively with increased negative symptomatology in young medication-naïve schizophrenic patients. (Ganguli, et al, 1987) During the performance of left hemisphere cognitive activation tasks it is possible to show a significant increase in

³³⁸ Using the electrocorticograph or EcoG the hope is to be able to map epileptogenic circuits in cases of TLE.

³³⁹ These have been implicated in the transmission of Creutzfeldt-Jakob disease (characterised by periodic sharp wave bursts on scalp EEG).

³⁴⁰ IV thiopental induces beta activity (less so over damaged temporal areas), characteristically with runs of spindles.

³⁴¹ Generalised spike and wave response to light is common in generalised epilepsy but rare in localisation-related epilepsy.

³⁴² Causing cerebral hypoxia by local vasoconstriction due to carbon dioxide depletion – may cause problems in cases of cardio-/cerebro-vascular disease or sickle cell disease.

³⁴³ A synthetic soluble derivative of camphor.

³⁴⁴ Although spikes and sharp waves are usually followed by slow waves, the term 'spike and wave complex' generally infers a very prominent slow wave that has a higher amplitude than the spike. *Spike and wave formations are found in 2% of people who do not have epilepsy.*

³⁴⁵ **Focal lesions** may be associated with localised EEG disturbance or a disturbance located at a distance from the lesion or with a generalised disturbance.

alpha (α) coherence in areas related to left focal frontal sites, but, in the Morrison-Stewart ea (1991) study schizophrenic patients did not show the same degree of focal activation of left frontal areas, which may reflect aberrant functional brain organisation, especially affecting the left hemisphere. The testing condition that has most consistently revealed hypofrontality³⁴⁶ (prefrontal cortical hypofunction) in schizophrenia is the Wisconsin Card Sorting Test. (Weinberger ea, 1986; hypofrontality is also associated with depression, regardless of cause: George ea, 1993) Perhaps due to partial failure of localised cerebral autonomy, the EEG in schizophrenia is excessively synchronous between temporal areas. (Flor-Henry & Yeudall, 1979) Maixner ea (1998) tested schizophrenic patients while medication-free and after a few weeks on antipsychotic medication. Sleep continuity improved consistently. REM³⁴⁷ latency increased, but one-third of individuals continued to exhibit short REM latencies of less than 60 minutes. Stage 3 sleep increased, while stage 4 remained unchanged. The authors wondered if shortened REM latency and disturbed sleep continuity may be reversible state markers, with reduced slow wave sleep representing an irreversible trait abnormality in schizophrenia. Harris ea (1999) used the so-called 'quantitative EEG' (qEEG) and found that 'psychomotor poverty' was associated with both delta and beta power, and 'reality distortion' was associated with alpha-2 power; no significant correlations were found between the positive and negative syndrome dichotomy and the qEEG. Kwon ea (1999), using auditory stimulation at different rates (20-40 Hz) and measuring synchronization of the EEG, found reduced EEG power at 40 Hz in people with schizophrenia. This, they suggested, might reflect dysfunction of the recurrent inhibitory drive on auditory neural networks.

qEEG³⁴⁸

Quantitative analysis of EEG in time, frequency, and space domains

Can detect changes that the eye cannot see

Changes in brain function reflected in amplitude, frequency, and topography

Computerised EEG topography (CET, qEEG mapping)

Construction of 2- or 3-dimensional matrix for topographic representation of qEEG parameters, e.g. instant amplitude and band power

Colour-coded maps were developed from the late 1980s

Low-resolution electromagnetic tomography (LORETA)

Allows localisation of electrical sources of surface field in 3-dimensional brain space

An *event-related potential* (ERP) is a recording of brain electrical activity linked in time to an event (such as an auditory stimulus). Components of an ERP may be positive (P) or negative (N) depending of the direction of deflection of the electrical stimulus. Numbers are an average of the time in milliseconds passed between stimulation and appearance of a component, e.g. P300³⁴⁹ or N400. The early components (< 150 msec.) derive from aspects of the stimulus, such as loudness. Later components derive from the cognitive workings (e.g. updating of memory within present context in the case of the P300) or the extent to which a stimulus is unexpected given the context (N400). The P300 latency is prolonged in depression and reflects a diminished ability to attend, which in turn may be dependent on serotonin. The P50³⁵⁰ is thought to index early gating of incoming sensory data (abnormal in most, but not all, schizophrenic subjects; also abnormal in their clinically healthy relatives; linked to polymorphism in alpha-7 nicotinic receptor).

Mismatch negativity (MMN)

An ERP sensitive to change in a stimulus during an otherwise repetitive pattern

³⁴⁶ Hypofrontality in schizophrenia is a rather contentious issue with many methodological caveats. (McKenna, 2007, p. 129)

³⁴⁷ Aserinsky and Kleitman discovered REM sleep in 1953.

³⁴⁸ See Gruzeliier ea. (2002)

³⁴⁹ Synonymous with P3, the third positive potential, which happens to occur 300 msec after the stimulus.

³⁵⁰ The **P50**, a positive deflection recorded by scalp electrodes 50 msec after an audible click, is generated in several parts of the human brain including the pyramidal cells of the hippocampus. Researchers have looked at P50 abnormalities as a potential endophenotype for schizophrenia. When 2 clicks separated by 200 msec are presented the patient the amplitude of the P50 wave following the second click should be smaller than that after the first click. In some cases of schizophrenia both waves are of equal amplitude, indicating a possible failure of sensory gating. To some degree this abnormality may be related to polymorphisms in or near the alpha-7 nicotinic receptor subunit gene (chromosome 15). Also, atypical antipsychotics are said to equalise the second P50 wave.

Reflects echoic memory (i.e. storing auditory stimuli) operations
 Arises from primary auditory cortex
 May reflect NMDA channel current influx in cortical layers II and III
 While attention may influence MMN somewhat, it is usually assumed to be uninfluenced by cognitive operations
 Salisbury ea (2003, p. 304) state that MMN is preconscious (unlike the P300 which reflects 'an updating of the conscious information processing stream and of expectancy')
 Salisbury ea (2002) reported pitch deviant MMN to be reduced by 47% in chronic schizophrenia along the sagittal midline but not in first episode schizophrenia
 Light and Braff (2005) found MMN deficits and their relationship to poor functional status to be stable over time in chronic schizophrenia

Edlund ea, (1987) described 6 cases of atypical panic attacks (hostile, irritable, severe derealisation, and social withdrawal) most of whom had temporary EEG abnormalities, albeit not sufficient to make a diagnosis of temporal lobe epilepsy (TLE), and some did well on carbamazepine or alprazolam. Wiedemann ea (1999) reported EEG findings in panic disorder suggestive of right frontal overactivity associated with an overactive avoidance-withdrawal system and disturbed cortical processing. Most sleep studies of panic disorder report normal sleep architecture, including normal REM latency. Some panic attacks occur at night, especially during the transition between stages 2 and 3 when dreaming is absent and cognitions are minimal. (Stein & Uhde, 1998) By way of contrast, night terrors appear in stage 4 whereas REM sleep behaviour disorder and nightmares occur during REM sleep. As demonstrated in 1965 by Shagass, EEG changes following ECT take about two months on average to normalise.

TLE is often characterised by spike discharges over the temporal region but up to half of recordings may be normal; the percentage of abnormal returns may be increased with sphenoidal electrodes in a sleeping patient. In a waking interictal EEG lasting 30 minutes, some 35% of epileptics consistently exhibit epileptiform discharges, 15% never do so, and 50% do so occasionally. (Ajmone Marsan & Zivin, 1970) The yield of relevant diagnostic information from a single waking EEG in a population with epilepsy is about 50%, but with repeated recordings it approaches 85%. A superior yield is achieved with sleep recordings: grand mal seizures are activated in n-REM sleep, and absences or minor seizures may be seen during REM sleep. (Morgan, 1993) Simple ictal phenomena such as déjà vu or a peculiar abdominal sensation are usually associated with an unaltered scalp EEG, i.e. the EEG may be normal during a clinically obvious focal seizure. Epilepsy should never be diagnosed from the EEG alone: there must be a clinical history of seizures. In rare cases, performing the EEG when the patient is doing what he says brings on an attack (e.g. phlebotomy, bathing, standing up quickly, reading) may change a diagnosis to one of epilepsy. The relatives of epileptics often have EEG abnormalities. (Fenwick, 1992)

After cranial trauma, an abnormal EEG may distinguish between behavioral psychogenic and organic problems. However, neuroimaging has largely replaced the EEG when searching for structural lesions. In dementia, the severity of EEG abnormality may not relate so much to intellectual status at the time of the recording as to the rate of progress of the disorder. The EEG in Pick's disease may reveal little in the way of abnormality. A normal EEG in a depressed individual who has other evidence of possible dementia is suggestive of depressive 'pseudodementia' (syn. 'dementia syndrome of depression'). The more severe a case of Tourette's syndrome the more qualitatively abnormal the EEG, especially characterised by excess generalised theta activity. (Hyde ea, 1994)

The EEG in sleep

Methods of studying sleep in the Sleep Laboratory include all-night polygraph (polysomnography) recordings, e.g. EEG; ECG; electromyogram (EMG³⁵¹: - the throat muscles are tense, with lots of small electrical spikes, in orthodox sleep, and relaxed in paradoxical sleep); electro-oculograph (EOG: - small, transmitted brain potentials are seen in orthodox sleep; more obvious variations are seen in REM sleep); pulse oximetry (records blood oxygen saturation); respiratory effort recording (nasal and oral airflow using

³⁵¹ Usually recorded submentally.

nasal thermistors plus thoraco-abdominal movement using strain gauges/inductive pethysmography); and snore monitor (microphone on side of neck). Most people have a number of brief awakenings during sleep but may not recognise them as such unless they persist for more than a couple of minutes. Humans tend to take all the day's sleep in one go (100% consolidation) whereas guinea pigs sleep in short bouts spread throughout the 24-hour period.

Non- rapid eye movement (n-REM sleep, orthodox, synchronised) sleep

This makes up the majority of sleeping time. Everything slows down, progressively with deepening sleep. Its 4 stages take about 90 minutes to complete.

Non-REM sleep stages

Stage 1 - starts when sleep starts (low voltage, fast waves – drowsiness, *slow rolling eye movements*: < 0.5 Hz)

Stage 2 - associated with K-complexes³⁵² and sleep spindles (spindles of 14c./sec. activity: brief episodes of fast activity)

Stages 3 and 4 (slow wave³⁵³ [SWS] or delta sleep) - deepest levels of sleep, with high amplitude slow-waves

After falling asleep, the normal person first enters n-REM sleep (each phase lasting 60-90 minutes). Each n-REM phase is interrupted by REM phases lasting 12-20 minutes). Throughout sleep there is progressive decline in SWS³⁵⁴ with an increase in the proportion of REM across successive REM/n-REM cycles.

REM (paradoxical, desynchronised) sleep

The term 'paradoxical' refers to the fact that the associated physiological measures (including the EEG), relative to non-REM and apart from hypotonia, are suggestive of an alert (active cortical) state. Bursts of conjugate rapid eye movements are seen in anterior leads. In young adults, about 25% of the night is spent in this stage (75% in non-REM: 5% in stage I, 45% in stage II, 12% in stage III, 13% in stage IV), up to one-half in infants (neonate goes straight into REM; by 4 months the pattern shifts so that REM is reduced to less than 40% of sleep time and there is an initial non-REM period; sleep spindles appear at 3-4 months), and with a slight reduction (in both REM and slow-wave sleep) in the elderly. The sleep cycle does not lengthen until adolescence, when the 90-minute cycle of the mature adult is achieved.(Anders, 1996)

REM sleep

Mostly packed toward the second half of the night

Becomes more frequent and lasting longer as sleep continues

Most, but not all, dreaming found here

EEG: low voltage, fast activity (alpha activity is present but slower than when awake)

Spontaneous penile erection³⁵⁵

Poikilothermia - no response to changes in ambient temperature

Increased metabolic rate/autonomic arousal - increased brain temperature, oxygen consumption, and blood flow, varying tachycardia, and sharp and frequent changes in respiration (irregular breathing) and blood pressure

Reduced ventilatory response to CO₂

Cardiac irregularities may occur³⁵⁶

No EMG activity

Apart from some twitching (of small muscles: hands, feet and face) the body is flaccid (with postural hypotonia) – extraocular, diaphragmatic and middle ear muscles are not inhibited

³⁵² Number of K-complexes and sleep spindles decrease with age. **K-complexes** are said to resemble the letter K: high amplitude biphasic waves, the first component being negative. K-complexes can be invoked during light sleep by ambient noise and may represent efferent cortical signals that travel to thalamus and brain stem. The **spindles** are complexes of increasing and then decreasing amplitude (12-14 Hz). They occur in short bursts and may be involved in cortical inhibition. They are found in stages 2 to 4 of non-REM sleep although they are masked to a large degree by other waves in the latter two stages.

³⁵³ Slow wave sleep declines with age (especially in males) leaving the majority of non-REM then consisting of stage 2.

³⁵⁴ I.e. non-REM stages 3 and 4 are mainly found early in the sleep period. There may be no SWS in the last cycle.

³⁵⁵ In males of all ages. Ejaculation occurs in response to dreams of a sexual content but the erection as such is content neutral. Clitoral erection also occurs in REM sleep.

³⁵⁶ Angina may occur on lying flat (decubitus angina) or during vivid dreaming (nocturnal angina).

Sleep becomes shallower as sleep progresses
Final REM period usually coincides with waking

In 'endogenous' depression (Kaufman, 1985) the first REM period is brought forward and is very long and intense; total REM is almost the same as normal but is mostly packed into the first part of the night, leaving very little REM for later; and the patient wakes early (EMW) and may experience increased sleep latency³⁵⁷. In 'major' depression there is increased sleep-onset latency, reduced total sleep time and sleep efficiency³⁵⁸, reduced percentage of total sleep time spent in stages 2 and 3, and reduced REM latency (comes on earlier) with increased REM density (longer time spent in REM). (Mendlewicz & Kerkhofs, 1991) From a diagnostic viewpoint, about 15% of depressed patients have normal or even prolonged REM latency³⁵⁹ and sleep deprivation, narcolepsy, and medical illnesses can also cause these phenomena. Also, depressives have their temperature nadir advanced by some hours and have an earlier secretion of both cortisol³⁶⁰ and the noradrenaline derivative MHPG. Therefore they experience a phase shift advance, the normal circadian rhythm having been brought forward in time. Neurones generating REM sleep are found at the ponto-mesencephalic junction. After a few sleepless nights a person becomes confused, incoherent and irrational. The amount of REM sleep is increased by LSD25, reserpine (a depressogen), thalidomide, γ -hydroxybutyrate³⁶¹, nefazodone, possibly by an effect on 5-HT_{2A} receptors, (Delgado & Gelenberg, 1996; Buysse ea, 1996; Leonard, 1997) and bupropion. (Buysse ea, 1996) Cholinesterase inhibitors increase REM in Alzheimer patients³⁶². (Moraes Wdos ea, 2006) REM is decreased by MAOIs³⁶³, tricyclic antidepressants (TCAs³⁶⁴), amphetamines, alcohol³⁶⁵, clonidine³⁶⁶, barbiturates, and large doses of benzodiazepines (BZD). Agomelatine does not suppress REM sleep. When REM suppressers are discontinued, there is REM rebound with insomnia and nightmares, which may last for several weeks. SSRIs and venlafaxine reduce the amount of REM sleep. Fluoxetine disrupts sleep continuity. Interestingly, combining fluoxetine with the hypnotic drug eszopiclone was associated with greater improvement in depression scores than when fluoxetine was given alone, and such improvement was not explained by better scores on sleep items within the depression scales. (Fava ea, 2006) SSRIs can cause insomnia and, when stopped too quickly, nightmares. While benzodiazepines initially reduce REM sleep there follows, after a week or so of adaptation, a return to a normal total REM time. If the drug is then stopped, there will be increase in REM to above pre-treatment levels (rebound, perhaps with nightmares) which slowly (up to 6 weeks max.) returns to baseline. (Cooper, 1995) In summary, BZDs increase total sleep time and the number of REM cycles (increased number of dreams) and decrease sleep latency, awakenings, all 4 stages of non-REM sleep, and total REM sleep. (Ballenger, 1998) Excess fast beta activity anteriorly on the EEG is suggestive of BZD or barbiturate consumption. Modafinil has minimal effect on sleep architecture when used in therapeutic doses but the high doses employed by the military presents sleep; when the soldier eventually sleeps the EEG is the same as for non-drug-induced sleep deprivation. Oxybate reduces fragmentary REM occurrence in narcolepsy.

The nadir (lowest point) of body temperature occurs in the second half of sleep; maximum body temperature occurs in the afternoon. Growth hormone is produced mainly as one nocturnal burst. Cortisol is produced in bursts throughout the night, reaching a daily maximum at c. 8 a.m.

Evoked responses/potentials: Averaged EEG tracings following stimulation of a particular sensory modality with 'background noise' eliminated has proven useful in the investigation of a number of neurological and psychiatric disorders. A graph of the typical contralateral response to tactile stimulation of

³⁵⁷ Sleep latency = lights out to first nREM stage I episode.

³⁵⁸ Sleep efficiency = time sleeping/time in bed X 100.

³⁵⁹ Therefore this cannot be depended on to make a diagnosis.

³⁶⁰ Phase advance of cortisol in depression is relatively small in magnitude and inconsistently reported. (Hajak & Popp, 2008, p. 82)

³⁶¹ Thalidomide and γ -hydroxybutyrate, both hypnotics, also increase slow-wave sleep. (Nishino ea, 1998)

³⁶² Anticholinergic/antimuscarinic drugs such as atropine, scopolamine, and TCAs can decrease REM sleep. (Wilson & Argyropoulos, 2005)

³⁶³ REM suppression by phenelzine is reversed by rapidly depleting tryptophan. (Landolt ea, 2003) This suggests that serotonin is involved.

³⁶⁴ But not trimipramine (Steiger, 2002), iprindole, or viloxazine, which have no significant effect on REM. (Le Bon, 2005)

³⁶⁵ Alcohol reduces sleep latency, REM and stage 4 sleep. It increases sleep fragmentation. 'Happy hour' or 'cocktail hour' drinking can cause initial insomnia.

³⁶⁶ Hence its use in treating REM sleep behaviour disorder.

an index finger would show an initial stimulus artefact followed in succession by a positive deflection P1, a negative deflection N1 and the P2 and N2 over a 60 millisecond (ms) period; amplitude is measured in μV . For example, Allen ea (1991) failed to find a significant difference in the lateralisation of tactile-evoked potentials when a stimulus was evoked to the index fingers of patients with schizophrenia and age- and sex-matched controls. P3 (P300) abnormalities (showing differences from controls) have been reported in schizophrenia, behavioural problems, (Iacono ea, 2002) memory disorders like Alzheimer's disease, attentional disorders, and, as a trait marker, in the offspring of alcoholics, (Polich ea, 1994) and in affective disorders (Hall ea, 2009); abnormalities may involve amplitude, latency or the positioning of the peak over the head. (Maurer, 1989) The P300 becomes prolonged with increasing age. (O'Donnell ea, 1995) Blackwood ea (1987) found the (auditory) P300 latency increased in schizophrenia and depression, returning to normal in the latter with recovery but remaining prolonged in the former and remaining uninfluenced by medication. The P50, a positive potential occurring 50 msec. after a stimulus, was examined by Siegel ea. (1984) Normal people show reduced amplitude in response to a second loud click presented half a second after a first loud click (heard through headphones), but many drug-naïve and medicated schizophrenic patients and about third to a half of their first-degree relatives fail to demonstrate this reduction, i.e. they fail to habituate.

Brain electrical activity mapping (BEAM) is a research tool wherein aspects of the EEG over the brain, such as frequency bands, are averaged by digital computer with the production of coloured areas representing levels of activity. (Duffy ea, 1979) BEAM offers a sensitive physiological measure of psychotropic drug effects. To a large extent, BEAM has been superseded by other neuroimaging techniques. An evoked potential is a time-locked average of the EEG in response to a specific sensory, motor, or cognitive event.

*Eye-tracking studies*³⁶⁷

SPEMs are responsible for slower moving targets than are saccades (see next) and involve continuous movements with fovea fixed on the target; they require stimulus activation and are maintained by attention to the target.

The subject looks at a smoothly moving target, such as a pendulum or a moving spot. The direction of gaze is measured by reflecting infrared light from the pupil. Most normal people will track in a smooth, sinusoidal fashion. Excess jerkiness - a disrupted, jagged pattern - is found in most, but not all, schizophrenic subjects, in about 45% of their parents and siblings - who may not have overt illness, and in around 8% of the general population. According to Kathmann ea, (2003) over 80% of have abnormal smooth pursuit tracking with about one in three of their relatives having similar problems.

Saccades

These are fast, ballistic eye movements that bring the fovea centralis and the target together, e.g. when a person hears a sound and turns the eye quickly to its source. Saccades can be voluntarily executed. The eye may jump ahead of the target (*anticipatory saccades*) or, because of reduced *gain* (speed of eye v speed of target), the eye falls behind the target and uses a *catch-up saccade* to bring it back to the target.

Antisaccades

A subject is asked to fixate a central dot that steps at random to left or right. When the target steps into the periphery the subject is asked to look away from the target to the opposite side. It requires inhibition of the temptation to look to the side where one remembers the target to be: when one must inhibit the reflex to look toward a light (*prosaccade*) and instead consciously look in the opposite direction (*antisaccade*), schizophrenic subjects have great difficulty not turning their eyes to the light. (Ford ea, 2004) There are reports (Sereno & Holzman, 1995) that antisaccade errors occur in schizophrenia and those schizotypal subjects, (O'Driscoll ea, 1998) with increased scores on the Perceptual Aberration Scale, (Chapman ea, 1978) tend to perseverate during this task.

Isotope brain scan

This technique is redundant.

*Cerebral blood flow (CBF)*³⁶⁸

³⁶⁷ Smooth pursuit eye movements: SPEMs.

³⁶⁸ CBF measurement using nitrous oxide was first described by Seymour Kety (1915-2000) and Carl Frederic Smith (1893-1988) in 1945.

CBF may be measured using Xenon 133 inhalation. Xenon is an inert gas that does not affect physiological or biochemical processes. Radioactivity can be measured using gamma detectors yielding a measure of regional CBF (rCBF). Because neuronal activity is directly correlated with blood flow, rCBF is a measure of local neuronal activity. However, this method tells us only about surface activity. Examination of deeper brain parts requires a technique such as PET (which allows a 3-dimensional quantification of brain physiological activity, either blood flow or receptor activity).

In normal healthy adults, the mean CBF is about 50 ml./100 g. of brain tissue/min. Values for white and gray matter are about 80 and 20 respectively. CBF tends to be higher frontally and to slowly decline with advancing age.

*Computerised tomographic (CT) Scans*³⁶⁹

The time needed for CT scanning has been reduced greatly (and continues to be) since its introduction. Spatial resolution of CT has also improved (< 1 mm). Whilst CT can image in the transaxial plane only, MRI can do so in transaxial, sagittal and coronal planes.

CT of brain

Voxel³⁷⁰ - volume element of CT scans: each brain slice is divided into a series of tiny cubes; a number representing the degree of the x-ray³⁷¹ beam (see Hounsfield number) can be assigned to each voxel, each then being assigned a shade of gray yielding a visual picture of brain function

Pixel (picture element) - the surface of a voxel and represents the average radiodensity of the entire underlying voxel

Hounsfield number – x-irradiation transmitted from a pixel is examined by a computer and its density is assigned a number; water has a 0 value, air = - 1000 units, and water = + 1000 units

CT may fail to demonstrate early infarcts, inflammation (cerebral abscess detection requires use of contrast), or very small lesions, especially if they are sited in brain stem or posterior fossa. The contrast dye used for CT has a high osmotic load that can cause acute renal failure in at-risk cases; patients must be well hydrated before receiving a contrast infusion. (Salloway et al, 2000) Seizures due to ionic contrast in CT affects 1 in 10,000 cases, more if the blood-brain barrier is significantly compromised.

Follow up of Swedish men who received radiation treatment for cutaneous haemangioma aged less than eighteen months found evidence of cognitive damage. (Hall et al, 2004) Because the doses received that led to adverse effects were equivalent to those from cranial CT, the authors warned of the need to re-evaluate the use of CT for children with minor head injuries.

³⁶⁹ The first prototype EMI head CT (low density x-rays) scanner was installed in Atkinson Morley's Hospital in London in 1972. Three years later a prototype whole-body scanner was installed at Northwick Park Hospital, Middlesex. When Eve Johnstone and co-workers conducted their CT work during the 1970s it was with one of two such machines in existence! Sir Godfrey (or Geoffrey) Hounsfield (1919-2004; Hounsfield, 1973) for which he received the Nobel Prize in 1979 invented the technique of CT. (Hemingway, 1991)

³⁷⁰ Voxel-based morphometry examines structural brain abnormalities using MRI: the data collected allows differences between groups in various brain areas to be identified.

³⁷¹ Radiation exposure with CT was said to be of the same order as a skull or chest X-ray making repetition problematic. However, there is increasing concern that the (over-) use of CT (e.g. in the private sector) may be causing cancer. (Kmietowicz, 2007) A typical scan is associated with a risk of 1 in 2000 of lifetime fatal cancer (natural risk = 1 in 4). (Kmietowicz, 2008)

Prospective studies in Alzheimer's disease patients have shown a worse prognosis in those with low attenuation density in the parietal lobes. One-quarter of schizophrenic patients show early signs which unrelated to inpatient care or medication; in two-thirds of these there is non-specific enlargement of the third and lateral ventricles; more localised lesions, such as aqueductal stenosis or septal cavities are also reported. A link between ventricular enlargement in more advanced schizophrenia and perinatal intraventricular haemorrhage has been suggested. (Lewis, 1986) reversible cerebral ventricular enlargement has been reported in both alcoholism (Carlen et al, 1978) and anorexia nervosa. (Heinz et al, 1977) Normal brain tissue shows as gray, CSF³⁷² as black, and white matter or the sagittal sinus and calcified pineal gland³⁷³ as white. CSF is also found in cerebral infarcts, chronic subdural haematomas and in brain oedema around tumours causing them to be darker than normal brain. *Hydrocephalus ex vacuo* infers an increased ventricular-brain ratio (VBR), e.g. in some cases of chronic schizophrenia. Some chronic cases of schizophrenic also lack the normal greater convolutions of the cortex over the dominant versus the non-dominant hemispheres, a finding that is not correlated with age, therapy, or electroconvulsive therapy (ECT). The normal elderly, even if highly intelligent, can have marked cerebral atrophy. The contents of a subdural haematoma are very dense at first, then become less dense³⁷⁴, and eventually are isodense with adjacent brain³⁷⁵.

Indications for CT

(a) *Psychiatric*³⁷⁶ (Renshaw & Rauch, 1999)

First episode of psychosis (Gewirtz, 1994)

Idiopathic confusion

Dementia

New psychiatric syndromes in > over-50s

Focal signs

History of head injury or seizures

(b) *Neurological*

Acute bleed (<1-3 days old)³⁷⁷

Acute injury

(c) *Patients with headache* (Peatfield, 1989)

Possible subarachnoid haemorrhage

Progressive increase in frequency/severity

Focal signs

Seizure (any type)

Vomiting

Endocrine dysfunction

Neurofibromatosis (including a family history of same)

Known malignancy elsewhere

Positron emission tomography (PET) Scans³⁷⁸

³⁷² Radiolucent – attenuates the x-ray beam the least.

³⁷³ Or other calcification or tumours, being radiodense – attenuates most, therefore appears lightest.

³⁷⁴ Due to haemolysis.

³⁷⁵ May be missed without contrast.

³⁷⁶ Great variation in diagnostic yield and type of referred patient in published studies make exact guidelines somewhat ephemeral.

³⁷⁷ Intracerebral bleeding becomes isodense with brain tissue by about the tenth day. **Diffusion weighted imaging** (DWI MRI) may oust CT from this indication. Diffusion weighted imaging detects random movement of tissue water and quantifies such movement using an *average apparent diffusion coefficient* which is then mapped onto the brain. Intracellular oedema (e.g. due to reduced blood supply) causes a reduction in this coefficient whereas diminished tissue integrity increases coefficient values. **MRI gradient echo sequences** picks up signals from paramagnetic material (e.g. iron) and so can detect haemosiderin, a residue of cerebral haemorrhage. One in twenty normal adults will have evidence of small parenchymal haemorrhages, although some haemosiderin deposits are removed over time.

³⁷⁸ PET ('PETT') was initiated by Michel Ter-Pogossian (1925-1996) of St Louis at a radiology meeting in 1974. The first PET scanner in the Republic of Ireland was housed at the Blackrock Clinic in Dublin. **Positron:** A positively charged particle with the same mass as an electron. If an isotope such as ¹⁵O₂ has more protons than neutrons it will emit positrons to achieve stability. The

PET scans inform us about cerebral metabolic activity. Energy is detected in the form of positrons produced during metabolism of substances such as fluorine-18-labelled fluorodeoxyglucose (FDG). FDG is metabolised just like glucose. Therefore, an increased positron³⁷⁹ emission rate indicates an increased metabolic rate and increased glucose utilisation. FDG has to be produced in a cyclotron. Radiation comes from the brain in PET scanning, but is passed through the brain in CT scanning. The very short half-life of the tracer allows collection of many images, separated by about 10 minute intervals, within a single session.(Liddle, 2000)

PET brain scan

Techniques have been used to highlight functions of different brain regions, the neurotransmitter function in disease, and to delineate dysfunctional brain areas.(Frackowiak & Jones, 1989; Dolan, 1989) Studies provide *in vivo* evidence for dopamine-2 (D2) receptor blockade by antipsychotic drugs,(Waddington, 1989) particularly strong in the case of typical agents. Schizophrenic patients with tardive dyskinesia (Fr *tardif*, late; *dyskinesia* [Gk. *dys*, bad; *kinēsis*, movement] simply means an abnormal movement and covers everything from tics and myoclonus to tremor, dystonia and chorea) may have increased metabolism in the basal ganglia with the opposite being found in Parkinson's disease. Mazziotta *et al.*,(1987) in a controlled study of Huntington's disease, reported a marked decrease in glucose metabolism in the caudate nuclei of both symptomatic and asymptomatic at-risk subjects. The reduced cerebral blood flow in Alzheimer's disease in posterior temporoparietal regions seen with SPECT shows as reduced glucose utilisation with PET. Multi-infarct dementia is characterised by patchy reductions in cerebral blood flow and metabolism,(Kumar, 1993) and fairly distinctive patterns are found in Pick's disease and Parkinson's disease with dementia. Major depression in the elderly is associated with reductions in whole brain glucose metabolic rates comparable in magnitude to those found in Alzheimer's disease.(Kumar, 1993) Areas of increased cerebral blood flow have been demonstrated in the hippocampal regions in patients with panic attacks.

*Single photon emission computerised tomography (SPECT or SPET)*³⁸⁰

While SPECT is mainly employed for measuring regional cerebral blood flow³⁸¹ (rCBF), PET measures rCBF, metabolic function, and neuroreceptor density. In SPECT the isotopes are single photon emitters whereas in PET they are positron emitters. Unlike PET, SPECT does not require an on-site cyclotron. Radio chemicals that emit a single photon or γ (gamma) ray, such as ¹²³I, are employed; the isotopes used in SPECT have a longer half-life than those used in PET. The latter fact makes it difficult to do multiple pictures at one sitting because one has to subtract residual radioactivity from any previous scan; also, high radiation exposure limits one to 2-3 scans/person/year.(Liddle, 2000) The resolution of PET is superior to that of SPECT, but SPECT imaging agents have greater half-lives than those used with PET, allowing a

positrons encounter (negatively charged) electrons causing mutual annihilation with simultaneous production of 2 photons (γ rays) of equal energy, but emitted in opposite directions. A scanner detects the photons and a computer reconstructs an image. While two photons are emitted with PET, only one is emitted with SPECT. Both PET and SPECT carry risks of radiation, disallowing repeated scanning.

³⁷⁹ A positively charged electron.

³⁸⁰ B. Leonard Holman (b. 1941) and Thomas C. Hill (b. 1945) of Boston introduced SPECT to neurology and psychiatry in 1984.

³⁸¹ Unlike PET, SPECT does not give an absolute value for rCBF. SPECT results were expressed as radioactive counts in each region of interest compared with a reference area (e.g. whole brain or cerebellum). However, the region of interest methodology has given way to various voxel-based techniques (e.g. *statistical parametric mapping* or SPM) in which voxel by voxel comparisons across the complete brain are used with the aim of finding patient-control clusters of disparity.

more prolonged and detailed neurochemistry study than is possible with PET.(Weinberger, 1993) For both SPECT and PET studies, an MRI or CT scan can be performed initially, with later superimposition of the PET or SPECT image: this allows for a more accurate anatomical location of functional data. Using the blood-flow marker hexamethylpropyleneamine (HMPAO) allows patterns of regional cerebral blood flow to be measured *in vivo*.

Up to 80% of Alzheimer patients show reduced blood flow (and glucose metabolism) in the cortex of posterior temperoparietal regions; there is relative sparing of primary sensory areas and subcortical regions.(Kumar, 1993) SPECT findings suggest a continuum between age-associated memory impairment and Alzheimer's disease.(Besson, 1998) Depression is associated with cerebral blood flow and/or metabolic changes in the fronto-temporal cortex and caudate nucleus.(Cummings, 1993) Lesser ea(1994) compared physically healthy depressives over 50 years of age with normal controls: rCBF was lower in older, medication-free depressives, involved the orbital frontal and anterior temporal regions, and was lowest in the right hemisphere. During tasks that activate the frontal lobes, patients with schizophrenia, unlike controls, fail to increase blood flow to the frontal cortex.(Weinberg ea, 1986; Lewis ea, 1992; Berman ea, 1993) In one study,(Marshall ea, 1993) 10 epileptic patients, half with schizophrenia-like psychoses, underwent SPECT; the psychotic patients had diminished rCBF in the left medial temporal region.

*Magnetic resonance imaging (MRI) or nuclear magnetic resonance (NMR)*³⁸²

MRI provides a high degree of contrast between gray and white matter and, unlike CT scan, is not impeded by bone. Paramagnetic contrast medium (e.g. gadolinium-DTPA: such media cross the blood-brain barrier and change tissue relaxation time; they are usually well tolerated) may distinguish between oedema and neoplasm (it is difficult to distinguish the two with MRI). MRI does not show calcification. It is useful for delineating problems in the posterior fossa, the cranio-cervical junction, and the neural canal.

MRI (e.g. Scheele ea, 1997)

Nuclei in a constant magnetic field can be made to resonate by applying an oscillating magnetic field in the radiofrequency range

As the resonance decays to zero the radiofrequency radiation emitted by the nuclei can be detected (the basis of the MRI signal)

Can measure time taken for nuclei to return to their original equilibrium

The proton relaxation parameters, T1 (spin-lattice: represents relaxation along *longitudinal* axis) and T2 (spin-spin: relaxation along *transverse* plane) are sensitive to pathophysiological change, particularly shifts in water distribution

Each tissue has specific T1 and T2 values

On T1 images, cerebrospinal fluid and abnormal areas are relatively dark, and vice versa on T2 images

T2 weighted sequences – good for showing abnormal tissue, for showing structure

T1 weighted images – good for showing structure

MRI may interfere with cardiac pacemakers and shift or heat prostheses, aneurysm clips or shrapnel; metal plates in the skull and cochlear implants are also a problem. Ferromagnetic material in a tooth filling can cause artefacts. With use of adjustable valves with subcutaneous magnetically controlled mechanisms to allow clinical manipulation of CSF drainage in normal pressure hydrocephalus the patient must avoid magnets, including MRI scanners. Loose metallic objects (such as a paper or hair clip) can become a lethal weapon when close to an MRI machine!

³⁸² An early discussion is provided by Steiner.(1987) The phenomenon of magnetic resonance was described in 1946, gaining the nobel prize for physics for Felix Bloch and Edward Mills Purcell in 1952. The first clinical demonstration of intracranial pathology using MRI was reported by Hawkes ea.(1980) Peter Mansfield of Nottingham and Paul Lauterbur of Illinois shared the nobel prize in physiology or medicine in 2003 for their work in developing MRI.(Mayor, 2003)

MRI of brain

Chick embryos are vulnerable to the increase in temperature associated with MRI suggesting that this procedure should only be used in the first trimester of pregnancy unless very necessary. (Godlee, 1991) Because MRI takes much longer (classically 5-60 mins.) than CT (classically 1-5 mins.) there may be difficulties with phobic or disturbed subjects; however, new, fast MRI techniques may allow a full brain image in seconds. (Liddle, 2000)³⁸³ Also, the clinician must inform the radiologist of what is being sought in order that the latter can produce the type of image most likely to show it up.

One American MRI study (Rauch & Renshaw, 1995) of psychiatric patients (N = 6,200) revealed only 1.6% with unexpected and potentially treatable findings. Brain responses were recorded by Mander ea, (1987) in 14 patients with major depression during a course of ECT. T1 relaxation time rose immediately after the fit, reaching a maximum 4-6 hours later, T1 values then returning to baseline. No long-term increase occurred over the course of treatment. Such results are consistent with an extensive but temporary breakdown of the blood-brain barrier during ECT. MRI (especially fluid-attenuated inversion-recovery: FLAIR³⁸⁴) demonstrates demyelinated plaques in multiple sclerosis, a task beyond CT. Psychosis in multiple sclerosis patients may be associated with a high total lesion score on MRI, and especially with lesions around the temporal horn. (Feinstein ea, 1992) Gaffney ea (1987) reported enlargement of the fourth ventricle in autism. According to Miller ea, (1991) patients with a first psychotic episode after 45 years of age have more MRI abnormalities, are more likely to have large white matter lesions or metabolic disorder, and do more poorly on neuropsychological tests, especially those evaluating frontal lobe and memory abilities, than healthy age-matched controls. Interestingly, in a very small study of patients with cerebral trauma, (Buckley ea, 1993) those with an illness resembling schizophrenia, but not those with a schizoaffective-like disorder, had left temporal lobe abnormalities. MRI has demonstrated reduced amygdaloid and hippocampal volumes in schizophrenia. (Carpenter & Buchanan, 1994) Stefanis ea (1999) found that exposure to obstetric hazards could be associated with small hippocampus volume; animal research has demonstrated that lesioning of neonatal ventral hippocampus reduces spine density in prefrontal cortex and accumbens nuclei and such rats, when mature, over react to amphetamine. In the Rangel-Guerra ea (1983) study of bipolar affective disorder patients, the latter had longer brain proton T1 relaxation times that normalised after lithium treatment, whereas lithium had no effect on this parameter in normal control subjects.

Knauth ea (1997) demonstrated multiple brain lesions in sport divers in association with a large patent foramen ovale³⁸⁵ that might be explained by paradoxical arterial gas embolism.

Subdural haematoma in T1-weighted images initially has an intensity between CSF and cerebral cortex; the signal increases thereafter; and finally it may be isointense with cortex.

Diffusion tensor imaging (DTI)

This MRI-derived technique examines the axes along which water diffuses. It provides information on the directional orientation of white matter tracts and informs us of their structural integrity. (Conturo ea, 1999) It can be used to detect disorders involving partial or complete disconnection between regions of the brain, or to detect demyelination. High values of fractional anisotropy³⁸⁶ indicate intact healthy neurones.

³⁸³ The MRI signal is detected by a receiver/detector coil. Newer coils allow parallel imaging. SENSE (sensitivity encoding) and SMASH (simultaneous acquisition of spatial harmonics) shorten image acquisition time.

³⁸⁴ FLAIR produces heavily weighted T2 images. CSF signal is suppressed and contrast between grey and white matter is reduced. The result is that lesions at the CSF-parenchyma junction are easier to see.

³⁸⁵ One-quarter of sport divers have a patent foramen ovale.

³⁸⁶ Anisotropic = directional. Tractography involves calculating fractional anisotropy, i.e. the degree of directional preference of bundles of fibres in a given voxel.

Fractional anisotropy results range from 0 to 1, higher values indicating greater directionality (more coherent fibre orientation) and lowers values reflecting poor white matter integrity or disruption.

DTI applications – some examples

Schizophrenia

Reduced white matter tract integrity in left uncinate and arcuate fasciculi (Burns ea, 2003)
 White matter microstructural disruption (Andreone ea, 2007; Skelly ea, 2008; Cheung ea, 2008)
 Reduced interhemispheric connectivity between frontal areas via corpus callosum (Kubicki ea, 2008)
 No differences in white matter abnormalities between schizophrenia and bipolar disorder (Sussmann ea, 2009)

Hallucinations

During inner speech, alterations in white matter tracts in patients with frequent hallucinations lead to co-activation in regions related to the processing of external sounds (Hubl ea, 2004)

Bipolar affective disorder

Decreased fractional anisotropy in superior-frontal white matter tracts in bipolar adolescents (Adler ea, 2006)
 Fronto-temporal white matter abnormalities (Bruno ea, 2008)
 Smaller anterior cingulum (Wang ea, 2008)

Major depression

Abnormalities of brain white matter in treatment-naïve young adult major depressives (Ma ea, 2007)

Geriatric depression

Lower fractional anisotropy in distributed cerebral networks associated with poor response to escitalopram (Alexopoulos ea, 2008)

Geriatric cognition

In dementia-free elders, white matter integrity is associated with cognitive function even when white matter appears normal on MRI (Vernooij ea, 2009)

Magnetisation transfer imaging (MTI)

MTI allows visualisation of protons that are bound tightly to macromolecular structures like myelin and cellular membranes in white matter. The normal brain signal, expressed as the magnetisation transfer ratio (MTR), is more or less the same in all voxels. MTI has revealed abnormalities in frontotemporal areas in schizophrenia. (Foong ea, 2001) Magnetisation transfer increases the contrast between liquids and solids and can visualise blood vessels when employed in magnetic resonance angiography.

Magnetic resonance angiography (MRA)

MRI variables can be made sensitive to motion to allow for angiography of small arterial branches or visualisation of venous outflow without the use of contrast agents. (Scheele ea, 1997)³⁸⁷

Event-related optical signal (EROS)

In this technique, near-infrared light is beamed through the skull into cortex. (Gratton & Fabiani, 1998) This light is deflected, providing cerebral haemodynamic information ('slow signal' which tracks changes over seconds) and data on neuronal shape alterations due to neuronal firing ('fast signal' measured in milliseconds). By controlling the position of light source and detector and by extremely fast recording (in milliseconds) one can get an idea of signal source and temporal change. Because of poor penetration of light, activation of deep brain structures are not detected.

Functional MRI (fMRI)

This fast (David ea, 1994) procedure does not requiring radioactive materials and permits measurement of neural activity with higher temporal resolution than SPECT or PET. It can be performed simultaneously with MRI. fMRI can carry out spatial resolution within the millimetre scale and can capture responses in brain occurring over a few seconds (including sensorimotor and cognitive activities, e.g. auditory hallucinations). It uses the brain's natural haemodynamic response to neural activity as an endogenous tracer. The commonest form is *blood oxygenation level dependent (BOLD) imaging*: this depends on the ratio of oxygenated to deoxygenated haemoglobin³⁸⁸. Tasks can be given to the subject to perform whilst brain activity is measured. BOLD fMRI measures an index of change in blood flow but cannot measure absolute resting/baseline blood flow³⁸⁹. The subject must tolerate scanner noise³⁹⁰ and close confinement

³⁸⁷ Thanks to the pioneering work of Charles Dumoulin during the 1980s.

³⁸⁸ Increased neuronal activity leads to increased local blood flow (*neurovascular coupling*) and a **decrease** in deoxyhaemoglobin because the increase in blood flow is greater than the power of the cells to consume oxygen. Oxygenated haemoglobin is slightly diamagnetic and causes weak disturbances in the local magnetic field. On the other hand, deoxyhaemoglobin is paramagnetic, aligns with an applied magnetic field, and increases the strength of the local magnetic field.

³⁸⁹ This may become possible with a magnetic resonance technique called *arterial spin labelling*.

³⁹⁰ A loud bumping noise caused by switching of the gradient coils.

within the magnetic bore, and the subject must not possess a magnetic implant. All that is required is upgraded software for standard MRI scanners.(Longworth ea, 1999) Artefacts mimicking changes in neuronal activity can be produced by movement of the patient.(Sheringham ea, 2002)

Magnetic resonance spectroscopy (MRS)³⁹¹

MRI goes beyond static visualisation of white and gray matter and enables measurement of cerebral blood flow and analysis of cerebral drug concentrations. While both SPECT and PET require the use of manufactured radioactive compounds, MRS utilises naturally occurring, nonradioactive nuclei. Natural emissions from atomic nuclei activated by magnetic fields are used to measure concentrations of molecules within the body. There are no 'pictures', just quantitative measurements, a display of the spectrum of certain chemicals. It has been used to study regional changes in GABA, to detect fluorine-containing drugs at receptor sites, and to image lithium in the brain.(Lock ea, 1990) N-acetyl aspartate³⁹² (NAA) is found mainly in neurones and can be measured by proton magnetic resonance spectroscopy.

Using this technique, Nasrallah ea (1994) found reduced NAA intensities in the right hippocampus/amygdala region of patients with schizophrenia, the left side being no different from normal controls; these findings led the authors to speculate that the right side might have less neurones or have biochemical alterations in NAA in schizophrenia. MRS findings suggest early abnormalities in the synthesis of membrane phospholipids in Alzheimer's disease but not in vascular dementia, which may prove helpful in differential diagnosis.(Besson, 1998)

Transcranial magnetic stimulation (TMS)³⁹³

TMS allows non-invasive induction of electrical currents in a restricted part of the cerebral cortex. When combined with electromyography (EMG), TMS of primary motor cortex can reveal changes in motor physiology evinced by experimental manipulations, as well as changes associated with psychiatric and neurological conditions. TMS can induce temporary, focal 'virtual lesions': this allows one to tell if a region of cortex identified by neuroimaging (e.g. PET) is essential for a particular cognitive task. The effects of relatively prolonged alterations in cortical excitability on a person's performance can be studied following use of repetitive TMS (rTMS). Combined PET and TMS is being used to assess neural connectivity: the effects of focal TMS is compared with changes in blood flow in another part of the brain. Assessment of local and distal blood flow changes with PET allows assessment of cortical excitability and connectivity respectively. TMS can be combined with EEG in other research.(Paus, 2003)

Magnetoencephalography (MEG)

MEG measures magnetic fields.(O'Donohoe, 1989; Sato, 1990) When current flows down a conductor a magnetic field surrounds the conductor, an effect that can be detected in nerve fibres. This very small field can be measured at the scalp (a magnetically shielded room and very low temperatures for the loop are required). Fluid or tissues do not attenuate magnetic brain waves. The ability to detect deep brain discharges using this method may obviate the need for indwelling electrodes.

In one study,(Reite ea, 1997) controls demonstrated asymmetry in an auditory-evoked field component (100-msec. latency); male schizophrenics showed less asymmetry and female schizophrenics showed more asymmetry than controls.

Magnetic field tomography, derived from MEG data, allows construction of a picture of dynamic brain activity. Resolution and spatial accuracy declines as the further one moves from the cortex. It remains largely experimental.

Magnetic source imaging (MSI) combines structural MRI with magnetoencephalography and has been used, for example, in studies of cortical reorganisation following limb amputation.

Echoencephalography (ultrasound)

³⁹¹ **Main techniques of MRS: (a) Proton spectroscopy:** measures the metabolite N-acetylaspartate, a marker of neuronal damage that is diminished in both Alzheimer's and Creutzfeldt-Jacob diseases. **(b) Phosphorus spectroscopy:** a direct measurement, in vivo, of phospholipid metabolism; phosphomonoesters reflect rate of membrane phospholipid synthesis; phosphodiesterases reflect rate of degeneration of membrane phospholipids. **Principle behind MRS:** In a magnetic field each distinct nuclear species has a unique spin frequency known as a Larmor frequency. This frequency varies with the compound containing the element in question. Application of a radiofrequency pulse tuned to the frequency of the specific element yields a spectrum that is caused by the different compounds containing the specific element.

³⁹² **NAA signal** is almost exclusive to nerve cells. A decrease in signal likely means dysfunction of neurones. Choline-related metabolites contribute to the Cho peak on MRS. Brain injury is associated with a higher Cho peak. Cr (creatine) peak is generally immune to the effects of brain damage. NAA and Cho activity are reflected respectively in NAA/Cr and Cho/Cr ratios.

³⁹³ The therapeutic use of TMS is discussed elsewhere.

This procedure has a high yield of false positive and negative results and has been superseded in studies of schizophrenia by CT and MRI. Directional Doppler ultrasonography may show narrowed blood vessels. Prenatal ultrasonography at 19-23 weeks gestation found a non-significant trend towards increased lateral ventricular width in offspring of mothers with psychosis.(Clarke ea, 2007)

Radioisotope (radionuclide) scan

An isotope is given by IV injection and is taken up by vascular tissue (tumours, infarcts). This procedure has become uncommon since CT was introduced.

Cognitive subtraction paradigm

An image of neural activity (be it blood flow or electrical activity) is taken before (control state) and during (task state) a task and the difference (subtraction) shows what brain parts are used for that task. In practice averages across intra- and interindividual repeated task performance are used in order to control for 'noise'.

Sleep disorders

Sleep disorders in children, although distressing at the time, are mostly developmental: they grow out of them. Behavioural techniques and education are often sufficient intervention. Clues to the need for further investigation are very frequent occurrence, onset in or persistence into late childhood, appearance after a traumatic event, and other evidence of psychological disturbance.(Stores, 1990)

Insomnia: Insomnia is the complaint that a person finds it difficult to fall asleep, stay asleep, or achieve good quality sleep. Chronic insomnia affects 10-15% of the population, and is more common in women and in older people.

Insomnia classifications

Primary ('psychophysiological' because psychological and physical factors operate)

Secondary (e.g. pain³⁹⁴)

OR

Transient e.g. on a long voyage or during a period of emotional distress

Prolonged e.g. in hypomania or other psychiatric illness

OR

True

Pseudo – see sleep-state misrepresentation below

OR

Early (onset, initial)

Middle (maintenance)

Late (early morning wakening)

Prolonged sleep deprivation may impair intellectual performance and disturb mood (During the 1950s, schizophrenic patients were kept awake because analysts considered dreaming as psychogenic! Wehr, 1990), even to the point of inducing mania.(Wehr, 1991) Loss of sleep on occasional nights is of little medical significance. Insomnia is usually secondary (e.g. depression or anxiety) if accompanied by diurnal symptoms. Alcohol taken in excess can itself cause insomnia and sleep disturbance may persist for weeks after cessation of heavy alcohol intake. It should be recalled that many people with 'insomnia' ('pseudoinomnia' or 'sleep-state misperception') probably do have enough sleep, e.g. 50% of 'insomniacs' have no abnormality on polysomnography.(Kelsey ea, 2006, p. 263)

Although estimates vary greatly, insomnia costs around \$100 bn annually in the USA.(Neylan ea, 2003, p. 978)

Treatment depends on the cause. Stimulating drugs, such as tranylcypromine, should not be taken later than noon. Buspirone³⁹⁵ may increase wakefulness.(Manfredi ea, 1991) Drugs should be employed for brief

³⁹⁴ Also medication (e.g. phenylephrine, corticosteroids, MAOIs, SSRIs), illegal drugs (e.g. amphetamines), tobacco, drug withdrawal (e.g. alcohol), orthopaedic or rheumatological disorders, COPD, asthma, sinusitis, peptic ulcer, gastro-oesophageal reflux, peripheral vascular disease (cramps in legs), paroxysmal nocturnal dyspnoea, congestive heart failure (orthopnoea), dementia, menopause (hot flushes), diabetes (e.g. polyuria), Parkinson's disease, dementia, etc.

periods only where possible and dose should be tapered when the drug is used regularly for more than a couple of weeks. Ultra-short acting agents may produce daytime anxiety but are less likely than longer acting agents to produce daytime drowsiness.

Ramelteon, useful for chronic insomnia, is an MT1 and MT2 melatonin receptor selective agonist and hypnotic that may lack abuse potential. Ramelteon reduces sleep latency with no significant rebound insomnia or abstinence syndrome. It appears to possess safe motor and cognitive profiles. Psychological approaches include education (e.g. sleep hygiene measures) and behavioural and cognitive techniques. CBT where available, is effective for insomnia where people associate the bedroom with arousal and upset (rather than with sleep and sex). Fear of bedtime and catastrophising about sleep loss (negative automatic thoughts) need to be confronted. CBT includes stimulus control (only stay in bed when asleep; write anything that is on one's mind down during the evening, e.g. what needs to be done next day; paradoxical intention – deliberately trying to stay awake may lead to sleep), and relaxation³⁹⁶ (muscle relaxation, warm bath, meditation, autogenic training). One should rise at the same time every day. The patient should confine time in bed to time spent asleep so as to increase sleep efficiency ([time asleep/time in bed]% = *sleep efficiency*).

Lack of sleep in young doctors may be associated with a significant slowing in cognitive processing, a decline in reaction times, and deleterious changes in mood.(Orton & Gruzelier, 1989) Sleep deprivation, popular in the 1970s, led to transient improvement in depression. Increased DA release in the basal ganglia is one suggested effect of sleep deprivation. Sleep advance involves bringing the sleep-wake cycle forward by about 5 hours; again, improvement in depressed mood may not be maintained for any useful length of time,(Sovetre, ea, 1987) although there is some evidence of augmentation of this effect by lithium.(Grube & Hartwich, 1990) It has been suggested that increased cingulate activity prior to sleep deprivation may herald a useful antidepressant response to this procedure.(Ebert ea, 1994) There is some evidence that the old adage 'early to bed and early to rise' (phase-advance) may, especially if combined with appropriate medication, may have longer-lasting (a week) ameliorative effects on depressed mood than has sleep deprivation (a day). Improved mood after one night's sleep deprivation favours depressive pseudodementia over organic dementia³⁹⁷; the latter is likely to worsen under these circumstances.(Leibenluft & Wehr, 1992) Lithium increases theta (slow) activity³⁹⁸ whereas benzodiazepines increase beta (fast) activity and depression is associated with reduced delta (very slow) activity.

Sleep deprivation effects (Uhde & Singareddy, 2002)

Major depression	improved ³⁹⁹
Panic disorder	worse
OCD	no consistent change

Various psychostimulants can cause insomnia.

High altitude insomnia

In severe cases it occurs as part of acute mountain sickness (AMS)

Possible mechanism: fluid imbalance secondary to hypoxia

Short half-life hypnotics (e.g. zolpidem) may relieve the insomnia

Acetazolamide at 250 mgs. b.i.d. prevents or ameliorates symptoms of AMS (Roberts, 1994)

³⁹⁵ Buspar was withdrawn, December 2009.

³⁹⁶ Imagery and muscle relaxation are learned during daytime and applied in bed.

³⁹⁷ People with dementia or brain damage may have irregular periods of sleep throughout the day. The total time spent asleep during 24 hours may be normal. It may be a voluntary practice in some people. This *irregular sleep-wake rhythm* is managed by engaging the patient in captivating diurnal activities, morning light exposure, and retiring at the same time each day.

³⁹⁸ Lithium is associated with a high frequency of paroxysmal EEG changes, even in subjects with therapeutic serum levels and no gross signs of toxicity.

³⁹⁹ Deprivation of sleep (total or second half of night only) quickly improves symptoms of depression in many patients but the effect is lost with a night's sleep. However, when used with lithium or antidepressant drugs, such deprivation may produce more sustained effects.

The elderly have very little deep (stage 4) sleep, waken often at night, have a slight diminution in total REM sleep and in total sleep duration, as well as an increase in sleep latency. In fact, the typical insomniac is the thin, old, 'neurotic' woman who smokes a lot. Many factors may aggravate sleep problems in the elderly, such as pain, bladder or bowel problems, anxiety, depression, and dementia. The morning drowsiness of the sleep apnoea sufferer and the syndrome of 'restless legs' are less common causes of sleeplessness. Geriatric in-patients suffer from the high levels of background noise to be found in our hospitals. The doctor himself may cause insomnia with thiazide diuretics or MAOIs⁴⁰⁰, calcium blockers, phenytoin, anovulants, stimulating TCAs, alpha-methyldopa, propranolol, thyroid hormone, caffeine, antimetabolites, some decongestants, bronchodilators, and corticosteroids or ACTH, or stopping antihistamines. The latter are useful as short-term sedatives but basically ineffective as anxiolytics. Elderly insomniacs should be encouraged to stop smoking⁴⁰¹, temper their intake of alcohol, avoid caffeine, take exercise, develop regular hours of sleeping and waking and, when necessary, use one of the hypnotics with a relatively short half-life. Alcohol is an often ineffective hypnotic because of dehydration, micturition and early morning rebound. Non-pharmacological measures such as sleep hygiene (Sateia & Nowell, 2004) or hot milk drinks should be tried before drugs. Chlormethiazole causes little in the way of hangover, can lead to troublesome sneezing, and there is an unpleasant taste from the liquid preparation. Chloral betaine can cause dyspepsia. One should remember that the half-lives of BZDs vary from one preparation to another, from flurazepam (long) to triazolam (very short). Use of a BZD of long half-life may cause confusion, incontinence, irritability, falls (Evans, 2003; Glass et al., 2005) and immobility.⁴⁰² Ideally, a hypnotic drug should be prescribed in the lowest dose possible, be eliminated quickly, used intermittently, the course should be short (max. 1 month), the patient should be counselled at the commencement of therapy, and alcohol should be avoided. CBT may be effective for insomnia. (Sivertsen & Nordhus, 2007) *Valerian officinalis* (Valerian) contains many chemicals (valepotriates). One such constituent, valerenic acid, has GABA-ergic properties and is sedative and anticonvulsant. Headache, blurred vision, gastrointestinal symptoms, dystonia, hangover and potentiation of other CNS depressants have been reported. It should be avoided in the presence of hepatic dysfunction. Some sleep disorders in *infants and young children* are briefly discussed here. Some young children will fall asleep in their mother's arms or in the parental bed. When asleep they are moved to the cot where they wake and refuse to sleep until taken back into mother's arms or the parental bed, a practice that reinforces the practice. This phenomenon is called *sleep onset association disorder*. The parent should settle the child in its crib/cot without removing it to a different setting and parental intervention should be gradually delayed throughout the night. As a bridging measure, a parent may need to spend some (decreasing) time sleeping in the child's room. Parents have to tolerate the child's crying and to intervene after longer periods of time, so-called 'controlled crying'. Antihistamines (e.g. trimeprazine) should only be employed for a short time and only to help parents through a period of extreme stress. Sleep hygiene measures in this age group include maintaining the same bedtime routine (short, pleasant, calm, predictable, with decreasing input from parent over time) and timing; give (non-stimulating) food/(non-excessive) drinks at least an hour before bedtime to obviate hunger; the room should be quiet and cool; do not play or feed the child in the sleeping environment; wake child at same time every day; and allow naps only as suits the age of the child. When parents do not insist on specific bedtimes the child will employ strategies to delay going to bed (*limit-setting sleep disorder*). A firm, non-hostile approach is needed that takes into account any fears the child may have (e.g. showing the child that there are no 'monsters' under the bed). The parent may spend a little time in the bedroom to sooth the child. Although sedatives are not indicated, medications are sometimes prescribed in practice.

Some sleep-related problems

Bruxism: involuntary, forceful grinding or clenching of the teeth during any stage of sleep; particularly likely in stages 1 and 2; diurnal bruxism is associated with dopamine blockade and recreational drug use

⁴⁰⁰ Give either early in the day.

⁴⁰¹ Smokers sleep less than non-smokers and nicotine withdrawal may cause drowsiness or arousal; nicotine itself causes initial insomnia and nicotine patches can cause vivid dreams/nightmares.

⁴⁰² However, whilst hypnotic/anxiolytic and antidepressant drugs are important predictors of falling, one study of elderly women found that chronic physical diseases (circulatory, COPD, depression, arthritis) were even more predictive. (Lawlor et al., 2003)

(especially ecstasy); anxiety, alcohol, malocclusion, venlafaxine (a 5-HT/noradrenaline reuptake inhibitor; responds to gabapentin), and SSRIs (treat by reducing dose or giving buspirone⁴⁰³; Romanelli ea, 1996; Wise, 2001) such as paroxetine, fluoxetine, sertraline, and citalopram (Cipramil), (Ellison & Stanziani, 1993) are associated factors in nocturnal cases; 15% of normal people may have bruxism; the noise may waken everyone except the patient; longstay inpatients with schizophrenia⁴⁰⁴ may have an excess of bruxism, severe dental wear, and temporomandibular problems. (Gurbuz ea, 2009)

Daytime drowsiness: There is a circadian tendency to feel mildly sleepy in the mid-afternoon. Causes of excessive daytime sleepiness include chronic sleep disorders such as obstructive sleep apnoea, narcolepsy, idiopathic hypersomnia⁴⁰⁵, insomnia, and periodic limb-movement disorder; depression; tertiary tricyclics such as imipramine⁴⁰⁶ or dothiepin (dosulepin) which cause hangover; BZDs and other sedatives; SSRIs (which can disrupt sleep – although paroxetine is more sedative); voluntary reduced sleep time (*insufficient sleep syndrome*), especially likely in young adults; and sleep reversal, e.g. psychiatric disorder, delayed sleep phase syndrome, coming off shift work, and travel. All of these may lead to accidents. (Leger, 1994; Hublin ea, 1996; Pilcher & Huffcutt AI, 1996; Terán-Santos ea, 1999) All dopamine agonists, to a variable degree, may be associated with somnolence. When somnolence occurs suddenly it may lead to accidents. Such adverse effects have most commonly been reported with ropinirole⁴⁰⁷, pramipexole⁴⁰⁸, and, less certainly, carbergoline. (Irish Medicines Board, 2002) The Multiple Sleep Latency Test (MSLT) allows a patient the chance to nod off in a dark room for 5 twenty-minute periods in 2 hour intervals across the subject's usual period of wakefulness: the average latency to sleep onset (measured with polysomnography) is a measure of the tendency to fall asleep. (Carskadon ea, 1986) Some centres test urine for drugs before MSLT in order to rule out people that are simply looking for stimulant drugs.

*Fatal familial insomnia*⁴⁰⁹: a very rare, untreatable prion⁴¹⁰-induced (caused by a mutation in the PRNP gene; Mastrianni ea, 1999) spongiform encephalopathy, is characterised by progressive insomnia (the usual presenting feature⁴¹¹), dysautonomia, ataxia, late diffuse EEG slowing, and thalamic nuclear, olivary and, to a lesser extent, cerebellar atrophy. Protease-resistant PrP (PrP 27-30) can be weakly demonstrated by immunoblotting; usually this is confined to the thalamus and temporal lobe. The average age of onset is 48 years and it lasts for about 18 months before death (range: 7-33 months) which is preceded by motor disturbance, wasting, and coma. Most, but not all, cases are familial with an autosomal dominant pattern.

Insomnia: (see text) difficulty initiating or maintaining sleep, or poor sleep quality; may be due to poor sleep hygiene⁴¹² (too much noise, caffeine [e.g. in chocolate], worry, heat, stuffy room, uncomfortable bed, etc; Espie, 1993), psychiatric disorders (e.g. anxiety disorder, agitated depression, etc), physical illness (, pain, age (need less sleep with age), jet lag, shift work, etc.

Jactatio capitis nocturna: Usually occurring at the start of sleep in infants, there is rhythmic head rocking (or banging) or, less commonly whole body rocking. Management involves measures to prevent injury. Clonazepam is used for severe cases.

Kleine-Levin syndrome (recurrent hypersomnia): rare disorder described by Kleine, 1925, and Levin, 1929; mostly affects adolescent males; periods of excessive eating (if food is put in front of them), sleeping and sexual activity lasting days or weeks; patient remains rousable and wakes spontaneously to eat, go to the toilet, etc; irritability (aggression sometimes), confusion, depression, elation, and visual and auditory hallucinations may occur; malaise, anorexia, and headache may follow attacks; little or none of the attack is recalled; most patients have 7-8 attacks and are well thereafter, i.e. it often improves with maturation (duration of disease is about 4-8 years: Gadoth ea, 2001); may have hypothalamic origin (Thompson ea,

⁴⁰³ Buspar was withdrawn, December 2009.

⁴⁰⁴ A number of factors may be responsible: illness, medication, dental hygiene, and lifestyle.

⁴⁰⁵ Hypersomnia (tendency to fall asleep during the day) should be differentiated from fatigue.

⁴⁰⁶ Imipramine (Tofranil), withdrawn 2006.

⁴⁰⁷ Ropinirole, a selective dopamine receptor agonist used for treating Parkinson's disease, can cause confusion and hallucinations.

⁴⁰⁸ Pramipexole, a dopamine agonist, may cause sedation, nausea, and hallucinations but has a reduced tendency to cause dyskinesia. It has antidepressant properties (including in Parkinson's disease) and may induce mania.

⁴⁰⁹ AKA fatal progressive insomnia with dysautonomia or familial thalamic degeneration.

⁴¹⁰ **Prion:** most basic of infectious agents; a single protein molecule with no nucleic acid; can catalyse conformational change in PrP (an endogenous protein) leading to changes in structure and function (i.e. disease): endogenous PrP^c is converted to the protease-resistant isoform PrP^{res}.

⁴¹¹ After some months the patient cannot sleep at all but may experience episodic stupor and enact dreams. Whilst conscious cognition is unremarkable. Persistent insomnia occurs in the last 1 or 2 years before death.

⁴¹² Clock-watching worsens insomnia. Clocks should be hidden or faced away from the sleeper.

1985); may follow acute viral infection; the experience of hunger is variable; EEG sometimes shows mild, diffuse abnormality, e.g. excess delta activity; however, EEG characteristics of sleep are normal. Similar disorders have been described in association with pathology in the midbrain and diencephalon. The syndrome has been treated with psychostimulants, SSRIs, MAOIs, or lithium.

Nocturnal paroxysmal dystonia: During sleep, especially stage 2, the patient awakens and experiences violent, uncontrollable movements. Much sleep is lost as a result. Treatment involves taking low dose carbamazepine.

Oneiroid psychosis (Gk.: dream, *oneiros*): described by W Mayer-Gross in schizophrenia; the patient feels and behaves as if in a dream; perplexity and disorientation are likely; may experience ecstasy and rapidly shifting hallucinations; while giving most of attention to an unreal world the sufferer is remains aware of the real world, e.g. while believing that one is flying one avoids walking in front of traffic.

Pickwickian syndrome: obesity; apnoea; short (seconds) bouts of CO₂ retention; EEG shows waking pattern or first 2 phases of N-REM sleep; uncommon cause of sleep apnoea.

*REM-sleep behaviour disorder*⁴¹³: recognised as a distinct condition in 1986 although lesions near the locus coeruleus in animals were already known to cause non-atonic REM sleep; increased frequency among elderly and in males; 'act out' their dreams with eyes closed and non-responsiveness to the environment; nocturnal vocalisation and violent limb movements; loss of normal REM-related atonia; reported in association with narcolepsy and with SSRIs, TCAs, MAOIs, and venlafaxine; treat with clonazepam (Schenck ea, 1987), carbamazepine, or donepezil. (Neylan ea, 2003, p. 987) Other suggested treatments include clonidine, melatonin, and pramipexole. It may be the presenting symptom of multiple system atrophy. (Plazzi ea, 1997) Parkinson's disease patients may develop REM-sleep behaviour disorder, sleep attacks (narcoleptiform; occur especially in those with general sleepiness and in those taking dopamine agonist drugs), restless legs, periodic limb movements, and an abnormal sleep-wake cycle. (Schrage, 2005) REM-sleep behaviour disorder may precede dementia with Lewy bodies by years. (Ericksen & Tsuang, 2007, p. 477) Multiple system atrophy, dementia with Lewy bodies, and Parkinson's disease are synucleinopathies and may be associated with REM-sleep behaviour disorder. As pointed out by Pivik (2002) motor inhibition can vary in degree during REM sleep, so movement of the sort reported in REM-sleep behaviour disorder is not impossible.

Shift work: If a person who normally sleeps at night naps early in the day they will experience an excess of REM, but a nap later in the day is associated with much less REM. People can readjust from a 24-hour pattern to a 36-hour or 18-hour pattern over a month or so. Shifts that rotate are more disruptive than fixed shift patterns. Shift workers do not adjust, especially as they age (presentation is usually after a number of years of shift work or because jobs or lives are put at risk). The fact that night shift workers may unknowingly fall asleep more often than day workers has significant safety implications. (Akerstedt, 1995) The main complaints are feeling unrefreshed, feeling sleepy, unable to sleep when required, and poor work or driving performance. An excess of depression and of anxiety has been reported in shift workers who undergo regular changes in their sleep-wake cycles. (Gordon ea, 1986) A major problem is lack of catch-up sleep during days off because of social reasons. There is some evidence that shift work (including airline personnel) increases the risk for cancer⁴¹⁴, especially cancer of the breast. (Fritschi, 2009) Use of melatonin in shift workers does not seem to be effective. (Arendt ea, 1995; Neylan ea, 2003, p. 985) Modafinil taken an hour or less before a night shift or a short-acting hypnotic for daytime sleep may be necessary. Extreme cases may need to change jobs. It is advisable that employers move their workers to progressively later shifts (phase delay) than *vice versa*.

Sleep paralysis: can be normal or part of the narcoleptic syndrome; can occur at least once in one-quarter to one-half of the general population, but as a chronic condition it has a prevalence of only 3-6% (Pivik, 2002); cannot move for brief time on waking. Some sufferers are able to indicate their distress with mini-movements or noises. If sleep paralysis occurs on falling asleep it is designated as predormital, and if it occurs on awakening it is called postdormital. Predormital sleep paralysis is much more likely to be due to narcolepsy than is the same phenomenon occurring on waking. Some patients complain of a crushing

⁴¹³ False reliance on alleged REM-sleep behaviour disorder as a defence in court would not be expected to pass polysomnography testing.

⁴¹⁴ If this is true, what is the mechanism? Depressed production of melatonin by light, depressed immune function by corticosteroids, changes in cell/tissue proliferation control mechanisms, lifestyle (smoking, alcohol, and lack of exercise), and reduced vitamin D production are contenders.

sensation in the chest or of feeling some ominous presence nearby (hence the word 'night-mare' – a heavy woman crushing the body). Sleep paralysis is exacerbated by alcohol. African Americans have an elevated risk of sleep paralysis.(Friedman & Paradis, 2002) *Night nurse paralysis* refers to the classic onset of sleep paralysis in a person recovering from night duty (or an all-night party). Sleep paralysis may sometimes be aborted by a bed partner touching the paralysed muscles.

*Snoring*⁴¹⁵: snoring is due to supralaryngeal soft tissue vibration; weight should be reduced in cases of obesity, and tobacco smoking and alcohol should be avoided.(Rees, 1991; Parker ea, 2005) The sleeping partner may find ear plugs helpful. Lying on ones side instead of one's back helps; tying an empty thread reel or tennis ball to the back of the pyjama top is a time-honoured ritual. Sleep nasendoscopy (flexible nasendoscope in sedated snorer) may indicate source of vibration. Nasal congestion, if present, should be attended to. Tonsillectomy, for large tonsils, may cure some cases. A mandibular advancement device may help in cases of a receding lower jaw (retrognathia). Uvulopalatopharyngoplasty and radiofrequency softening of the soft palate are specialist procedures. Thyroid dysfunction and sleep apnoea should be considered in the differential diagnosis.

Somniloquy (sleep-talking): common in children and adults; can occur in any sleep stage; usually difficult to decipher what is said; longer sessions concern daytime preoccupations; do not reveal dream content and most unlikely to reveal secrets, contrary to popular opinion; may sometimes be associated with somnambulism or night terrors.

Sundowning: onset or exacerbation of delirium during evening or night, with improvement or disappearance of delirium during the day; increases during winter months because of less available natural light.(Bliwise ea, 1989)

Jet lag (JL): The traveller who crosses a number of time zones finds that the circadian pacemaker tries to maintain the phase set to the time zone of departure. The symptoms of JL include tiredness, difficulty in initiating sleep and in awakening, mood disturbance, anxiety, poor concentration, and, in some cases, gastrointestinal upset. To compensate, some travellers use a short half-life hypnotic for a few nights after arrival at their destination. If travelling east it is advised that melatonin should be taken in the late afternoon for one day before the flight and for 4 days at local bedtime after the flight to achieve an advance phase shift. Phase delay occurs after travelling west if post-flight melatonin is taken for 4 days at local bedtime.(Arendt ea, 1995) However, controlled studies of melatonin therapy in JL are negative.(Neylan ea, 2003, p. 985; Buscemi ea, 2006) According to Leonard,(2003, p. 144) the 5-HT₂ antagonist ritanserin may improve sleep quality in JL sufferers. Alcohol should be avoided on such journeys and the traveller should attempt to adopt the sleeping schedules of his/her destination.

Sleep apnoea: Most cases are undiagnosed (Ancoli-Israel ea, 1991) and may be mistaken for depression⁴¹⁶. It may affect about 25% of people over 65 years of age, the classic case being a fat man with a fat neck⁴¹⁷. Not all cases are obese, in which case there is excess fat in the nasopharynx or enlarged tonsils. There are recurring episodes of apnoea and hypopnoea during sleep.(West ea, 2009) Severe oxygen desaturation may develop which may cause serious ventricular arrhythmias⁴¹⁸. Most cases are due to intermittent obstruction of the upper airways but there is a central form due to intermittent failure of the central respiratory drive during sleep.⁴¹⁹ In the obstructive type the patient makes strong efforts to overcome the block, even to the point of *paradoxical breathing* when chest and abdomen move in opposite directions. In central cases there is no attempt to initiate thoraco-lumbar respiratory effort. Mixed apnoeas may be the commonest type – here a central apnoea precedes an obstructive apnoea. The chief symptoms of sleep apnoea are loud

⁴¹⁵ The uncommon condition of *cathathrenia* or **sleep-related groaning** occurs during inhalation whereas snoring occurs during exhalation. Cathathrenia occurs in the last hours of sleep, especially during REM or deep sleep, and does not appear to be due to stress. The partner may find it disturbing and might wish to wear ear plugs. There is limited evidence for the efficacy of CPAP (see sleep apnoea).

⁴¹⁶ Fatigue, hopelessness, and low libido are common to both conditions.(Ancoli-Israel ea, 1991)

⁴¹⁷ Craniofacial anomalies (e.g. micrognathia), Down's syndrome, adenoidal/tonsillar hypertrophy, stroke, hypothyroidism, myotonic dystrophy, COPD, and Shy-Drager syndrome (one cause of laryngeal abductor failure) are also associated with apnoea.

⁴¹⁸ Severe sleep apnoea is an independent risk factor for ischaemic CVA in older people.(Munoz ea, 2006)

⁴¹⁹ The **central type** (known as *periodic breathing* if there is hypopnoea instead of apnoea) is due to respiratory centre dysfunction secondary to diminished cardiac output associated with cerebrovascular disease. Symptoms resemble those of the peripheral/obstructive type. It may lead to hypertrophy and fibrosis of heart muscle, declining cardiac function, arrhythmias, hypertension, and CVA.

snoring, daytime drowsiness⁴²⁰, and, in childhood, enuresis. Other symptoms include unrefreshing sleep, restlessness or choking during sleep, morning headache and drunkenness, reduced libido, and ankle oedema. Boring activities may induce attacks. Long distance lorry drivers are often overweight and suffer from obstructive sleep apnoea. Transient, mild sleep apnoea may occur during pregnancy. The road traffic accident (RTA) rate of patients with obstructive sleep apnoea is up to 7 times greater than that of normal drivers. The condition resembles hypertension in that there is a continuum from normality to severe abnormality. (Stradling, 1989) Physical examination may show obesity, narrowing of the upper airway⁴²¹, and, rarely, disorders of the brain stem. The main complications are nocturnal arrhythmias, hypertension⁴²², and, again rarely, polycythaemia and cor pulmonale. Patients with sleep apnoea may represent problems for anaesthetists, especially after nasal surgery when packs are used. (den Herder ea, 2004)

The best treatment, not often achieved, is weight reduction. (Peppard ea, 2000) Nasal continuous positive airway pressure (CPAP⁴²³) is effective but may be cumbersome. CPAP treatment of sleep apnoea in patients with heart failure reduces systolic blood pressure and improves left ventricular function, (Kaneko ea, 2003) and reduces the risk of serious cardiovascular events. (Marin ea, 2005; Bradley & Floras, 2009) If the patient remains sleepy during the day despite CPAP a trial of modafinil (Provigil) may prove beneficial. Other approaches include sleeping in lateral or face up position, avoiding respiratory depressants (alcohol - probably causes hypotonia; hypnotics), correcting any anatomical abnormality of the upper respiratory tract⁴²⁴, losing weight (Johansson ea, 2009), muscle tone improvers such as theophylline or protryptiline or respiratory stimulants like acetazolamide, and, rarely, bypass of obstruction with tracheostomy.

Patients with sleep apnoea or chronic obstructive pulmonary disease who are hypoxic tend to have greater oxygen desaturation during REM sleep; by reducing REM, protryptiline may be helpful in such cases. (Moxham & Costello, 1994) SSRIs are helpful in some cases, independent of any REM effect. (Doghranji, 1998) Indications for treatment in mild elderly cases include excessive sleepiness, cognitive impairment, or associated cardiorespiratory abnormalities. (Prinz ea, 1990) A dramatic resurgence of REM sleep may occur early during effective treatment of sleep apnoea.

Garrigue ea (2002) point out that many patients with sleep apnoea have nocturnal bradycardia, paroxysmal tachyarrhythmias, or both. Permanent atrial pacing can prevent these. They found that those patients who received atrial overdrive pacing at a rate of 15 beats/min above baseline rate had a significant decrease in the number of episodes of central or obstructive sleep apnoea without reducing total sleep time. This procedure might work by reversing excess vagal tone.

Sleep apnoea may be more common in children than was thought heretofore. (Stores, 2000) Most cases are not obese, children may be overactive by day, apnoeic events are less frequent and of shorter duration than in adulthood, and enlarged tonsils and adenoids are a common underlying cause.

Sleep-related laryngospasm

Episodes of abrupt interruption of sleep with sensation of suffocation followed by stridor

Can exhaust the sufferer

Aetiology obscure but some cases seem to be caused by gastro-oesophageal reflux and may respond to treatment of this disorder

Cheyne-Stokes respiration

Impaired respiratory centre response to CO₂

Associations: left ventricular failure, CVA, cerebral atherosclerosis, head trauma

⁴²⁰ **Daytime sleepiness** can be measured with the *Epworth Sleepiness Scale*. (Johns, 1991) The scale poses certain scenarios (e.g. sitting and reading) and asks the patient to score 0-3 for the likelihood of becoming sleepy during them. A score > 9 on a 0-24 scale is abnormal (sometimes confusingly expressed as 5 +/- 4). E.g. severe obstructive sleep apnoea might score 16 and narcolepsy might give a higher score.

⁴²¹ Tonsils, S-shaped nasal septum, myxoedema, acromegaly, micrognathia. In acromegaly there an increased serum somatomedin-C level and failure of serum growth hormone levels to be suppressed to < 1 ng/ml after an oral glucose load.

⁴²² A (CARDIA) study has shown a positive relationship between reduced sleep duration and increased systolic and diastolic blood pressure. (Knutson ea, 2009)

⁴²³ **Bilevel positive airway pressure (BPAP)**, an alternative approach, is different in that pressure is higher during inspiration than expiration.

⁴²⁴ Tonsillectomy. Laser-assisted uvuloplasty [LAUP], performed under local anaesthetic, has largely replaced uvulopalatopharyngeoplasty, which required a general anaesthetic. Dental devices to prevent mandibular collapse or tongue protrusion during sleep.

Exacerbating: sleep, sedative/hypnotics, opioids
 Cycles of slowly decreasing in breathing leading to apnoea – increasing respiration (hyperventilation)
 Hyperventilation associated air hunger and panic

Nightmares, or bad dreams, occur during REM sleep. There is very little associated movement because of reduced muscle tone. (Yousaf & Sedgwick, 1996) If a child has a nightmare he will either wake up spontaneously or be awakened with ease by those looking after him. He will vividly remember what he was dreaming about, which often reflects some daytime event or preoccupation. Occasional nightmares are unimportant. Nightmares may accompany nocturnal hypoglycaemia, the partner noticing that the patient is sweaty and restless during sleep and the patient complaining of hangover and headache next morning. Nightmares may be troublesome in some survivors of disasters, e.g. the famous Coconut Grove nightclub fire of 1942 in Boston. (Adler, 1943) Many drugs have been reported to cause vivid dreams and nightmares⁴²⁵. Abrupt withdrawal of baclofen, a muscle relaxant, may precipitate delirium. Rehearsal of a repetitive nightmare may cause it stop if it is given an imaginary happy ending, so-called elimination of the threat through mastery. (Davis, 1985) Hartmann *et al* (1987) examined lifelong sufferers and reported raised scores on the 'psychotic' side of the MMPI and on the 'boundary deficit' score of Rorschach; there was also an excess of first and second degree relatives with nightmares, psychological problems, and psychiatric in-patient treatment.

*Night (sleep) terrors*⁴²⁶ and *somnambulism*⁴²⁷, occur during stage 4 of N-REM sleep⁴²⁸ and tend to occur early at night (within 2 hours): sleepwalking is most likely to occur within two hours of falling asleep⁴²⁹. Both conditions are strongly familial⁴³⁰, may be associated with daytime anxiety/stress, and can be provoked by centrally acting drugs⁴³¹. Somnambulism may occur in patients with bipolar affective disorder on a combination of lithium and an antipsychotic agent. (Cookson, 1998) Zolpidem has been reported to be associated with somnambulism. (e.g. Madden *et al*, 2009) Children with either terrors or somnambulism are very difficult to waken⁴³², are confused and do not remember⁴³³ what happened. In sleepwalking, the subject, who has a blank stare, sits up and makes repetitive movements or, less commonly, walks or goes to the toilet and urinates; standing the child during stage 4 may induce walking. In a night terror, the child appears to wake in great fear but is, in fact, asleep; there may be dramatic screaming, agitation, sweating and tachycardia. They affect 3% of children between 1 and 14 years of age, are uncommon in adults, and occur only in predisposed people who usually have a family history of sleep problems. In content, 'terrors' usually involve falling, being trapped, attacked, or choking. Somnambulism may rarely be associated with violence toward others. (Oswald & Evans, 1985) An erect penis would serve as evidence against somnambulism in forensic cases. Stairs, fires and other potentially dangerous items should be made secure for somnambulists⁴³⁴. The child should not be roused from a terror as this will prolong the attack and leave the child confused. Therapy for *severe* cases aims at lightening stage 4 sleep with a tricyclic antidepressant (TCA) or a benzodiazepine (BZD), particularly clonazepam. One report of success with paroxetine was contaminated by early co-prescription of clonazepam (Lillywhite *et al*, 1994) but paroxetine does seem to be effective and often more quickly than any antidepressant action could account for. (Wilson & Nutt, 2008, p.

⁴²⁵ E.g. reserpine, beta-blockers, clonidine, indomethacin, alpha-methyl dopa, verapamil, baclofen, famotidine, nalbuphine, pergolide, stanozolol, nicotine (patches), digoxin (toxicity), and withdrawal from hypnotic drugs such as BZDs, alcohol, barbiturates, and opiates. Note that pergolide (and carbergoline) are ergot derivatives and may cause serosal reactions (e.g. retroperitoneal fibrosis) and pergolide has been implicated in restrictive valvular heart disease.

⁴²⁶ *Pavor nocturnus* in children, *incubus* in adults.

⁴²⁷ Sleepwalking.

⁴²⁸ Both disorders can be exacerbated by sleep deprivation. (Morin & Edinger, 2007, p. 614)

⁴²⁹ The same applies to sleep-talkers.

⁴³⁰ And concordance is greater in monozygotic than in dizygotic twins. Pockets of high prevalence of night terrors and somnambulism have been discovered, e.g. in the descendants of Welsh people who emigrated to Patagonia. (Wilson & Nutt, 2008, p. 53) Familial somnambulism may be associated with excess of DQB1*05 and DQB1*04 haplotypes (DQB1 genes are also associated with narcolepsy and REM sleep behaviour disorder).

⁴³¹ Lipid soluble beta-blockers, some TCAs, and some BZDs. Alcohol may precipitate night terrors and somnambulism. Shift work, alcohol, neuroleptic drugs, stimulants, and antihistamines may induce somnambulist episodes.

⁴³² Whereas nocturnal panic attacks call full awakening.

⁴³³ Unlike nightmares, which are recalled.

⁴³⁴ Unfamiliar environments carry intrinsic dangers, e.g. the not uncommon situation where a person sleeping in a hotel falls out of the window presuming it to be a door (as at home)! (Wilson & Nutt, 2008, p. 54)

55) Clonazepam may cause daytime hangover. Other suggested treatments for night terrors have included propranolol. Night terrors are benign⁴³⁵ and usually resolve within a few years, but can be very distressing. Lask (1988) suggested that parents note the timing of night terror episodes on 5 successive nights, and the presence of any signs of autonomic arousal (e.g. tachycardia). The child is then roused for 10-15 minutes prior to an episode (use autonomic arousal as timer if it is difficult to time the onset of the terror). Five minutes later the child is allowed to sleep again. This regime is continued until the terrors stop; in many cases the terrors stopped within one week; if there is a recurrence, then the treatment is continued for another week. Lask suggests that this approach can also be used for sleepwalking on its own. Apparently, it interrupts faulty slow wave sleep.

Older children with terrors may be helped by relaxation treatment or hypnosis.

Some children with terrors have medical problems (reflux, periodic limb movements, sleep-related breathing difficulties) that need attention. Sleepwalking with onset after childhood may be associated with stress, personality problems, (Sours ea, 1963; Calogeras, 1982) or medication. Sleep deprivation, migraine, head trauma, stroke, encephalitis, and hyperthyroidism can also precipitate somnambulism.

*The narcoleptic syndrome*⁴³⁶ consists of narcolepsy, cataplexy⁴³⁷, sleep paralysis, and hypnagogic/hypnopomic hallucinations⁴³⁸. The full 'tetrad' is found in under one-tenth of cases of narcolepsy. Nocturnal sleep fragmentation⁴³⁹ and even insomnia are other aspects of the syndrome. Extremely short (seconds) micro-sleep periods may occur that are not noticeable to either patient or onlooker. Total sleep duration per 24 hours is not increased in narcoleptic subjects.

Cataplexy: Laughter, anger or surprise may precipitate cataplexy⁴⁴⁰, a paralysis of voluntary muscles; the patient, whose jaw and head drop and whose knees become weak, may fall to the ground, mute but fully awake; sufferers are often awake during brief cataplectic episodes, whereas longer episodes merge with sleep and the EEG shows REM phase characteristics. Prolonged attacks may be accompanied by visual hallucinations. Cataplectic attacks may be focal/partial⁴⁴¹ or generalised. The affected parts may twitch as muscle tone gradually returns. The condition responds to TCAs like clomipramine, but the SSRIs are preferred because of their side effect profile. There is some evidence for efficacy for mirtazepine and venlafaxine. Sudden cessation of antidepressants should be avoided because of the potential danger of precipitating episodic or continuous cataplexy⁴⁴².

Rare cases of familial cataplexy without narcolepsy have been reported.

*Narcolepsy*⁴⁴³: Narcolepsy usually begins in childhood or early teens (age range: 5-70, rare after 40). The commonest victim is a young male. About one in 2,500 of the population have narcolepsy⁴⁴⁴, a disorder of REM inhibition: the sufferer enters REM sleep on falling asleep; sleep-onset REM periods have also been reported in depression, sleep apnoea, disturbances of the sleep-wake schedule, drug and alcohol withdrawal, and some structural brain lesions.

Suggested diagnostic criteria for narcolepsy

Average sleep latency of < 5 minutes
REM onset within 5 minutes of falling asleep
CSF hypocretin-1 level < 110 pg/ml

⁴³⁵ Cases starting beyond childhood are thought sometimes to be early harbingers of temporal lobe epilepsy.

⁴³⁶ Or *Tetrad of Gelineau*, after the French physician, Jean-Baptiste-Édouard Gelineau (1859-1906), who described it in 1880.

⁴³⁷ By right, narcolepsy should be narcoplexy (Gelineau confused catalepsy and cataplexy, as do many modern practitioners).

⁴³⁸ 25-30% of narcoleptics have such hallucinations: auditory, visual, or occasionally somatic.

⁴³⁹ Many awakenings.

⁴⁴⁰ Cataplexy may be exaggerated by enjoyment, fatigue, poor sleep, sporting activity, coughing, sneezing, sexual activity, or simply blowing ones nose.

⁴⁴¹ E.g. head dropping, object dropping, knee weakness, or double vision from involvement of neck, hand, or external eye muscles.

⁴⁴² *Status catalepticus* comprises continual cataplectic episodes over hours. It can be spontaneous or evoked (by the emotional response to cataplexy itself or by stopping antidepressant treatment for cataplexy). Cataplexy is similar to the atonia of REM sleep. (Dauvilliers ea, 2007)

⁴⁴³ Term first used in 1880 by Gelineau.

⁴⁴⁴ Doherty ea (2010), who believe that narcolepsy is 'hugely under-diagnosed' in Ireland, give a prevalence of 25/100,000. The Japanese may have a higher susceptibility to narcolepsy. (Morin & Edinger, 2007, p. 611)

Controversially, Douglass *et al.* (1991) believed that about 7% of patients with 'schizophrenia' really had narcolepsy. However, schizophrenia-like disorders do appear to be more common in narcoleptics than in the general population. (Davison, 1983) and narcoleptic patients with hallucinations may be misdiagnosed as having schizophrenia. (Aldrich, 1990; Haba-Rubio, 2005) Hyde and Lewis, (2003, p. 190) believe that the 'association between narcolepsy and psychosis most likely reflects a side-effect of amphetamines used in treatment, rather than the disease itself'. Langdon *et al.*, (1984) found that all of 37 patients with narcolepsy expressed the major histocompatibility complex antigen HLA (human leucocyte antigen) DR2⁴⁴⁵ compared with 21.5% of 200 normal controls, linking narcolepsy with the short arm of chromosome 6. (Langdon *et al.*, 1984) More specifically, almost 100% of cases are associated with DQB1-0602 and DQA1-0101 HLA antigen genes. (Mignot *et al.*, 1994) Forty to eighty percent of patients with multiple sclerosis are DR2 positive, as are 20% of the British white population. One to two percent of typical narcoleptics do not have the DR2 haplotype, although related findings are found on analysis of restriction fragment length polymorphisms. In general, it can be said that HLA DR2 and DW2 haplotypes are markers for narcolepsy. (Hobson & Silvestri, 1999) These findings suggest the possibility of an autoimmune process. Six candidate genes for narcolepsy discovered in a genome-wide association study (Shimada *et al.*, 2010) are NFATC2, SCP2, CATNA1C, TCRA, POLE, and FAM3D.

Most cases of narcolepsy appear to be sporadic. (Linkowski, 2002) although such cases may have an underlying genetic susceptibility. Westphal, in 1877, reported narcolepsy occurring in a mother and son. Since then familial narcolepsy has been described; some dog breeds (e.g. Doberman pinchers) suffer from familial narcolepsy; narcoleptic phenomena also occurs in mice. Focal lesions of the posterior hypothalamus are a rare cause of narcolepsy.

Orexins/hypocretins⁴⁴⁶ are novel neuropeptides produced in the lateral hypothalamus⁴⁴⁷. Orexin is involved in the sleep-wake cycle and CNS arousal.⁴⁴⁸ Canine narcolepsy (autosomal recessive with full penetrance⁴⁴⁹) is associated with mutations in the orexins/hypocretins receptor-2 gene.⁴⁵⁰ Hypocretin-1 levels are reported as very low or undetectable in the CSF of narcoleptics (Nishino *et al.*, 2000; Dalal *et al.*, 2001), the serum concentration of the same substance has been reported to be normal in such cases. (Dalal *et al.*, 2001) and postmortem studies of narcoleptic patients have shown a loss of orexin-containing cells in the peri-fornical hypothalamus. (Thannickal *et al.*, 2000) The cause of hypocretin cell loss is unknown. (Dauvilliers *et al.*, 2007) Knockout mice⁴⁵¹ lacking orexins/hypocretins show episodes of behaviour arrest. The same neurones that produce orexins/hypocretins in mice are activated by modafinil. (Taheri & Hafizi, 2002) Modafinil may inhibit the dopamine transporter. (Wisor & Eriksson, 2005)

Two parts of REM sleep occur separately while one is awake: muscle atonia and presleep dreaming. Narcolepsy is essentially an overpowering desire to sleep. Short episodes of sleep are repeated frequently and, with time, such naps may become less restorative and nocturnal sleep may become disturbed. Sleep can occur at awkward times or in dangerous places. During an ordinary night's sleep the narcoleptic is prone to myoclonus, broken sleep, and pulse and breathing abnormalities. Patients may have disturbing dreams and may complain of sensing a 'presence' in the room. Narcoleptics have problems at work, in marriage, in industry, and in traffic throughout life. There is a tendency to increased BMI and even obesity. (Schuld *et al.*, 2000)

Some cases experience episodes wherein they continue an activity but do so less efficiently, e.g. writing muttering, gibberish, or missing turns when driving; on recovery, the sufferer has no recall for the events that transpired during the episode.

⁴⁴⁵ Also called HLA DRw15.

⁴⁴⁶ Orexin was demonstrated in brain in 1998; in fact, orexins and hypocretins are the same, but were discovered by different researchers independently: orexins A and B are also known as hypocretins 1 and 2 respectively.

⁴⁴⁷ With projections to the monoaminergic and cholinergic parts of the ascending reticular activating system.

⁴⁴⁸ Release of hypocretin increases during waking hours, more so if the person is active. Levels also rise during REM sleep but reach a nadir during non-REM sleep.

⁴⁴⁹ Penetrance is the probability of manifesting a phenotype given a particular genotype.

⁴⁵⁰ Two hypocretin receptors, hcr-1 and -2, have different affinities for the 2 hypocretins.

⁴⁵¹ Mario Capecchi, Martin Evans and Oliver Smithies won the 2007 Nobel prize in physiology or medicine for their work on knockout mice. Knock-out, knock-in, and traditional transgenic mice are genetically engineered mice with genetic material removed from a particular locus, inserted into a particular locus, and randomly inserted (not into a particular locus) respectively.

Frequent daytime naps may reduce the need for stimulant drugs.(Aldrich, 1990) Amphetamines⁴⁵² or methylphenidate (Ritalin; a piperazine derivative of amphetamine) are used in treatment These agents were assumed to show a 'paradoxical' calming effect in children (barbiturates, but not antipsychotics, may stimulate children) but this mechanism seems unlikely.

Gamma-hydroxybutyrate (sodium oxybate) has been used for insomnia in narcolepsy⁴⁵³ but it has to be taken a number of times during the night; it has been abused by athletes (increased slow-wave sleep increases growth hormone secretion) and alcoholics,(Caputo & Zoli, 2007) and as a euphoriant.(Nishino ea, 1998) It is helpful for daytime somnolence and sleep attacks and cataplexy.(Littner ea, 2001)

Modafinil (Provigil, 100 mg and 200 mg tablets), a new non-amphetamine stimulant with possibly low abuse potential or tendency to induce tolerance,(Buguet ea, 1995; Anonymous, 2004) 200-400 mgs./day (100 mgs./day in elderly) in divided doses (morning and noon), can cause severe renal and hepatic impairment, suggesting that lower doses (100-200 mgs./day) may be safer. Interestingly, it is not recommended for children. It should be used with care in anxious patients. Blood pressure and heart rate should be monitored in hypertensives. Modafinil, the first specific compound for narcolepsy, should be avoided in people with left ventricular hypertrophy or ischaemic ECG changes, chest pain, arrhythmia, or mitral prolapse. Modafinil induces cytochrome P-450 isoenzymes⁴⁵⁴ so that at least 50 µg of ethinyloestradiol needs to be given in anovulants to prevent contraceptive failure⁴⁵⁵. Like St John's Wort, modafinil may lower cyclosporine levels. Although adverse data is lacking, caution is advised with co-prescribed TCAs. Care should also be taken when combining modafinil with anticonvulsants. Adverse effects of modafinil include anxiety, agitation, aggression, central stimulation, headache, insomnia, anorexia, abdominal pain, nausea, gastric discomfort, dry mouth, palpitation, tachycardia, and tremor. Occasionally a pruritic skin rash appears, and very rarely one may encounter buccofacial dyskinesia. Psychotic symptoms attributable to amphetamines may abate when the dose is lowered or the medication is changed to modafinil.(Vourdas ea, 2002) Interestingly, an actigraphic⁴⁵⁶ study in schizophrenia recorded increased motor activity attributable to modafinil.(Farrow ea, 2006)

*Periodic leg/limb movements*⁴⁵⁷: In this disorder there are abrupt stereotypic and periodic flexion of the legs and feet associated with repeated awakenings throughout the night. Incidence appears to increase with age. It does not occur during REM sleep. Feet may be very hot or cold. Sleep apnoea is a common accompaniment. Antidepressants, including SSRIs, can exacerbate the condition.(Buysse ea, 1996) Dopaminergic drugs, including short term L-DOPA use, and carbamazepine are helpful. Eighty percent of patients presenting with restless legs syndrome also have periodic limb movement disorder.

*Sleep starts*⁴⁵⁸: Brief benign sudden limb or neck movements occur on falling asleep. A person awakened by hypnic jerking may experience *siderealism* (feeling as if falling in space). A similar picture may be caused by nocturnal or fragmentary myoclonus and hyperekplexia syndrome (startle disease⁴⁵⁹).

Idiopathic hypersomnolence is the commonest of the primary hypersomnias. The patient cannot wake up fully for hours after rising. He remains confused and disorientated, so-called sleep drunkenness, and complains of prolonged and deep nocturnal sleep. Many sufferers have diurnal periods of automatic behavior. Small doses of a stimulant are helpful. Most patients are DR2 positive, suggesting a genetic relationship with narcolepsy.

Menstrual-related hypersomnia involves excessive daytime sleepiness for some days prior to menstruation. It may improve with anovulants.

Painful legs, moving toes: Continuous unilateral pedal sinusoidal flexion-extension with ipsilateral leg pain whilst awake, with continuation during sleep at a reduced intensity, usually associated with peripheral nerve lesions such as in the lumbar roots. *Painful arm, moving fingers* is a similar disorder.(Verhagen ea, 1985)

⁴⁵² Which may potentially stunt growth by speeding up epiphyseal crossing: monitor child's height.

⁴⁵³ As Xyrem in the US.

⁴⁵⁴ 1A2 and 3A4 induction and inhibition of 2C isoforms.

⁴⁵⁵ A second non-hormonal method of contraception can be suggested.

⁴⁵⁶ **Actigraphy** uses a piezoelectric movement detector (actometer) worn like a wrist watch and allows recording of information for up to four weeks.

⁴⁵⁷ Formerly called *nocturnal myoclonus*.

⁴⁵⁸ *Hypnagogic* or *hypnic jerks*.

⁴⁵⁹ A rare disorder in which myoclonus follows minor stimulation during sleep or whilst awake.

Circadian rhythm sleep disorders can be divided into delayed sleep phase syndrome, advanced phase syndrome, non-entrained type, irregular sleep-wake type, and shift work type (QV).

Delayed sleep phase syndrome: This circadian rhythm disorder may affect up to 10% of insomniacs attending sleep disorders clinics. It typically starts in adolescence or young adulthood and is often familial. The patient cannot get to sleep until after everyone else and, if allowed, sleeps on that much later. Structural polymorphisms on one of the haplotypes of the period-3 gene *hPER3*) have been implicated in this disorder: a long allele favours morning preference and a short allele favours evening preference. Hypnotics are generally ineffective, only producing drowsiness. Bright light exposure in the morning and light restriction in the evening may help. There have been positive reports for melatonin and for vitamin B12.

Where sleep phase is *advanced* (*advanced sleep phase syndrome*) treatment is by evening exposure to bright light. Some such cases are due to a mutation in the period-2 gene on chromosome 2q⁴⁶⁰.

The phase-response curve (PRC) to melatonin is about 12 hours out of phase with the PRC to light. (see box)

In the *non-entrained circadian rhythm sleep disorder* (see *hypernyctohemeral* or *non-24-hour-day* or *free-running syndrome*) there is a progressive delay of the sleep period over days. It was originally described in the blind but can occur in the sighted.

The *irregular sleep-wake type of circadian rhythm sleep disorder* was described in physically sick people who spent years in bed and were socially isolated. However, it is more likely to be seen in association with intellectual disability, brain damage, and dementia. There is an absence of any pattern to sleeping and waking, patients sleeping for a few hours at irregular intervals. This may lead to complaints of poor sleep and tiredness.

Bright light v melatonin (Dagan & Borodkin, 2005)

Bright light in the morning causes phase advance

Bright light in the evening causes phase delay

Melatonin in the morning causes phase delay

Melatonin in the evening causes phase advance

Interpersonal and social rhythm therapy (IPSRT: Swartz & Frank, 2008) is aimed at helping patients regulate their social rhythms and to manage interpersonal relationships in the hope of reducing the risk of developing depressive and manic moods. Three strategies are interwoven in IPSRT: interpersonal psychotherapy (e.g. managing role transitions), psychoeducation (e.g. daily mood ratings and information about the illness), and social rhythms therapy (e.g. adapting to changes in routine and searching for triggers that disrupt rhythms). The therapist 'blames' the mood disturbance and not the patient for the latter's dysfunction and suggests that (as well as psychosocial stress) predisposed people may be made more vulnerable to mood disorders by disruptions in circadian rhythm. The interpersonal psychotherapy (IPT) component includes an exploration of the dynamics of relationships with past and present 'important others' in the patient's life. In addition to areas normally included in IPT the IPSRT therapist seeks 'grief for the lost healthy self' (e.g. the person I would have been without the illness and how can I adapt to having a chronic disorder). The 'social rhythm metric' is a paper record of daily activities and help needed in doing things chronically by the patient. The therapist recommends very gradual re-scheduling of activities such as time of going to bed, e.g. 5-minute extensions.

6

Basic sciences⁴⁶¹

Brian O'Shea

'There is nothing wrong with wanting to make the world a better place, but utopianism has its dangers'. (LeFanu, 1999)

'Most of life is qualitative: we use numbers simply to facilitate our understanding of it, not to define it'. (Duffin, 2000)

Psychology

Psychology, the *scientific study of behaviour and mental processes*, is discussed only briefly here; aspects of medical psychology will be discussed as they arise throughout the text.⁴⁶²

Perception is the active, automatic process whereby patterns of sensory stimuli are changed by the nervous system into a conscious experience. Knowledge and experience are then brought into play in order to bring meaning to what is experienced. The brain maintains perceptual constancy by combining what is experienced via the senses⁴⁶³ with previous knowledge. However, our interpretations of what we experience via the senses is open to bias from preconceived ways of thinking and classifying (schemata). Figure-ground differentiation is a classic example of how the same sensory data can be interpreted differently depending on what part of an image one chooses to emphasise: the famous (central) chalice/goblet and (peripheral) faces (looking at one another) that adorn so many psychology texts. Lower cognitive ability measured on enlistment into military service at mean age 20.4 years was associated with increased risk of depression, generalised anxiety disorder, alcohol abuse or dependence, and post-traumatic stress disorder assessed by structured diagnostic interview at mean age 38.3 years. (Gale et al, 2008)

Grades of intellectual disability by IQ⁴⁶⁴

⁴⁶¹ There follows an overview of some basic science issues of special interest to psychiatrists. Prescribing for the pregnant and nursing mother is discussed here for convenience. When reading North American literature, the reader should be aware of spelling (e.g. foetus versus fetus), abbreviation (e.g. hs means nocte in the US), and name (e.g. paracetamol versus acetaminophen, or adrenaline versus epinephrine) differences from what are found in these islands. Trade names may differ entirely or by as little as one letter from one country to another. Pharmacologists use the words uptake and reuptake interchangeably. Neurotransmitter typing changes rapidly and no book can claim to be up to date.

⁴⁶² The interested reader is referred to Atkinson et al (1996), Gross (1996) and Mowbray and Rodger (1978)

⁴⁶³ Often partial information, unusual views of objects, varying distance from objects, body movement, etc.

⁴⁶⁴ **Some examples of genetically determined disorders associated with intellectual disability** (do not expect full syndrome in every individual case):

Fragile X syndrome: dysfunctional FMR-1 gene at Xq27.3 (trinucleotide repeat: CGG); most common inherited cause of intellectual disability (1 in 4,000 boys – *Down's syndrome is genetic but is not inherited*); moderate to severe intellectual disability, long face, prominent forehead and jaw, large ears, macro-orchidism, hypotonia, seizures, ADHD, pervasive developmental disorder, affected females can show full severity range; tremor-ataxia in boys; premature ovarian failure in girls.

Fragile X syndrome.

Turner's syndrome: 1/3,000 female births (others are miscarried); females with only one X chromosome; gonadal dysgenesis (no secondary sexual characteristics), infertile, short stature, webbed neck (congenital lymphoedema), broad flat chest, bicuspid aortic valve, coarctation of aorta, hypothyroid, kidney problems, difficulties with vision and hearing, problems with doing more than one task simultaneously, poor social skills, poor at mathematics, 90% have IQ in normal range, and depression as adults.

Mild – IQ 50-70 (80% of cases)

Moderate – IQ 35-49 (12%)

Severe – IQ 20-34 (7%)

Profound – IQ < 20 (< 1%)

Distribution of Intelligence

IQ = (mental age/chronological age)X 100. Average IQ = 100 (< 70 = intellectual disability; > 130 = superior). The left side of a graph showing IQ in a population is higher than the right side. People represented by the extreme left side usually have pathological causes for low IQ. Those with higher IQs than the 'pathological' group are affected by many genes acting in concert and also by sociocultural deprivation. People with mild intellectual disability account for 2% of the population, those with lower IQs accounting for only 0.4%.

Because IQ measurement error is 5 points it is possible for someone with an IQ of 75 to be intellectually disabled if he/she is unable to adapt to demands. Likewise, a person with an IQ of 65 might be sufficiently adaptive to negate a diagnosis of intellectual disability.

Intelligence tests

Tests used should correlate strongly with overall intellectual function⁴⁶⁵ or involve batteries that specifically assess intelligence⁴⁶⁶.

Problems

- based on a particular population that was used originally to standardise the test, e.g. the WAIS was originally based on Americans between 16-64 years of age; the WAIS-R-UK is an adaptation for British use although many norms are still American
- personality variables such as motivation and persistence
- inability or refusal to concentrate
- fear of failure
- confusion
- anxiety, depression, etc

Uses

- to measure degree of intellectual behaviour
- to detect specific learning deficits and assets
- to detect organic brain lesions
- to follow progress of intellectual deterioration⁴⁶⁷
- research, e.g. effects of diet, environment or other factors on IQ
- To detect influences of IQ on risk of developing psychiatric illness⁴⁶⁸

Klinefelter's syndrome: 1/600 live male births; often recognised at puberty; affects males with one or more extra X chromosomes (sex chromosomes fail to separate at meiosis); shy, lacking in confidence, tall stature, long legs, small testes, gynaecomastia, infertile, low testosterone/high FSH and LH, increased rate of ADHD and some aspects of psychosis (e.g. hallucinations).

Williams syndrome: microdeletion at 7q11.23; elfin facies, short stature, stellate iris, pulmonary artery stenosis and other cardiac defects, mild-severe intellectual disability, good verbal ability, reduced response of amygdala to new faces, somatisation, narrow interests, and obsessiveness.

Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency): The condition arises from mutations in the DHCR7 gene (11q13.2-q13.5) that makes 7-dehydrocholesterol reductase, an enzyme involved in the first step in cholesterol synthesis. Cholesterol is needed for normal development of the embryo and is part of the structure of cell membranes and is found in myelin. It is also important in the synthesis of some hormones and gastrointestinal acids. The infant is hypotonic, has feeding difficulties, and grows slowly. Syndactyly and, less often, polydactyly may be found, as may anomalies of various internal organs. There is a distinct facies (e.g. broad nose, small lower jaw, and low-set ears), microcephaly, and a low IQ and behaviour problems.

Smith-Magenis syndrome: microdeletion at 17p11.2; mild-moderate intellectual disability, broad, square-shaped facies, prominent forehead, deep-set eyes, short nose, tenting of upper lip, relative prognathism, short hands/fingers/feet, deafness, hypotonia, skeletal problems, impulsiveness, poor sleep, temper tantrums, aggressiveness, pull own nails and pick at skin, self-hugging, and stereotypies.

Duplication 15: extra chromosomal material within chromosome 15 (mainly 15q11-14) or as separate mass; findings vary with amount of duplicated material and paternal origin of abnormal and normal chromosomes; infantile spasms, ataxia, hypotonia, genitor-urinary problems, low IQ, pervasive developmental disorder; may have Angelman syndrome (happy disposition, developmental delay, severe intellectual disability, seizures, ataxia) or Prader-Willi syndrome.

⁴⁶⁵ E.g. the *National Adult Reading Test* (NART) or the *Wechsler Test of Adult Reading* (WTAR).

⁴⁶⁶ E.g. the *Stanford-Binet Intelligence Test* or the *Wechsler Intelligence Scales*.

⁴⁶⁷ Lack of multiple versions of the WAIS can lead to misleading results if the test is repeated too soon after a previous session.

⁴⁶⁸ Koenen et al (2009) found lower childhood IQ was associated with increased risk for schizophrenia spectrum disorder, adult depression, adult anxiety, greater comorbidity and persistence of depression and possibly of generalised anxiety disorder, and

Self-esteem (a personal sense of efficacy, self-regard, hope, and confidence) is developed from infancy onwards. Parents accept and admire their babies which allow infants to begin to develop a sense of self-value. If youngsters are required to perform tasks that are outside their capabilities they will fail at the task, will not receive positive feedback and self-esteem suffers.

Paternal influences on the psychosocial development of children may have been relatively neglected by researchers. Most paternal psychiatric disorders increase the risk for behavioural and emotional problems in their offspring, probably to a similar degree to that stemming from such disorders in the mother. There is some indication that sons may be more adversely affected than daughters and that behaviour may be more disturbed than emotions. (Ramchandani & Psychogiou, 2009) Pathways for risk transmission include genes, poor parenting, and effects on the mother. Of course, paternal effects are modified by other variables such as child factors (age, sex, and temperament), maternal parenting and psychopathology, degree of paternal presence, and economics.

Personality is discussed elsewhere. Jean Piaget⁴⁶⁹ (see box), described four stages of cognitive development in children: sensorimotor (so-called because sensory impressions are closely linked with motor activity – starts with reflex gaze and grasp in newborn and ends with attempts at thinking about a problem at up to two years), preoperational (symbolism to metacognitive representational regulation at 8 years), concrete (from classification to simultaneity at 9-11 years – concreteness is well illustrated by asking a child to relate a joke: limited grasp of nuances impairs the ability to do so), and abstract reasoning (hypothetical deductive logic, etc).

Piaget's developmental stages

Sensorimotor – 0-2 years – information received via senses and motor activity – no reflective or conceptual thinking – knows an object as something that can be manipulated in certain ways

Preoperational – 2-6 years – development of symbolism (including language) – one object can stand for another object – egocentric (chiefly sees matters from own viewpoint and assumes others feel and think in the same way as does the self) – can only consider one dimension (e.g. confuses volume and height of liquid in different receptacles)

Concrete operational – 7-11 years – can understand and use logic; interprets objectively instead of intuitively; can use multiple perspectives; uses concepts e.g. conservation (such as preservation of volume despite moving liquid between receptacles of different heights), taxonomy (classification, e.g. houses, animals), and seriation (e.g. arranging objects by size) – still mostly confined to consideration of that which is tangible

Formal operations – 11 years onwards – can think abstractly and consider hypotheses; can look at a variety of outcomes/possibilities; absolutism gives way to relativism; can grasp motivations and principles; can apply principles to solve new problems

Piagetian theory has been modified over the years (researchers are now better at couching tasks in age-friendly ways) and it is now accepted that children can understand more than they can say. (Shapiro & Hertzog, 2003) Piaget also considered moral development. At first everything is black or white, wrong or right, and rules are not to be questioned. Later on the child understands that strict adherence to a rule might have adverse consequences. Finally the child understands fairness and reciprocity.

Memory involves registration (storage is not guaranteed), storage (retrieval is not guaranteed) and retrieval (possible only if information has been stored). Psychologists divide memory into sensory (lasts little longer than the stimulus producing it), short-term (a small number, averaging 7, pieces of information, held for up to half a minute), working memory (more complicated than short-term memory and is required for the carrying out of complex cognitive work), and long-term memory (potentially limitless information held for

increased risk of adult mania. Is this explained by premorbid low IQ as an integral part (including consequence) of early illness (or tendency to same), low IQ among carers, or poor coping powers (leading to referral)? Urfer-Parnas et al (2010) in a Danish draft-board study found that all future individuals hospitalised with (various) mental disorders had lower premorbid IQs than controls and in each diagnostic category decreasing IQ was associated with increasing risk of becoming a patient (odds ratios 0.5-2.5 over the full IQ spectrum).

⁴⁶⁹ Piaget (1896-1980) was a Swiss psychologist.

very long periods of time). Semantic memory involves information such as one's first language whereas episodic memory is concerned with personal data.

Lesion studies in monkeys suggest that various parts of the prefrontal cortex⁴⁷⁰ are required for the performance of different tasks that test working memory. (Liddle, 2001, pp. 30-32)

In order to retrieve information it must have been stored in some accessible and logical manner. One can use recall in the relative absence of cues, i.e. one actively searches for an answer⁴⁷¹. We may recognise a correct answer from a list of possible solutions without being able to generate it in the absence of the list. Relearning what has apparently been forgotten usually takes less time than was the case at the first attempt. 'Re-constructive' memory is a term applied when a person retells a story learned from someone else; as it passes on details tend to change. This is well known to criminal lawyers! Redintegration refers to the triggering of memory traces when one hears a certain sound or experiences a particular smell⁴⁷². Retrieval of information may be aided by context (e.g. revisiting the site of a crime) or state (e.g. remembering what happened when last intoxicated with alcohol when again in an inebriated state).

Theoretically, stored information may be unavailable because of so-called passive decay (chemical or structural changes), distortion of information, or interference (two similar stored items create confusion). These theories of 'forgetting' are just that: theories.

Cognition and growing old (Anderson, 2008)

Changes are mild but a large industry has grown up selling 'cures': *Ginkgo biloba*, procaine products, Nintendo puzzles, etc

Older people react more slowly than do younger subjects

The more demanding the situation the greater the difficulty in coping – unfamiliar tasks⁴⁷³, having to think through a problem, and having to come up with strategies cause the most problems

Two types of intelligence: fluid and crystallized (Horn & Cattell, 1967)

Fluid intelligence – use of reason to find structure in a problem and apply appropriate strategies to solve it

Crystallized intelligence – use of learned methods of solving tasks

Verbal IQ (depends on crystallized intelligence) preserved better than performance IQ (depends on fluid intelligence) with ageing

Older people are less flexible and strategic in their thinking – less able to abstract structure from a problem and at employing feedback to grasp rules and concepts

Novelty is more of a challenge

Preservation of problem-solving when over-practiced skills are required

Preservation of immediate memory (e.g. telephone number) and established bank of knowledge

Reduced ability to learn new information that can be recalled later – performance on paired associate⁴⁷⁴ learning tests of Wechsler Memory Scale declines gradually from mid-life

Support (cues) during learning improves formation of long-term memory

The more difficult the test the more obvious will be deficits in recognition tests

Naming difficulties are more likely with uncommon words and proper nouns: tip of the tongue phenomenon

⁴⁷⁰ The **prefrontal cortex** (PFC) does not function in a vacuum. It has important interconnections with the striatum, thalamus, and the medial temporal lobe, so that lesions in these areas (e.g. amygdala) or disconnection from these areas may mimic PFC lesions. The PFC may be divided into orbitofrontal (important in regulating emotional activity), medial prefrontal, and dorsolateral (DLPFC) cortices. The medial prefrontal cortex (MPFC) sends input to, among other areas, the periaqueductal gray (PAG) and stimulation of the lateral column of the PAG (by excitatory amino acids) leads to raised heart rate and blood pressure and diminished pain perception (part of the 'attack mode'). The ventral MPFC has been dubbed the *visceromotor cortex* because of its effects on cardio-respiratory and alimentary function. The ventral MPFC is activated at rest and deactivated during cognitive tasks which suggests that it has a role in monitoring the body's internal state during rest. Craving for a drug of abuse induced by environmental cues (e.g. a room where the drug was consumed in the past) appear to be transmitted to the nucleus accumbens shell via the MPFC. The DLPFC is important for working memory.

⁴⁷¹ If a patient gives accurate answers with the help of prompting the likelihood is that he has a problem with retrieval (fronto-subcortical circuitry) rather than a storage (hippocampal) problem.

⁴⁷² The author has noticed the same in relation to drawings or paintings he has done in the past – looking at them brings back a flood of memories surrounding the time of the drawing/painting.

⁴⁷³ Alzheimer's disease also affects familiar and practiced skills and knowledge.

⁴⁷⁴ Two paired words, e.g. 'sponge-trumpet'. Easier pairs have been introduced since the original test was developed, e.g. 'knife-fork'.

Greater difficulties in following conversations involving multiple participants, especially when the topic is not familiar

Reduced spatial intelligence from mid-life onward – increased difficulty in heavy traffic or an unfamiliar shop – these are probably influenced by demand on memory

Working memory, an elaboration of short-term memory, is used in solving and understanding problems, i.e. brief storage of information in the service of current cognitive activity; a limited amount of data is kept immediately accessible for current employment or manipulation. It consists of an articulatory/phonological loop that holds data in mind by using sub-vocal speech, a visuo-spatial scratch pad that maintains data as visual images, and a central executive that directs ‘slave systems’ such as the visuo-spatial scratch pad (the inner eye) and the articulatory (phonological) loop (‘inner voice’). The central executive appears to occupy the dorsolateral prefrontal cortex (DLPFC) and the anterior cingulate (ACC)⁴⁷⁵ and the slave systems lie posterior to the central fissure: parietal (spatial), temporal (language/knowledge) and occipital (visual) lobes. Cognitive changes in old age might be a consequence of a disruption in the ACC/DLPFC network⁴⁷⁶.

Neuropsychological assessment⁴⁷⁷ involves applying standardised measures to define the relationship between suspected brain impairment and associated behavioural and cognitive accompaniments. Many instruments are used in this endeavour, e.g. the age-appropriate *Wechsler Intelligence Scale* and the *Halstead-Reitan*⁴⁷⁸ *Neuropsychological Test Battery*. The present *Halstead Impairment Index*, a global measure of brain dysfunction, looks at abstract reason (Category Test), a Tactual Performance Test (blindfolded patient places blocks into holes in a board), fine motor speed (Finger Tapping Test), ability to distinguish musical rhythms (Rhythm Test), and a Speech Sounds Perception Test (after hearing nonsense words on an audiotape the patient underlines printed response on answer sheet).

Motivated behaviour, by definition, has a purpose and is directed at a specific goal. It has been ‘explained’ by theorists varying from the humanists who write about self-actualisation to the psychoanalysts (unconscious drives), behaviourists (learning/reinforcement), cognitive theorists, and neurophysiologists. Primary drives (e.g. hunger) are necessary for mere survival and will force one to behave in a way that satisfies those drives (e.g. foraging for food). Secondary drives are those that are said not to satisfy a physiological need; play is often given as an example of a secondary drive but play teaches the animal many skills that may be necessary for efficient functioning and hence survival. Behaviour is in fact much more complicated than any of our attempts to explain it.

Girls are said to be more sociable and interested in others, whilst boys may be more content to play alone. It has been suggested that these characteristics are exaggerated in schizophrenia and contribute to the higher frequency of negative symptoms in male cases. (Castle & Murray, 2002)

Learning theory concerns the behavioural underpinnings of learning, the latter relating to more or less enduring changes in behaviour that can be observed objectively. Learning arises from experience and is not innate. In *classical (respondent or Pavlovian) conditioning* there is the pairing of two stimuli, usually a reflex (e.g. salivation on smelling food) with a neutral response. Ivan Pavlov’s dogs at first only salivated (unconditioned response, UCR) when given food (unconditioned stimulus, UCS). A bell (conditioned stimulus, CS) was paired with sufficiently often that it eventually elicited salivation (conditioned response, CR) on its own (without food being presented). Stimulus generalisation occurs where a similar conditioned stimulus generates the same conditioned response, as when different bells elicit salivation. If the bell is presented on a sufficient number of occasions without the presentation of food it will lose its power to elicit

⁴⁷⁵ See Andreescu et al. (2009): anxious depressed elderly use the ACC more intensely than do elderly with depression only when performing a cognitive task designed to activate these brain areas.

⁴⁷⁶ In old age, reduced performance appears to be related to under activation of DLPFC and overactivity of the temporal and inferior frontal cortices (word recognition/speech). Activity may not be task-focused and distractibility is relatively common. There is frontal volume loss, demyelination, and reduced synaptic density as well as diminished lateralisation of hemispheric function. Fronto-striatal circuits (involving thalamus and basal ganglia) may also play a role in executive function and the speed of thinking. (Hedden & Gabrieli, 2004)

⁴⁷⁷ **Factors that may affect results of neuropsychological tests** include the effort expended by the patient (motivation), the premorbid ability of the patient, education, occupation, experience, psychic distress, psychiatric disorder (e.g. depression, anxiety), medication (e.g. benzodiazepines), somatic health, and factors in the tester (qualifications, experience, scoring or interpretation errors). (Simon, 2005, p. 599) For an introduction to cognitive assessment see Hodges. (2007)

⁴⁷⁸ In 1947, Ward Halstead of Chicago published work on many patients with frontal lobe damage. In 1955, Ralph Reitan, Halstead’s pupil, modified Halstead’s battery to include laterality, to measure aphasia, and to take account of aging effects.

salivation, so-called *extinction*. Removal of the subject from the experiment following extinction for some hours will lead to recommencement of salivation, *spontaneous recovery*⁴⁷⁹. Skinner, influenced by fellow-American Edward Thorndike⁴⁸⁰, developed *operant (instrumental or Skinnerian) conditioning*, i.e. an animal⁴⁸¹ (or person) *operates on* the environment and the behaviour is instrumental in leading to consequences. If every time a dog presses a level it receives a pellet of food it will be more likely to repeat the behavior than if no food was received. Reinforcers are stimuli that increase the chances of a behavioural response happening before their presentation and can be primary (stimuli meeting biological needs, e.g. thirst) or secondary (one has to learn their value – they are not inborn, e.g. financial reward).

Reinforcement may be positive (pleasant) or negative (removal of an aversive stimulus such as an electric shock). Punishment (e.g. giving an electric shock every time an unwanted behaviour occurs), on the other hand, is less effective in *shaping* (reinforcement of successive approximations what is desired) behaviour. There are a number of possible reinforcement schedules: continuous (every time the response occurs it is reinforced), partial (only some responses are reinforced), fixed interval (regular reinforcement, e.g. every X seconds), fixed ratio (a fixed number of responses are reinforced), variable interval (regular but unpredictable reinforcement), and variable ratio (regular reinforcement but with a change in the number of required responses with each sitting). The last two, variable interval and ratio are powerful forms of reinforcement, it being very difficult to extinguish the new behaviour. Pathological gambling is sometimes explained as stemming from lack of ability to predict the next win (variable ratio reinforcement schedule) but this tells us more about why the behaviour is maintained rather than why it starts in the first place.

Observational learning, championed by Bandura⁴⁸², is learning by observing (*modelling*) rather than doing and is of great importance in child development. *Insight learning*, championed by Kohler, states that learning is a cognitive process and not dependent on the simple trial and error implicit in stimulus-response theories of Pavlov and Skinner. Normal adults can override conditioning (lose the CR) if they are informed that the unconditioned stimulus will not occur; otherwise the CR would extinguish slowly. Language is on the side of the adult, a fact reflected in the current trend toward cognitive-behavioural instead of pure behavioural approaches.

Anthropology

The Concise Oxford Dictionary defines anthropology as '*the study of mankind, esp. of its societies and customs; study of structure and evolution of man as an animal*'. Foulks, ea (1977), and Keshaven, ea (1989) are useful sources on anthropological psychiatry.

A person lives within a culture and is expected to live by its rules. Psychopathology *per se* causes considerable personal and socio-economic disability across cultures.(Ormel ea, 1994) Delusions are influenced by culture; they may be highlighted or partially hidden by different cultures. Psychoanalysts, such as Jung, drew extensively on cultural myths in their thinking and writings about the evolution and behaviour of men. On the other hand, to say that someone is from a particular country, although subject to stereotyping, tells us very little about him. Comparisons between cultures of the epidemiology and manifestations of various psychosocial variables and disorders are of help in increasing our understanding of such dysfunctions as long as both the cross-sectional and longitudinal diagnoses are fundamentally similar⁴⁸³. Witness the claim for a better outlook, in the sense of a low relapse rate, for schizophrenia in developing countries, and the dispute as to whether some cases diagnosed as schizophrenia should in fact be diagnosed as brief reactive or acute and transient psychoses.(Susser ea, 1995) Poor tolerance levels, high expressed emotion (EE) levels, or environmental demands might affect western schizophrenic patients adversely.(O'Shea, 1997) Urban Indians with schizophrenia, when compared to those in Cincinnati, were

⁴⁷⁹ The extinction of CS is suppressed rather than eliminated – this may go some way to explaining why abstinent addicts resume drug use when re-exposed to the drug. Other 'explanations' include memory, hedonism, peer pressure, emotional immaturity, etc.

⁴⁸⁰ Thorndike worked with 'puzzle boxes' and found that a stimulus-response connection was 'stamped in' if an animal received pleasure from an act and was 'stamped out' if no pleasure followed the act, the so-called *law of effect*.

⁴⁸¹ Originally rats in Skinner's experiments. There is no conditioned stimulus in operant conditioning: no stimulus is presented before an operant response that led to the behaviour.

⁴⁸² Bandura's **social learning theory** posited that there were cognitive mediating variables (e.g. self-esteem, self-monitoring, and self-efficacy) between a stimulus (S) and a response (R), i.e. the 'black box' was active. It was simply S – R but rather S – Cognition – R. Pathological gambling might start when a (vulnerable?) person observes others gambling and be maintained by variable ratio reinforcement scheduling.

⁴⁸³ Yang and Link (2009) suggest that difference in prevalence rates of disorders between studies may be explained by response rates since mental disorders may be more prevalent in non-responders.

more often married, employed, cared for by their families (versus community mental health services), and more compliant with drug therapies.(Dani & Thienhaus, 1996) Attendance at a day centre may mitigate the effects of high EE relatives.

Members of the same culture share many things in common, e.g. beliefs, attitudes, and ways of evaluating and categorising. Similarly, members of the same culture usually describe perceived stimuli with the same words. Cultural beliefs such as possession by ghosts should not automatically lead to a diagnosis of psychiatric disorder. The meaning of the experience for the patient and the community should be ascertained from the family, using a local interpreter if required.(Jadhav, 1995)

Institutions may contain a therapeutic atmosphere or they may breed dependence. Lack of independent social activity within a mental hospital is largely a result of a complex interaction of the social atmosphere and the incapacity of illness. Mental illness exists in all cultures, albeit in modified form. The poorer, less educated sectors of society in developed countries, and a much larger part of Third World populations, tend to shun psychological explanations and presentations of their distress and to express it in somatic terms, as if 'a weight on my shoulders' became 'a pain in my neck'! Porter (2001, p.86) points out that the word pain is derived from the Latin for punishment (*poena*), a notion at least as old as the Bible which 'construed pain as the penalty for disobedience'.

Various cultures believe in non-medical causes of mental illness, such as witches, spells, sorcery, breaches of taboo, soul loss, and possession by demons.(Last, 2004; El-Adl ea, 2008) An element of this is to be found in all of us. Hence the success of the horror movie, the persistence of certain avoidance behaviours like not walking under a ladder or, in women, not wearing green to a wedding, and the employment of lucky charms such as a rabbit's foot. Folk healers abound in most cultures; e.g. 'cures' handed down by grandparents, the seventh-son-of-a-seventh-son, and shamans. Quite often such healers are noted for some personal characteristic, such as disfigurement, great age, or scholarship. Much ritual is involved, often involving a participating public audience. The depth of belief in the efficacy of such interventions is illustrated by the fact that a sick shaman will seek the help of a fellow shaman.(Magner, 1992, p. 9) In Africa, the mentally ill are sometimes required to live for long periods at the healer's home.(Karim ea, 1994) *Rootwork* (e.g. voodoo rootwork) refers to a belief that illness is caused by a curse/spell/hex/evil eye, witch, sorcerer, or some other ill-intentioned person. Some cultures shun doctors in favour of local healers while others may utilise both.(Cole ea, 1998)

Illnesses, mental or physical (e.g. tuberculosis), were, and sometimes still are, often seen as been sent directly by God, sometimes as punishment for the sins of relatives. The Irish call the mentally handicapped the 'Children of God'.

It is not unusual for a patient to seek help from a doctor, a priest, and a faith healer simultaneously or at different stages of his illness. The Church sometimes practices exorcism, although much less often today. The concept of Original Sin holds that we are prone to sickness because of the sin of our First Parents. It is increasingly important that we try to understand and get on with faith healers, as long as the health of our clients is not harmed thereby.

When making a diagnosis in someone from another culture certain confounding variables should be borne in mind.(Littlewood & Lipsedge, 1988) Among these are selective pattern of migration; experience of migration and 'status' striving in a climate of low opportunity; culturally determined response to adversity; patterns of service utilisation (non-recording of birthplace may confuse hospital admission statistics); and diagnostic accuracy of our techniques when applied to other cultures. Longitudinal studies of immigrant populations are essential.

According to Bhugra and Ayonrinde,(2004) susceptibility to mental disorder among migrants can be divided into vulnerability (biology, psychology, social skills deficits, forced migration, persecution, negative life events, bereavement, culture shock, cultural conflicts, and discrepancy between what is achieved and what it was hoped would be achieved) and protective (psychology [e.g. resilience], high socioeconomic status, voluntary and adequately prepared migration, strong cultural/ethnic identity, and social support/networks) factors, both being divisible into those operating before, during and after migration. Family dysfunction and migration have been reported to interact in the histories of children and adolescents with psychosis.(Patino ea, 2005)

People with severe mental disorders who are caught up in a disaster setting may have their condition exacerbated by stress, lack of medication, and loss of normal social support.(Jones ea, 2007) The most important intervention is to see to their basic needs.

Mental health problems in *refugees*⁴⁸⁴ are discussed by Saraceno *et al.* (2002). The most commonly reported disorders are post-traumatic (PTSD), mood, anxiety, and adjustment disorders. It is to be expected that many refugees would show suspicion, excess vigilance, anxiety, and fearfulness. Psychoses and disorders of childhood and adolescence (PTSD, depression, anxiety, conduct disorder) are also prevalent. Some authors suggest that PTSD is over-diagnosed in refugees and that a grief model may often be more appropriately applied. Religious faith, political beliefs and being psychologically prepared are protective. Information is lacking on exactly when psychotic states start in refugees, i.e. before or after becoming a refugee. Longterm follow-up of Vietnamese refugees in Norway (Vaage *et al.*, 2010) suggests that self-reported psychological distress may decline significantly over time but that a substantial number still have symptoms after almost a quarter of a century of resettlement. *Koucharang*, a culture-bound syndrome found in Cambodian refugees, is defined as excessive thinking following exposure to traumatic events. *Bebatchel* is a depressive state found among the same people under similar circumstances. Children absorb a new culture quicker than do their parents, a fact that may lead to their being required to handle social problems for their elders.

Problems associated refugee status

Problems in old country:

Threat to lives/security of self/loved ones
 Loss of relatives, friends, community, property, occupation, physical health
 Trauma including torture, rape, head injury (perhaps with epilepsy)
 Forced dislocation, concentration camp experiences
 Precipitation/exacerbation of mental disorder

Problems in new country:

Detention⁴⁸⁵
 Insecure residency⁴⁸⁶, adaptational problems, racial discrimination, poverty, poor housing, unemployed⁴⁸⁷, barriers to accessing services, family disruption/violence
 Precipitation/exacerbation of mental disorder: anxiety, depression, grief, dissociation, somatisation, impulsivity, substance abuse
 Cultural transference/countertransference⁴⁸⁸

Abbreviated version of 'The Mental Health Service Requirements for Asylum Seekers and Refugees in Ireland' of the the College of Psychiatry of Ireland, March 2009⁴⁸⁹

The asylum process needs to be rigorous in order to be fair to legitimate asylum seekers. Many genuine cases are treated as economic migrants. Asylum seekers are placed in a position of dependency on others. Their skills and qualifications may atrophy, because they are barred from employing them. This can contribute to loss of self-worth. As self-esteem declines they can become less assertive in seeking basic human rights and necessary medical health care. A Dutch report found that if the asylum process was extended beyond two years there was a doubling of psychiatric illness. Insecure residency and associated fears of repatriation contribute to persistence of psychiatric symptoms and associated disabilities. The RCPsych recognised 3 main areas of state action needed in relation to asylum seekers and refugees: a stated and enacted public policy that minimises the impact of social risk factors for physical and mental illnesses; equitable access to a full range of health, social care and legal services (both for ease of access and to ensure that individual needs are delivered in a coordinated manner services are best provided together at a designated centre); public bodies should deliver such care to standards required by national and international law. In 2002, the Irish Psychiatric Association (IPA) recognised that treatment of asylum seekers is highly specialised and involves particular skills not normally found in conventional mental health settings. This is especially so for asylum seekers who have experienced torture. The IPA recommended that services should be improved so that adequate and appropriate mental health interventions could be delivered to this vulnerable group stating. The policy of dispersing asylum seekers around Ireland to avoid ghetto formation and to hasten integration into the wider community may unwittingly lead to the social isolation of asylum seekers. This may aggravate any underlying mental health difficulties. Asylum

⁴⁸⁴ The 1951 *UN Refugee Convention* defined a refugee as an 'eligible' person who seeks foreign asylum because of a legitimate fear of persecution because of ethnicity, race, political affiliation or religion, at home. Immigrant refugees may be kept in such miserable conditions in the host country (Anonymous, 2010) that it would be surprising if they went unscathed.

⁴⁸⁵ This appears to have negative effects on mental health and there is evidence of some (but incomplete) improvement following release. (Robjant *et al.*, 2009)

⁴⁸⁶ Particularly high levels of depression have been associated with being an illegal Hispanic in the USA. (Oquendo *et al.*, 2004)

⁴⁸⁷ E.g. qualifications may not be recognised.

⁴⁸⁸ Positive or negative transference/countertransference based on perceptions of the other person's ethnic background, e.g. excessive curiosity or suspicion, or excessive therapist anger as a reaction to past trauma experienced by the patient.

⁴⁸⁹ Original document prepared by Izu Nwachukwu, David Browne, and John Tobin on behalf of the Faculty of Adult Psychiatry, College of Psychiatry of Ireland.

seekers have little say in where they are placed. They can become dislocated with little chance to develop social networks. They may be forced to live in accommodation with asylum seekers of other nationalities with whom they share little in common. Such geographical spread impedes development of expertise in the treatment of asylum seekers.

The *Irish Times* (May 5, 2008) reported that there were 6,844 asylum seekers living in 62 accommodation centres around Ireland in April 2008. Their asylum seeking status precluded them from obtaining work. They were provided with accommodation, food and €19.10/week. As they await the results of the protracted process of being granted asylum they are caught in a situation of dependency and idleness that can erode self-esteem. This may lead to substance abuse as a consequence of boredom and may aggravate underlying mental health problems that may exist. Current arrangements for asylum seekers in Ireland leave them in a situation of controlled poverty. 2,798 immigrants were held in Irish prisons during 2003 and 2004. Two-thirds of those imprisoned were held there in excess of 51 days during 2004. *SPIRASI*, a non-profit, non-charging agency accredited by the International Rehabilitation Centre for Torture Victims, is attempting to fill the void in service provision for asylum seekers. *SPIRASI* treated 892 victims of torture from 66 different countries during 2007. Because of current financing stringencies they now confine referrals to North-East Dublin. *SPIRASI* (in their communications with the College of Psychiatry of Ireland) has emphasised the need for a professional network of interpreters and the requirement to train staff in how to work with interpreters. They have noted a tendency among the medical profession to inappropriately diagnose asylum seekers as mentally ill because of a lack of cultural awareness.

In a questionnaire prepared by the Irish College of Psychiatry in 2008 (completed by 57 consultant psychiatrists) the great majority of respondents recognised that asylum seekers were a particularly difficult group to treat and most felt they were insufficiently resourced to cater for specific needs in this area. Because of the complexity of such cases a higher level of mental health assessment and care is needed than is the norm. This complexity arises from language barriers, problems with obtaining suitable translators, a lower level of trust among asylum seekers when dealing with authority, time constraints, and cultural barriers to talking about areas such as being victims of torture, intimidation, physical/sexual/emotional abuse.

Half of the respondents felt that asylum seekers were over-represented at their community mental health clinics relative to their actual number within their catchment areas. There was a willingness to prepare the necessary medico-legal reports required for the asylum process and to provide the best quality service that they could deliver. They believed that the HSE did not recognise that asylum seekers had special mental health needs and the necessity of the extra resources required. Clinics were already overburdened and under-resourced in caring for the current indigenous population. There felt that they did not have adequate resources to liaise with outside agencies with responsibility for asylum seekers. There was an acceptance that the psychiatric reports that they were already providing require a high input of time and effort. The need to collect collateral information and adequate and appropriate translation services placed high demands on clinical time. There was consensus that special skills are needed and that transcultural psychiatry must be developed further.

Recommendations: 1. Consultant led multidisciplinary teams with special interest in mental health of asylum seekers and refugees to be established in the major urban centres. 2. Special interest section on transcultural psychiatry should be established within the College of Psychiatry of Ireland. 3. The College or other appropriate organisations should provide training courses on the preparation of psychiatric reports on asylum seekers. 4. There must be rapid access to mental health care and high quality social and legal services for unaccompanied minors. 5. Prisons should not be used as places of detention for people with legal difficulties related to their immigration status.

Some important terms are defined in the box.

Some useful terms

Acculturation: assumption of characteristics of larger or more advanced society.

Acculturation problems: difficulties in adapting to a different culture or environment that cannot be attributed to a coexistent mental disorder.

Actualisation: realisation of one's full potential.

Alloplastic adaptation: adapting by changing the environment (alloplastic = externalised).

Assimilation: total absorption in the larger society, and therefore calling for greater change than in acculturation.

Autoplastic adaptation: adapting by changing own behaviour and responses.

Culture: a set of values, norms, beliefs, and understandings common to a human group.

Cybernetics (Gk. for steersman): study of control systems and communications in animals and machinery.

Ecology: science of organisms as effected by their environment; human ecology applies ecological principles to the study of human societies.

Ethnicity: a person's sense of belonging to a human group who share the same origin, history, and culture.

Ethnography (Gk. *ethnos*, race): examination of written records, folk tales, myths, language, key informants, life histories, questionnaire surveys, psychological tests, and participant observation in order to study cultural forms.

Ethology: study of animal behaviour, including its origins; classically studied in natural settings, but increasingly performed in experimental situations; associated with the Austrian Konrad Lorenz (1903-88), Karl von Frisch (1886-1982) and Nikolaas Tinbergen (1907-88), a Dutch zoologist based in Britain.

Multiethnic countries: an example is the USA; however, the values of the white middle class predominate (WASP: White Anglo-Saxon Protestant).

Sun dance and spirit dance: practices of certain Native American tribes to focus on personal, group, ancestral and behavioural issues; those engaged in the spirit dance must abstain from drugs and alcohol. *Sweat:* water is poured over hot rocks in a confined place by Native Americans; the resultant steam is used for prayer, cleansing and healing.

Sociology⁴⁹⁰

'The more a form of behaviour deviates from current social norms the more likely are its perpetrators to differ from the rest of the population'. (Sims, 1992)

'...governments are dependent on their electorates, who too often resist the allocation of more services and resources to poor families and communities'. (Heath, 2002)

'The key to promoting youth mental health is through strengthening of the fundamental nurturing qualities of the family system and community networks while explicitly acknowledging the rights of young people'. (Patel et al, 2007)

The Concise Oxford Dictionary defines sociology as the *'science of the development and nature and laws of human (esp. civilized) society; study of social problems.'* It is the study of how groups of people organise themselves.⁴⁹¹ Man is a social animal.⁴⁹² He has a uniquely long period of dependence and immaturity⁴⁹³.

Western adolescents are expected to walk a thin line between responsibility for the self (individuation) and being responsible to their elders. In many 'underdeveloped cultures, the transition to adult responsibility is less obvious. Early relationships are extremely important in determining how the final product, the adult, functions. Highly developed Western societies have more nuclear (parents and immediate offspring only) than extended (grandparents and other relatives) families; this, and broken relationships, significantly reduce the available pool of family carers. (Drury, 2005)⁴⁹⁴

Starting at home with his parents, the child begins to view himself as others do, to learn what he is permitted to do and what is frowned upon, and to learn how to act in concert with others as part of a group. We all assume or are designated roles within society. Such roles are a function of biology (e.g. father), education (e.g. barrister), and the needs of the self (e.g. patient) or of society (e.g. military conscript). These roles may be partly or completely a result of our own choice, e.g. priests, redundant labourer. However, even when they seem to be wholly our own doing they may have been primed by numerous other factors acting independently of us, e.g. failing markets, religious parents. Middle class parents encourage an internal locus of control in their children. Working class parents are more likely to teach a more passive message.

We internalise the norms and values of our society. Nevertheless, subgroups within the same society may vary widely in terms of what is seen as acceptable behavior and what constitutes reprehensible acts. Labelling (individual characteristics ascribed meaning by others), e.g. as a troublemaker, may force conformity to such roles on the individual. Societies, which measure success, perhaps financially, may be so structured as to erect barriers against the attainment of goals for some members, and so they promote deviancy. Hence we have terms such as 'subcultural sociopathy'. Some sociologists lump criminal conviction and applying a psychiatric diagnosis together as acts whereby a label of primary deviance (from what society expects) is given to individuals. This deviance is then amplified (secondary deviance) by the changes that follow in the labelled individual's behaviour. Thus, both legal and medical authorities are responsible for alienating individuals, i.e. creating forcing people to adopt deviant styles and paths in life. There is undoubtedly some truth in this but, at least in part, the flaw may be in applying the result to

⁴⁹⁰ The burden of mental and personality disorders in society is reflected in the early onset of most such conditions. For example, the median age (in years) of onset in the **Epidemiologic Catchment Area (ECA) Study** in the USA (Robins et al, 1991) were as follows: antisocial personality disorder, 8; phobias, 10; somatisation disorder, 15; drug abuse, 18; schizophrenic and manic episodes, 19; OCD, 20; alcohol abuse/dependence, 21; panic disorder, 23; and major depression, 25. The ECA looked at > 20,000 adults in 5 cities in the USA (community and institutional); trained interviewers used the *Diagnostic Interview Schedule* to determine DSM-III diagnoses; individuals with a lifetime history of a mental disorder had odds ratios of 2.3 and 4.5 for lifetime history of alcohol use disorder and drug use disorder respectively. (Regier et al, 1990)

⁴⁹¹ Useful early references include Hudson (1982) and Keeper (1987). The word 'therapy' comes from *therapeutae* (Gk.) meaning small extended family villages organised to deliver assistance to poor and disabled people.

⁴⁹² Apart perhaps from those of us with schizoid personality disorder.

⁴⁹³ This has been lengthened somewhat in modern society by education and apprenticeship

⁴⁹⁴ The 'typical' nuclear family with 2 parents and 2.5 children and the father acting as breadwinner is actually atypical in modern England, comprising just over one-quarter of households in 1991. According to official sources, (HMSO, 1991) twenty-five percent of households were one-person households in that year and the number of young persons living in such homes had been increasing at a greater rate than old people in such circumstances had. Also, by then, most married women worked outside the home.

medicine alone rather than to a problem with civilisation. Avoiding a necessary diagnosis does not make it go away and psychiatrists are more aware than ever of their obligations in terms of keeping their restrictions on individual liberty to what is necessary in the patient's interest and also their crucial role in areas such as enabling, promoting recovery, and fighting stigma, lack of resources, and inequalities. Some societal attitudes have changed over the years. The author remembers well when tuberculosis and cancer, not to mention homosexuality, were subject to the same stigma as mental illness. A major aim of the medical profession is to improve the efficacy of our interventions, an important way of reducing the fear associated with diagnosis!

Social support⁴⁹⁵ (types of) – help provided by others (relatives, friends, school, work, professionals)

Esteem – respect and positive statements ('You can do it!') increase self worth

Emotional – the concern and warmth offered by others

Informational – pertinent information helps one to cope more effectively

Instrumental – direct assistance, e.g. what are ones entitlements such as how/where to get a widow's allowance

Social support following violent crime victimisation (Andrews ea, 2003)

Both sexes report equal receipt of positive support

Females received more negative responses from close others than did males

Negative responses predicted PTSD at 6 months, especially in females

The happiness of people depends, at least to some degree, on the happiness of others with whom they are connected. (Fowler & Christakis, 2009) Western family changes promote distancing from certain support systems and greater reliance on psychiatry. (Gilbert, 1999, p. 52) Social support, such as integration into the community and having a confidante, protect against illness. (Segal & Phillips, 1967) and lack of it seems to promote depression⁴⁹⁶ and anxiety. (Mirza & Jenkins, 2004) Perceived low social support and living alone increased the likelihood of using primary and mental health services in the Netherlands. (Have ea, 2002) Women undergoing hysterectomy benefit from such support. (Robinson, 2000) In a 10-year follow-up in Oslo, (Dalgard ea, 1995; 1997) the buffering effect of social support may only apply to those people with an external locus of control⁴⁹⁷ (feel powerless and lacking in control over their own lives). Those with an internal locus of control do not have the same need for social support in order to cope with life's stresses, and have low symptom scores even when negative life events are combined with weak supports. The buffering effect of social support was especially strong for depression. Kendler ea (2005) point out that women have higher rates of major depression than men, but they also have stronger, more intimate social networks! However, they found that emotional support protected women more than men from major depression. An internal locus of control is more highly valued in individual oriented Western society with its emphasis on the autonomy of the person than it is in traditional societies where decisions are made by the family. (Okasha, 2002) Social changes probably play a vital role in reports from America (Cole ea, 1998) and elsewhere of increasing 'depression' and suicide (Atakan & Davies, 1998) as well as substance and alcohol abuse among younger age groups. Casey and Craven (1999) state that large scale attempts at reducing the suicide rate may be more of a socio-political and religious issue than a medical one. It is often not realised that psychiatric patients in general have increased standard mortality ratios for all three major classes of unnatural death: suicide, homicide, and accidents. (Hiroeh ea, 2001) Young children of parents with mental illness may also have elevated mortality risk, particularly for unnatural causes of death. (Chen ea, 2010)

Coping with illness (Laubmeier ea, 2004; Schlozman ea, 2008)

⁴⁹⁵ See Cobb (1976). The term **social capital** refers to trust and give-and-take among neighbours as well as a tendency to stand by one another. It also refers to education, having a job or the possibility to train for one, and retention of family ties.

⁴⁹⁶ Whilst a twin study suggested that one may inherit attributes that attract social support (Schoevers ea, 2000; Agrawal ea, 2002) the study lacked sufficient power (low numbers) to detect shared environmental effects.

⁴⁹⁷ *Locus of control* was described first in 1966 by Julian B Rotter (b. Brooklyn, NY). Compare with *sociotropy* (defining ones worth by reference to interpersonal relatedness) and autonomy (sense of worth derives from attaining ones goals and being independent and a free agent) from Beck. (1983) In patients with schizophrenia an external locus of control, whilst not specific to their disorder and more related to personality, does correlate with less periods of wellness and with depressed mood. (Harow ea, 2009)

Coping involves a response to and a method of dealing with difficulties - these may have good and bad effects not only on the patient but also on those caring for the patient
 Illness is a burden carrying risks and threats
 Reactions are often disproportionate to objective danger
 Uncertainty about how one will cope is a common source of distress
 For some patients being sick provides a favoured alternative to the responsibilities of wellness; such patients may complain excessively and blame those caring for them
 Determinants of coping include the problem itself and the availability of internal (mental, emotional, somatic) and external (financial, social, organisational) resources
 Existential issues such as 'why me' and death must be struggled with
 Religion may offer peace, meaning, hope, and improved prognosis
 Good communication between patient and the treating team may defuse problems and promote coping
 Psychiatrists may be used by other professionals to take on the burden of dealing with difficult patients
 Successful copers have high morale and are optimistic even when progress is uneven; they deal with issues as they arise and have a flexible, broad array of approaches to problem-solving and can weigh up likely outcomes; they listen to advice and are able to pace themselves
 Unsuccessful copers are rigid, intolerant, inflexible and unable to lean on others when necessary; their ability to focus on the problem at hand is sub-optimal and may have strongly held preconceptions; they may latch on to questionable advice; denial and rationalising are common; passivity smothers initiative; and responses may sometimes be chaotic and impulsive

Feral children, those who are reared away from humans, are intellectually backward and have a distorted identity.(Itard, 1801) Women who recollect poor early maternal care may be poor at relating, marry early, have poor quality marriages, and be divorced from a previous marriage.(Birtchnell, 1993)

The way in which children are reared and corrected in the home varies widely between social classes, with physical chastisement being more likely among the working classes and verbal approaches predominating at the top of the social ladder.(Newson & Newson, 1970) Regardless of socio-economic status, alcohol, cannabis and tobacco abuse is more common in the children of parents who leave them alone at home for long periods.(Richardson ea, 1989) A Swedish group (Weitoft ea, 2003) found that children who grew up in a single parent family had excess mortality, severe morbidity, and injury, even when household resources were taken into account. Lone mothers⁴⁹⁸ suffer from an excess of depression and material disadvantage.(Targosz ea, 2003) Lone mothers were more likely to have psychiatric disorders and to have experienced physical and sexual violence than were partnered mothers in one Australian cross-sectional survey.(Butterworth, 2004) Violence was a better predictor of psychiatric disorder than were being a lone parent or having a particular socio-demographic profile. Cooper ea (2008) found that psychiatric disorders could be explained by financial problems in lone mothers but not in lone fathers; the former had an excess of such problems but lone fathers were even more likely to have them.

Children of psychiatric patients are often adversely affected across a wide range of functions; they are often ignored in routine anamnesis; parents may fear being blamed and having their offspring removed from their care; and a significant minority of childhood psychiatric problems persist into adulthood.(Ramchandani & Stein, 2003)

Sexual intercourse is occurring at an earlier age than heretofore. This may be postponed by a broad based sex educational approach in schools.(Wellings ea, 1995; Mellanby ea, 1995; Bearinger ea, 2007) A broad range of psychiatric disorders, antisocial personality disorder, and substance misuse increase the likelihood of risky sexual activity, early sexual activity, and sexually transmitted disease.(Ramrakha ea, 2001) Society often expects the elderly to hand over authority to the young, and that certain activities are given up (work, sex, and some pastimes). Such expectations may be a source of conflict. Also, while reminiscence may be enjoyed many by senior citizens, it may be irritating for others. Leaving home may be resisted tenaciously, and change of any type may be traumatic.

⁴⁹⁸ Respectively, there were 57,900 and 60,500 births in the Republic of Ireland during 2001 and 2002, of which 18,000 and 18,800 were births outside wedlock, and 2,900 and 2,700 were to teenage mothers; the number of lone parent families with children aged less than 20 years increased by 88% during 1994-2003.

*Stress*⁴⁹⁹ is 'a situation where environmental demand exceeds a capacity for effective response'. (Fisher, 1993) There are many factors that feed into stress: life events (these do not predict type of disorder), inability to predict or escape traumatic circumstances, difficult life problems (poverty⁵⁰⁰, loss, etc), personality, (Kendler et al, 2003) genes, (Federenko et al, 2006) lack of work outside the home, and chronic high levels of ACTH and cortisol (reduced response to infection) and catecholamines (→ functional change → physical change). Stress hormones, neurotransmitters and cytokines⁵⁰¹ are among several mediators that are essential for maintaining stability (or homeostasis) through change, a process known as *allostasis*. Release of these chemicals in response to stress promote adaptation. If release is not switched off following cessation of stress, if they are excessively employed in response to numerous stressors, or if they are inadequately turned on, then the body experiences damage⁵⁰². (McEwen, 2004) Too fast changes in modern society is a source of considerable stress⁵⁰³, although such observations are not new. (Clouston, 1888) It may be that with two human beings subjected to similar stress, it is the one who feels he can control the source of stress, even if he doesn't exercise the control, who develops less dysfunction. (Glass & Singer, 1972) The alleged reduction in suicide rates during war⁵⁰⁴ may be due to greater social cohesion, projection of hostility onto the enemy, a relative lack of alcohol⁵⁰⁵, and/or reduced levels of unemployment. Social institutions are given overt roles that may be markedly different from their latent roles. In some countries the army is meant to protect the inhabitants from external aggression but in fact it is employed to enforce conformity on the internal citizenry. Goffman's (1961) 'total institution', an attack on badly run asylums, described regimes where everything is done in the one place and in a regulated fashion, where patients have no social roles and progressively lost autonomy⁵⁰⁶, and where patients and staff are kept socially apart. Nurses, the 'culture carriers' of the hospital, decided who should see a psychiatrist. Nevertheless, not all research points the finger at institutional environments, and patients with schizophrenia may still have negative symptoms or a 'clinical poverty syndrome' almost a decade after discharge. (Johnstone et al, 1981) Quality of care may be more influential than hospital conditions. (Coid, 1993)

Some strategies used in the face of stress⁵⁰⁷

Avoiding the source of stress – can be realistic as when a potential assailant is avoided or unrealistic as when someone stays away from essential school examinations; use of distraction or temporary withdrawal may be helpful

Help-seeking – this can be appropriate (family, friends, GP, confessor, accountant, etc) or inappropriate (e.g. advice sought from a severely dysfunctional peer or someone with extreme views)

⁴⁹⁹ Stress: Latin, *stringere*, to compress/draw tight. 'Stress' may indicate the *response* to extreme forces and attempts to maintain the status quo or the *stimulus* (the stress) itself.

⁵⁰⁰ **Poverty** is a risk factor for PTSD. (Muldoon & Downes, 2007) Poverty is an important correlate of mental disorder worldwide. (Patel & Kleinman, 2003) Jenkins et al (2008), in a cross-sectional survey of British private households, found that both low income and debt are related to mental illness, with the effect of income being mediated by debt. Social disadvantage is related to risk for psychosis. (Morgan et al, 2008) US employees develop depressive symptoms for different reasons depending on their financial circumstances, the poor because of job insecurity and the non-poor because of high psychological demands and low support from supervisors and co-workers. (Simmons & Swanberg, 2008)

⁵⁰¹ **Cytokines** are members of a diverse group of small proteins that change parent or other cell behaviour. They may be implicated in the genesis (e.g. multiple sclerosis) or used in the treatment (e.g. hepatitis C) of disease. Most act briefly and locally. They usually act as part of a cascade/network. Some (e.g. colony stimulating factors) act distally. Among the great array of functions attributed to cytokines are cell multiplication/repair/migration (including embryogenesis/organogenesis), angiogenesis, and immunity/inflammation/fibrosis. *Interleukin* (IL) referred to proteins that communicated between white cells but we now know that this is but one of their functions; interleukins are numbered IL-1, IL-2, etc. *Tumour necrosis factor* (TNF) includes cytokines that kill tumour cells, e.g. TNF-alpha. *Interferons* are divided into alpha and beta (type-1, antiviral) and gamma (type-2, immunostimulation, from cells such as natural killer cells and some helper T cells). *Haematopoietins* include granulocyte- and granulocyte monocyte-colony stimulating factors. Functions of cytokines include inflammation (e.g. IL-1, TNF), anti-inflammation (e.g. IL-4), specific immunity (e.g. IL-2 and interferon gamma are involved in proliferation and differentiation of T and B cells), chemoattraction (influence immune cell movement), and haemopoietic activity (stem cell proliferation/differentiation, e.g. IL-3 and colony stimulating factors).

⁵⁰² *Allostatic overload*.

⁵⁰³ Working conditions are probably becoming more stressful. (Reichenberg & MacCabe, 2007)

⁵⁰⁴ How many are reported or investigated?

⁵⁰⁵ Derived from the Arabic for essence, *Al kahl*.

⁵⁰⁶ See Biegler (2008) on the promotion of autonomy in psychotherapy.

⁵⁰⁷ Different lists can easily be compiled by readers and some examples might readily be transferred from one heading to another.

Relaxation – can be adaptive (e.g. progressive muscle relaxation, breathing exercises, yoga, music, art, light reading) or maladaptive (such as alcohol in excess)

Learning from the challenge – the positive quest for personal growth derived from mastery

Problem-solving – defining and clarifying the problem, listing options and choosing the best one, and monitoring effectiveness

Relying on past experience – drawing on relevant past personal experiences or the experiences of others

Realistic appraisal – ‘I might have only got 58% in my exam but it got me through’ or ‘If I spend more time on my weak subjects I’ll pass the exam’ or ‘Not everyone is good at that subject’

Humour – seeking a balanced perspective and releasing anxiety (not unknown in operating theatres): ‘It could be worse’, ‘I’ll have something to tell my grandchildren’, ‘You should have seen the other fellow’, and ‘McGonigle’s Correction’ (Murphy of ‘Murphy’s Law’ was an optimist – the truth is worse)

Sublimation – kicking the table instead of the boss

Reaction formation – killing a bully with kindness

Stoicism – ‘That’s life’, ‘It’s not worth being upset about it’

The ‘sick role’⁵⁰⁸ carries certain privileges, such as being excused from work, as well as obligations, such as seeking appropriate help and co-operating with caretakers. Of course, being human, we may abuse this role. The term ‘illness behaviour’ refers to the various ways in which a symptom(s) may be perceived, evaluated and acted upon, i.e. what people do when they are sick, such as being stoical or melodramatic. Such behaviour may derive from personal or observed experiences.

There were 286,129 marriages and 156,814 *divorces* in the UK in 2001. Divorcees die earlier⁵⁰⁹ and have more psychiatric (depression, anxiety, alcohol abuse) and physical illness than married people.(Richards ea, 1997) There is an increased risk of morbidity (such as depression [Gilman ea, 2003] and substance abuse [Mack ea, 2003]) for their children, particularly for a child who is less than 5 years old at the time of the divorce. The exact direction of causality is probably complex and variable between couples.(Sims, 1992; Weiss, 1998) Harper (2008, p. 24) points out that women generally have better social networks than men and are more likely to retain them following divorce, men being cut off from contacts by marital dissolution. Anyway, it is usually the woman who holds on to the children. Divorced older men may fare worse than younger males in the same situation⁵¹⁰. Older divorcees of either sex are at increased risk of experiencing poverty.(Waite, 1995)

Adoption may be associated with childhood psychological difficulties,(Ounsted & Humphrey, 1963; Mackie, 1982; O’Connor & Rutter, 2000) although prospective studies stretching into adulthood are sparse. McWhinnie’s (1967) retrospective analysis found that 10 of 58 adopted adults had suffered from mental illness. Wieder (1977) found a 15-30% incidence of adoptees in the psychiatric population compared with 2% of the general population. There may be an association with eating disorders in some instances.(Holden, 1991; McWhinnie, 1967) Children placed from care may show emotional distance, distorted expression of feelings, slow attachment formation, indiscriminate socialisation, overactiveness, opposition-defiance, and, less commonly, rage/aggressiveness.(Rushton, 2007) Rushton and Dance (2006) found that disruption (following placement from public care) was predicted by older age when placed, longer duration in care, excess behavioural difficulties, and ‘having been singled out from siblings and rejected by birth parents’. A major research difficulty is attribution of direction of causality, i.e. is vulnerability to breakdown already over represented among people presenting for adoption, or indeed among those seeking to adopt?(Mednick & Finello, 1983) Adopted patients offer unique challenges to the diagnostician who seeks a biological family history. Illegitimacy, along with new genetic mutations and low penetrance, complicate counselling.

Intercountry adoption in Sweden may be associated with an excess of suicide and attempted suicide, psychiatric admission, drug/alcohol abuse, and criminality.(Hjern ea, 2002) There are many possible reasons: poor nutrition in country of origin leading to neurodevelopmental problems, problems in the biological parents, problems in the infant that prompt referral for adoption, adoption after infancy⁵¹¹, excessive expectations of the adoptees, and racism due to having a foreign appearance. According to

⁵⁰⁸ Term dating from The Social System of 1951 by Harvard sociologist Talcott Parsons (1902-79).

⁵⁰⁹ Especially for males aged 35-45 years.

⁵¹⁰ Men are more likely to die before their wives but may spend more time alone in old age because of divorce.

⁵¹¹ Adoption during infancy was associated with better adjustment in the Netherlands.(Bieman, 1992)

Odenstad et al (2008), who looked at adoptions from abroad into Sweden and testing performed at military conscription, negative pre-adoption circumstances can have negative influences on cognitive development but the outlook could be positive if the adoptee had received good care before adoption and if adoptees were not chosen because of an excess of risk factors.

Using a modified *Edinburgh Postnatal Depression Scale* Payne et al (2010) looked at adoptive mothers during the first post-adoption year and found that the mothers may become depressed as a result of stress and problems of adjustment.

The term 'eugenics' literally translates as 'of good stock'. China's 1995 *Law on Maternal and Infant Health Care* ordered compulsory premarital examination for serious genetic diseases, some infectious diseases, and 'relevant' mental disorders. Options for those with 'positive' testing were long-term contraception or tubal ligation. Otherwise they were not allowed to marry. (Anonymous, 1995)

Family limitation methods include various forms of contraception, artificial insemination by donor, and, where available, abortion/termination. It is *abortion* in this sense that is discussed here⁵¹². The Irish Supreme Court defined 'unborn' as applying to embryos only following implantation in the womb.⁵¹³

Abortion is an emotive subject accompanied by 'strong and polarised opinions'. (Fergusson, 2008)

Casey/Oates et al (2008) describe the issue as being 'primarily moral and ethical, not psychiatric or scientific'.

Legal abortions were carried out in Britain on 'women' giving an Irish (Republic) address⁵¹⁴

Year	Number
1970	261 ⁵¹⁵
1994	4,590 ⁵¹⁶
1997	5,336
1998	4,473
1999	6,214
2000	6,391
2001	6,673
2002	6,522 ⁵¹⁷
2003	6,320 ⁵¹⁸
2004	5,585 ⁵¹⁹
2006	5,042
2007	4,686 ⁵²⁰

⁵¹² About 3% of countries have a blanket ban on abortion. (Moloney, 2009) According to Ahmad (2002) world-wide there were an estimated 50 million abortions performed annually, 40% done illegally. There might be 70,000 deaths among women from unsafe abortions, and perhaps 5 million women were temporarily or permanently disabled. According to Anonymous (2007c) each year there are 210 million pregnancies world-wide, one in five end in abortion, ¾ such women live in developing countries, 97% of the 20 million annual unsafe abortions occur in developing countries, ¼ of the women are aged 15-19 years, 68,000 women die from unsafe procedures, and 5.3 million are left with temporary or permanent disabilities. Sedgh et al (2007) estimated 46 and 42 million induced abortions worldwide in 1995 and 2003 respectively; there were 31 abortions for every 100 livebirths in 2003; and 48% of abortions were unsafe and 97% of these were in developing countries. Males exceed females in China, probably because of selective abortion of females. (Zhu et al, 2009) Nicaragua banned abortion for any reason in 2008 and this seems to have had extremely adverse effects on women (death, suicide, etc). (Moloney, 2009) Blum (2009) points out that where abortion is illegal and clandestine the likelihood of the woman dying is much greater than where the practice is legal: from as high as 60 to as low as 0.6/100,000 women respectively.

⁵¹³ This definition excludes frozen embryos.

⁵¹⁴ It is unclear how many individual repeaters are counted more than once. Also, when abortion became legal in South Africa there was a huge reduction in maternal mortality.

⁵¹⁵ From 1970-93, 70,000 Irish women procured abortions in Britain. By 1995 and 2000, this figure had risen to 78,577 and 107,315 respectively. Between 1980 and end of 2005 123,258 Irish women travelled for an abortion.

⁵¹⁶ 628 of them being less than 20 years of age and 574 of whom were at least 35 years old.

⁵¹⁷ Plus 1,391 from Northern Ireland.

⁵¹⁸ Plus 1,318 from Northern Ireland.

⁵¹⁹ In addition, 1,164 went from Northern Ireland.

⁵²⁰ Plus 445 having abortions in the Netherlands, compared to 42 in 2005.

Births in Ireland outnumber Irish abortions procured in Britain by a factor of about 10. The rate for British women having abortions⁵²¹ is much higher than for Irish women. Single women outnumber other categories in abortion statistics, although Clare (2000, p. 103) would not agree. Pushing a pregnant young female to marry the child's father cures nothing and may make matters worse. (Zabin ea, 1989) According to one source, (Anonymous, 2003) about half of US pregnancies are unintended after half of the end in abortion. The Irish Medical Council approved (December, 2001) an amendment to its *A Guide to Ethical Conduct and Behaviour*, Fifth Edition 1998, recognising 'that termination of pregnancy can occur when there is real and substantial risk to the life of the mother'.⁵²² In 2009 the Irish Medical Council added a 'clear and substantial' risk of maternal suicide.

Abortion became legal in the US in 1973⁵²³. Since 1967, the law in England and Wales allows abortion act on grounds of likely damage to the health of the mother or her children. Therefore psychiatrists are less involved in evaluation, the GP or gynaecologist often making the decision about health risk. Before 1967, a serious risk to the mother's life had to be present and a psychiatrist was asked to evaluate suicide risk.

Post-abortion psychiatric problems (PAPPs)

Much research originates from societies condoning abortion (Marteau, 1993; Statham & Green, 1993)

Incidence of PAPPs (admissions or referrals) appears, from the literature, to be low, perhaps one-fifth of or equal to that associated with childbirth (Gilchrist ea, 1995)

Predisposition toward PAPPs is increased by

Younger age

Having more children before abortion

Pre-abortion psychiatric problems

Severe anxiety at time of discovery of pregnancy

Marked ambivalence about abortion

Cultural/religious prohibitions

Being forced to have abortion

'Going it alone'⁵²⁴

Woman may regret past abortion and calculate 'current' age of aborted child, especially on anniversaries of its expected date of delivery – may be more likely if woman was pressured by others into having the abortion (Ashton, 1980)

Abortion in late pregnancy may be associated with depression in a later pregnancy because of unresolved grief or because of a fear of divine retribution⁵²⁵ such that the expected baby will be deformed (Kumar & Robson, 1978)

Anonymous (1989b: review article): women who have an abortion for medical or genetic reasons⁵²⁶ and those presenting in the second trimester were thought to be more at risk for PAPPs

Abortion is associated with a 'small' (30%) increase in mental disorders among women (Fergusson ea, 2008)

Pregnancy loss *per se* (be it due to abortion or miscarriage) is associated with increased risk of mood and substance use disorders in Australian women (Dingle ea (2008)

Systematic review of literature (Charles ea, 2008): best research found no excess of psychiatric problems whereas flawed research found negative outcomes

⁵²¹ 1 in 5 English pregnancies; 0.44 per woman; mostly young, single, childless; 27% have repeat abortions according to Raleigh.(1998) The government launched a 10 year strategy in 1999 to halve teenage pregnancy in England. An English analysis of 1994-2000 showed that teenage pregnancies peaked in 1998, declining thereafter; this was associated with less conceptions and births and a 7.5% rise in abortions.(Wilkinson ea, 2006)

⁵²² This appears to be a reference to rare instances where obstetrical procedures are necessary to save the mother's life but where the baby has little prospect of survival (e.g. because of extreme immaturity), rather than condoning abortion for social reasons. In other words, the aim is to save mother, not lose baby.

⁵²³ Supreme Court: *Roe v Wade*.

⁵²⁴ I.e. not involving partner in decision/being abandoned by partner.(Lask, 1975; Stotland, 1992; Clare & Tyrrell, 1994; Gilchrist ea, 1995; Major ea, 2000)

⁵²⁵ Belonging to a faith that condemns abortion appears not to represent an insuperable barrier to seeking one.(Stotland ea, 2007, p. 349)

⁵²⁶ Abortion because of congenital anomaly or fetal death may lead to guilt or grief for the 'normal' baby that didn't happen. The partner may suffer similar feelings.

New Zealand study (Fergusson ea, 2009) found that abortion was associated with high rates of both positive and negative emotional reactions; almost 90% of respondents believed that abortion was the right decision; and number of negative responses was associated with subsequent mental health problems.

Satisfaction with abortion and negative emotions may decrease and increase respectively with the passage of time. (Major ea, 2000) Lazarus (1985), in the USA, found a low incidence of serious short-term psychiatric sequelae in a questionnaire study: the main reaction was relief, 15% had guilt and depression, and 10% found the whole experience to have been negative. Lazarus suggested counselling for certain at-risk patients, e.g. women who delay the decision to have an abortion, those with a severe psychiatric disorder prior to the procedure, and those with medical or genetic indications for termination of pregnancy. Suicide is rare in both pregnancy and after refused abortion. Gissler ea (1996) in Finland found a suicide rate in the year after abortion to be thrice that of the population rate. The first problem here is weeding out whether abortion leads to suicide or whether a common cause operates for both abortion and suicide, and the second difficulty is that the same authors report a doubling of suicide after miscarriage. There is evidence that if the mother of an unwanted pregnancy is forced to proceed to term, both she and her offspring will experience later psychosocial difficulties. (Clare & Tyrrell, 1994) Kubicka ea (2002) found that women in Prague denied abortion had children who as adults had poorer mental health than their siblings or matched controls. One might speculate that unwanted pregnancy might correlate with psychosocial difficulties in the first place. Because some women do experience psychological problems following abortion it is important that appropriate follow-up care be available. (Anonymous, 2008b) Reardon & Cogle (2002) assessed women for a depressive outcome using the National Longitudinal Study of Youth⁵²⁷: *married* women carrying an unintended first pregnancy to term were at less risk of subsequent depression than women who aborted, but rates of high risk depression scores were comparable among *unmarried* women.

In January 2002 the French Parliament adopted a bill which overturned a court ruling that had compensated a boy⁵²⁸ disabled by rubella contracted in utero. The court had held that because doctors had failed to diagnose rubella (because of laboratory error) that an abortion had not been recommended! Amid heated debate, 'medical' abortion (e.g. mifepristone) became legal in Italy in 2010.

Lack of social competence, an inability to attain and perform certain social roles, and a lack of self-confidence characterises a group of people who show increased vulnerability to mental breakdown. Social variables (status, roles, home circumstances) may be as important as severity of symptoms in determining who receives treatment and in what setting, as well as the type of label (e.g. affective v schizophrenic) and treatment (e.g. psychotherapy v drugs) offered. Social factors are also important in relation to readmission and relapse rates: lack of social supports, high levels of expressed emotion. Unemployment appears to have a real but complicated relationship with depression (Gavin ea, 2010) and suicide in both sexes. (Kreitman, 1993; Stuckler ea, 2009) completed and attempted. (O'Shea, 2000c) Suicide is high in the lowest social class anyway. Unemployment rates are a very powerful indicator of the serious mental illness requiring inpatient treatment in the working-age population. (Kammerling & O'Connor, 1993) Patients with chronic schizophrenia are affected disproportionately in the community in times of high unemployment⁵²⁹ and when the demand is for skilled workers; also, jobs have become more complicated and stressful. (Morgan & Cheadle, 1975) Butler ea (2010) found that older age and a diagnosis of schizophrenia amongst people with severe mental illness were associated with being unemployed. The best chance for the severely mentally ill, including first-episode psychosis cases (Killackey ea, 2008), getting a job is to offer supported employment (placement in competitive work while offering on the job support) rather than offering prevocational training⁵³⁰. (Crowther ea, 2001) It is illegal in Ireland, under the *Employment Equality Act 1998*, to

⁵²⁷ Begun in 1979 in the USA.

⁵²⁸ Nicholas Perruche.

⁵²⁹ And even at times of increasing employment. (Perkins & Rinaldi, 2002) *Individual placement and support* (IPS) or 'place and train' emphasises a quickly conducted job search on basis of patient preference and continuing support to patient and employer from a person who specialises in this area and who works as part of the psychiatric service. It is an effective approach. (Burns ea, 2007)

⁵³⁰ Period of preparation before going into competitive work.

discriminate against an employee because of mental health problems. The *Employment Equality Act 1998* was amended by the *Equality Act 2004*⁵³¹.

Organisational downsizing (reduction in personnel numbers) may increase sickness absence and the risk of death from cardiovascular disease in those who are left in the job.(Vahtera ea, 2004)

The role of exposure to media violence in breeding violence is controversial, with some defenders of the media suggesting that violence-prone individuals seek out violent material. This is hardly relevant in the case of minors or other vulnerable groups⁵³². The role of propaganda in spreading racism can hardly be disputed given the many examples of history. Obviously, many factors⁵³³ potentially interact in an individual to promote violence (Anonymous, 2008a) and research has been poor at weighting them, even at the population level.

The *stigma* attached to mental illness is still very strong, perhaps deeply seated in humanity⁵³⁴,(Haghighat, 2001; Warner, 2001; Eagles ea, 2003; Rutz, 2003; Angermeyer & Matschinger, 2005; Jamison, 1995, 2006; Thornicroft ea, 2007; Gurej & Kola, 2007; Mehta ea, 2009) and carries certain negative expectations, e.g. violence and lack of productivity, not to mention underfunding for services.(Dinan, 1999) Stigma may lead to poverty, poor quality of life, and marginalisation within society.(Thornicroft ea, 2009)

Stigma is present when people judge others 'not on their personal qualities but on the basis of a mark or label which assigns them to a feared or unfavoured group'.(Gelder ea, 2006, p.24)

The *Stigma Scale* (King ea, 2007) is a 28-item self-report questionnaire derived from interviews with mental health service users; it has a three-factor structure (discrimination, disclosure, potential positive aspects of mental illness); and scores are negatively correlated with global self-esteem).

Relatives of patients may conceal their association with the mentally ill (Murphy, 1999) or may experience stigma by association, especially if experiencing mental health problems of their own.(Östman & Kjellin, 2002) Media messages often reinforce negative stereotypes about mentally ill people, e.g. dangerous, odd, unpredictable.(Miller, 2007) Prejudice may involve projection of unwanted or devalued attributes onto a scapegoated group.(Lawrie, 1999) Unfortunately, prejudice is found within the medical profession, among landlords, at work,(Brosnan ea, 2002; National Disability Authority, 2002; Diffley, 2003) in the media,(Page, 1980; Alisky & Iczkowski, 1990; Jamison, 1998; Wilson ea, 2000; Mukherjee ea, 2002; Eagles ea, 2003) and even among psychiatric patients themselves – stigma directed towards self and/or others.(Swanson & Spitzer, 1970; Brohan ea, 2010) People often do not acknowledge the simple fact that psychological distress is a part of living.(Doherty ea, 2007⁵³⁵) In one Irish survey⁵³⁶ one-third of the public stated that people with schizophrenia should not have children.(Kinsella, 2010) Mental illness is too often unworthy of news coverage unless something 'spectacularly negative' happens.(Bowers, 1999; Miller, 2007) The RCPsych launched an anti-stigma campaign in which consultation and collaboration with a wide variety of people, groups and the media would be combined with an emphasis on a number of major disorders. The results were followed to see if attitudes changed.(Byrne, 1999) The results showed that severe depression, panic, or phobia carried the least stigma.(Crisp ea, 2005) McKeon and Carrick (1991) found that personal experience of depression, or depression in a friend or relative, or even visiting someone in a psychiatric hospital, engendered more positive attitudes to depression and its management. Luty ea (2007) found that didactic factsheets largely failed to alter stigma for schizophrenia and alcoholism.

According to some authors,(Murphy ea, 1993; Wolff ea, 1996a) older age, low educational level, and low socio-economic status predict negative attitudes towards the mentally ill, whilst greater knowledge about the subject is associated with more sympathy and less fear. However, Crisp ea (2005) found that 16-19 year

⁵³¹ Under the former the employer had to make accommodations for disabled employees up to a nominal cost, whereas under the latter the employer is obliged to do so unless such accommodation would constitute an undue burden or hardship for the employer.(Conroy, 2005) The first successful case brought by a person who felt he was discriminated against by his employer on grounds of psychiatric illness in Ireland happened in early 2005 (almost €30,000 awarded).

⁵³² Excessive media exposure during adolescence may be associated with depression in young (especially male) adults.(Primack ea, 2009)

⁵³³ E.g. criminal activity, family breakdown/abuse, substance abuse, poverty, and some cases of mental disorder.

⁵³⁴ Quarantined individuals have problems with stigma, loneliness, isolation, a worries about their families not coping without them.

⁵³⁵ In this national survey, almost 90% of respondents would contact their GP, but only 31-48% would contact a psychiatrist, counsellor or psychologist. Most would approach family/friends.

⁵³⁶ *Public Attitudes Towards Mental Health*.

old harboured the greatest proportion of negative views, a finding reflected in male Dublin secondary school students.(Burke *et al.*, 2008) Thornicroft *et al.* (2009) spoke with people with schizophrenia in 27 countries and found that they were rarely in receipt of positive discrimination. Negative discrimination was common and centred around making or keeping friends, the family, finding and keeping employment, and intimate and personal relationships. Patients anticipated discrimination in job/education/training application and seeking a close relationship. 72% tried to keep their diagnosis secret. Probably related to low self esteem, people with schizophrenia did not always experience the discrimination they feared. Stigmatising attitudes in young Australians were affected by personal experiences, parental attitude and exposure to campaigns.(Jorm & Wright, 2008) Jorm and Griffiths (2008) asked Australian adults questions about four vignettes and concluded the behaviour associated with mental illness and a belief that such illness derives from a flawed character were stronger sources of stigma than are biomedical explanations. Higher education may be relatively incompatible with negative views of mental disorder.(Crisp *et al.*, 2005) London people with children or who are Caucasian were most likely to object to community placement of the mentally ill in one study.(Wolff *et al.*, 1996b) The provision of properly resourced services are essential in the fight against stigma (Kelly, 2005) but stigma influences resource allocation negatively.(Sartorius, 2007) Admission to a general hospital psychiatric unit may be less stigmatising than admission to a stand-alone psychiatric hospital.(Pillay & Kelly, 2009) Professionals and consumers need to be more proactive in educating the media.(Miller, 2007) The *Time to Change*⁵³⁷ initiative in Britain was launched in 2009 and aims to tackle stigma attached to mental illness.(Eaton, 2009; Henderson & Thornicroft, 2009) According to the Department of Health in the UK in 2009⁵³⁸ the public there are broadly sympathetic towards people with mental health problems. More attention needs to be paid to bolstering the self esteem of people with mental illness.(Thornicroft, 2009)

The lower socio-economic classes are more likely to be referred by the police and the courts, whereas physicians more often refer the upper classes (or the latter may self-refer). Attitudes towards and knowledge of treatment resources differ between social classes. Inner London boys (West, 1982) were more likely to be delinquent if they came from big or poor families, if there was poor parenting or marital disharmony, if the parents had criminal records during the boys' youth, or if they had below average intelligence. Women are far more likely to be killed by their present or former partners than are men.(Home Office, 1995) Associations of offending with physique, the old somatotype chestnut, are irrelevant when social factors are taken into consideration.

Stalkers are a heterogeneous group. About 8% of women and 2% of men experience unwanted contacts and intrusions that cause significant fear and apprehension.(Mullen *et al.*, 2000) Doctors and health care professionals are at increased risk of being stalked, particularly by their patients.(McIvor & Petch, 2006) Stalkers who harass the British Royal Family are most likely (83.6%) to suffer from serious mental disorder.(James *et al.*, 2009) Most stalkers are men, often unemployed, and relative to criminals in general, better educated.(Nadkarini & Grubin, 2000) Most victims are women. Female stalkers are equally likely to be violent as are male stalkers, they tend to stalk professional helpers more than strangers, and, unlike their male counterparts, they are more likely to target same gender victims.(Purcell *et al.*, 2001) Homosexual victims may not receive needed help because of homophobia. Stalking activities include following a victim, communicating⁵³⁹, ordering goods or services for the victim, and aggression/violence⁵⁴⁰. Motivation arises from different forms of psychopathology, including psychosis and severe personality disorder.(Kamphuis & Emmelkamp, 2000) Prolonged stalking can have long-lasting deleterious effects on the victim, in the form of anxiety, depression, PTSD, and even consideration of suicide.(Purcell *et al.*, 2005)

Based on an Australian study (Purcell *et al.*, 2009) juvenile stalkers are mainly males and victims are female and previously known to the perpetrator and the stalkers directly approach the victim or use the telephone or send texts; assaults (physical and verbal) and threats are common; and stalking could be described in

⁵³⁷ Comic Relief and the National Lottery funded this campaign and the London Institute of Psychiatry undertook to evaluate its effects. Among the many approaches taken were prime time TV advertisements and beer mats stating that some of your co-workers probably have mental illness. Among the celebrities appearing in the campaign was the actor Stephen Fry. See www.time-to-change.org.uk.

⁵³⁸ 'Attitudes to Mental Illness 2009'.

⁵³⁹ Including on the Internet: cyberstalking.

⁵⁴⁰ According to McEwan *et al.* (2009) previous violence is especially predictive of violence among stalkers, as are threats among ex-intimate stalkers.

terms of bullying, revenge for perceived harm, reaction to being rejected, and, in a small minority, sexual predation or infatuation.

Zona ea (1993) divided stalkers into simple obsessional (commonest; prior relationship with victim; violent), love obsessional (especially female; victim a male of higher social status; often psychotic; celebrity stalkers; no prior relationship), and erotomaniac (deluded that victim loves them) groups.

Substance misuse increases the risk for violence. Psychosis requires treatment. SSRIs might help with intrusive thoughts. A co-operative approach, based on a risk-benefit assessment, by legal⁵⁴¹ and medical personnel is best.

According to Frude (1994), although early research suggested that marriage was better for men than for women, this has not been confirmed, and on average women benefit emotionally from marriage.⁵⁴² Women are more likely to acknowledge dependency needs than men if asked directly, but both sexes acknowledge such needs equally if the questions do not reveal their purpose, as in projective testing. (Millon & Davis, 2000, p. 13)

Loss of social attachments, such as job or spouse, increases vulnerability to mental breakdown. Downward social mobility is associated with a schizophrenic diagnosis. Migrants and minority ethnic groups have often been found to possess a high rate of psychiatric morbidity. This might have many causes, e.g. racism⁵⁴³, poverty⁵⁴⁴, (Brown ea, 1998) nutrition, housing, language problems, and different customs. Schizophrenic patients tend to migrate to the anonymity of urban centres. Many migrant workers are illegal or badly treated by employers.

The premorbid characteristics (e.g. schizoid) of patients may militate against the development of social ties and supports. The elderly are given important roles in some societies and not in others, with consequent loss of self-esteem and material goods.

The availability of psychiatric institutions and treatment may explain differing hospitalisation and treatment rates more than do urban-rural or other variables. Diagnostic disparities, such as wide and narrow definitions of schizophrenia, are also important here. Some hospital personnel possess negative expectations for their patients that may have deleterious consequences. Psychiatry and other social institutions may be used by some people for manipulative reasons, e.g. to get a new house; ex-patients may simulate or exaggerate symptoms to regain admission.

*Non-compliance*⁵⁴⁵ with prescribed medication and other aspects of the therapeutic regimen is a major problem in psychiatry⁵⁴⁶ (O'Shea, 1995) as it is in other branches of medicine. (Powsner & Spitzer, 2003) Simon (2008), for example, states that 'sustained use of antidepressants is probably too rare to have much overall effect on risk of suicide in people living with depression.' Psychiatrists and patients may not always agree on the reasons for non-adherence. (Hoge ea, 1990; Haddad, 2008) Many patients stop treatment when

⁵⁴¹ In 1990, California passed the first antistalking law, making stalking a crime, the UK following in 1997. The Protection from Harassment Act 1997 in England states that psychological damage and the intent of the perpetrator must be demonstrated before a legal action can be pursued. Whilst the term 'stalking' is not used in the relevant Irish legislation, this activity is dealt with under Section 10 of the *Non-Fatal Offences Against the Person Act 1997* and conviction can attract a maximum of seven years in prison.

⁵⁴² However, Clare (2000, p. 82) suggests that for women, happiness within marriage is more important than it is for men!

⁵⁴³ African and Caribbean patients in the UK are overrepresented in UK psychiatric admission, involuntary admission, and duration of hospitalisation statistics. (McKenzie & Bhui, 2007)

⁵⁴⁴ Indian women show increased psychiatric morbidity if poor, married, smoke, have abnormal vaginal discharge, report a chronic physical illness, or have many psychological symptoms as baseline. (Patel ea, 2006) Numerous factors feed into mental health, e.g. poverty, disasters, war, aggressive recruitment of health workers by rich nations, education, etc. Poorer countries spend disproportionately less on mental illness than do wealthy nations. (Gureje & Jenkins, 2007)

⁵⁴⁵ *Non-adherence, non-concordance, non-cooperation.* Prof Elyn R Saks of California (2009), herself a law professor and patient on clozapine for schizophrenia, said 'part of the way I could prove that I was not mentally ill was to get off medication...(she then recounts her becoming psychotic)...all around me was evil beings...would slice me up...tell them not to kill me...all the explosions...I give life and I take it away (grandiose)'.

⁵⁴⁶ For example, up to 2 out of 3 patients with schizophrenia are non- or only partially-compliant with medication (O'Callaghan & McTigue, 1999), 50% of depressed patients stop treatment within 10 weeks, (Demyttenaere, 1997) people take lithium for a median of 72 days before stopping it without medical permission, (Scott, 2004) and over one-fifth of suicides were non-adherent to medication in the preceding month and nearly one-third had disengaged from services. (Swinson ea, 2007) The Clinical Antipsychotic trial of Intervention Effectiveness (CATIE: McEvoy ea, 2006) found that 74% of 333 (intent to treat) patients had stopped treatment within 4 months. Using pharmacy refill records, Dolder ea (2002) found that compliance was somewhat better for atypical (54.9%) than for typical (50.1%) antipsychotic drugs at 12 months, although not all studies would agree. (Gilmer ea, 2004) The Irish HSE reported almost 8 tonnes of medicines returned to 167 pharmacies in a 12-month period, 26.3% of which were classified as nervous system drugs that include psychotropics. (Culliton, 2008) Non-compliance is not confined to psychiatry, e.g. a patient who only takes thyroxine replacement therapy before bloods are due would show raised TSH as well as high T4 and T3.

they begin to improve. The stigma of being treated for an illness may discourage compliance.(O'Shea, 1995; Kemp ea, 1996) as may side effects or a feeling of not being in control.(Kemp & David, 1995) Sair ea (1998) classify barriers to compliance into medication related such as adverse effects, patient-related like unrealistic expectations, clinician-related such as ignoring patients' dissatisfaction, and organisational like an aversive clinic setting. At a much deeper level, some people cannot understand why disorders of an ephemeral 'mind' are treated physically, while others may see the necessity of such interventions as lowering humanity to the level of the common beast. Non-compliance in seriously ill patients, especially if combined with alcohol or substance abuse⁵⁴⁷, may be associated with violence.(Swartz ea, 1998) Cognitive dysfunction may be an important factor in decision-making capacity in the older schizophrenic.(Palmer ea, 2004) 'Compliance therapy', which involves going into a very detailed analysis of all possible issues with the patient, may improve adherence to prescribed treatments,(Kemp ea, 1996, 1998) as may involving patients in decision making (Britten, 1998) or primary care counselling.(Peveler ea, 1999) Motivational interviewing, assertive community care, precise instructions about what to take and when to take it, and intermittent reminders about the importance of adherence during follow-up may help.(Zygmunt ea, 2002) Not all research results find that compliance therapy is useful in schizophrenia.(O'Donnell, 2002, 2003) Bebbington and Kuipers,(2003, p. 618) having reviewed the literature, note that 'there was little evidence that effects of family therapy [in schizophrenia] might be mediated through improved compliance with medication'. Controversially, paying patients to take their medication has been suggested!(Giuffrida & Torgerson, 1997; Claassen ea, 2007; Burns & Shaw, 2007) Checks on compliance may be a two-edged sword, sometimes giving false reassurance.(Farragher, 1999) In fact, blood sampling is not a solution as patients are more likely to take their medication around the time of a clinic visit!(Cramer ea, 1990) However, serum levels of prescribed drugs may suggest poor compliance when all else (e.g. smoking) is considered, e.g. with clozapine.(Mennickent ea, 2010) Mutual respect between patient and prescriber is essential for treatment adherence (Shooter, 2003) and attitudes to treatment at baseline predicted adherence at one year.(O'Donnell, 2003) Many American states have strict laws requiring patients to comply with extramural treatment.(Rand & McKee, 1998) Attempts to introduce similar legislation on this side of the Atlantic have spawned considerable debate.(Burns, 1999; Moncrieff & Smyth, 1999)

Prisoners

Almost 9 million prisoners world-wide (Fazel & Danesh, 2002; Birmingham, 2004)
 USA has highest imprisonment rate (686/100,000 pop. in prison in USA)
 Men far outnumber women in prisons
 Women tend to outnumber men in psychiatric care
 Prisoners much more likely to be psychotic or suffer from major depression; 10 times more likely to have an antisocial personality disorder, than the general population (Fazel & Danesh, 2002)
 Multiple incarceration is associated with psychosis and major mood disorders (Baillargeon ea, 2009)
 Female gender and poverty⁵⁴⁸ strongly associated with common mental disorders (Patel ea, 1998) although the nature of relationship probably complex (Weich & Lewis, 1998; Sturm & Gresenz, 2002)
 Factors associated with excess of prison suicides include psychiatric disorder (psychosis, depression, substance abuse) and ecology (bullying⁵⁴⁹, isolation, inactivity) (Casey, 2007)

⁵⁴⁷ Patients who believe (correctly) that one should not mix medication with alcohol or substances may decide to omit medication!(Brennan & Herman, 2008, p. 51)

⁵⁴⁸ 1.2 billion people around the world live on less than \$1/day. Even in Europe low socioeconomic status is associated with higher death rates and poorer subjective health, although smoking and alcohol contribute in part to such findings.(Mackenbach ea, 2008)

⁵⁴⁹ Kelleher ea (2008) found that 6.6% of interviewed North Dublin adolescents reported at least one psychotic experience and such symptoms were associated with childhood physical abuse, domestic violence exposure, and being a **bully** or being **bullied**. It is difficult to interpret such findings: pitfalls of interviewing, retrospection, direction of causation, and possible confounders (nature of vulnerability, poverty, drugs, etc). Schreier ea (2009) in England followed children and found that being a victim of bullying at 8 and/or 10 years of age increased the risk of psychotic symptoms two-fold at age 12 years and associations with peer victimization were stronger when victimization was chronic or severe, i.e. experience of relational and overt victimization. In a Finnish nationwide birth cohort study (Sourander ea, 2009) frequent childhood victimisation predicted later psychiatric problems irrespective of psychiatric problems at baseline, but frequent bully, victim, or bully-victim status did not predict and psychiatric problems among males, a finding that might possibly reflect methodological factors such as numbers or lack of sub-categorisation of bullying. Another

Female prisoner suicide standardised mortality rate (SMR) in England and Wales 1978-2004 was 20.7 (especially high in younger women) and SMR may be increasing (Fazel & Benning, 2009)
Prevalence (current, 6-month, and lifetime) of any psychotic disorder is more common in remand than in sentenced prisoners whereas the opposite seems true for major depression, especially lifetime prevalence (Curtin ea, 2009)

Response to treatment for depression may be retarded by poverty.(Cohen ea, 2006)

Being ill affects interpersonal relations, finance, jobs, accommodation, and so on. It may also symbolise failure to carry out ones social role. Patients and their relatives may go to great lengths to avoid consulting a psychiatrist because of stigma. This is particularly common in old age where dementia may be at an advanced stage before social breakdown forces referral. The discovery of mental illness in successive generations may be hushed up and rationalised, as often happens with Huntington's disease. Feelings of guilt in the relatives or disruption of a precarious social balance in the family may complicate the medical management of patients. Society condemns alcoholism and drug misuse and yet it also grants the same activities a certain prowess.

City life is generally associated with poor mental health in both children (Rutter, 1981) and adults,(Blazer ea, 1985; Weich ea, 2006) which may be a complex product of various factors including viral infections(Torrey, 1988) and childhood head trauma.(Field, 1976) Megacities in the third world with their rapidly expanding populations have been blamed for an expanding army of mentally ill people.(Klerman, 1976; Anonymous, 1997a) The role of housing⁵⁵⁰ in depression is complex, depending on who lives there, the social status of environs, and interactions between them.(Birtchnell, 1992) Mortality rates at all ages tend to be higher the lower the socio-economic status of the individual. Racial minorities in city centres may be at risk of not having their psychological problems identified.(Odell ea, 1997)

Irish in Britain

Reported to have very high level of service use, depression, alcoholism, schizophrenia, suicide and attempted suicide, admissions including involuntary admission rate, residence on secure wards, seclusion rates, referral from criminal justice

Described as mostly migrant workers, often unemployed, following employment, and homeless, and passing on their difficulties to the next generation (Bracken ea, 1998)

Walsh (1999; 2007) claimed that high British involuntary admission rates, older age (long-stay), low socio-economic status (more likely to be admitted) and out-of-date-data may account for these findings

Poorly planned migration blamed for depression in London Irish (Ryan ea, 2006)

Both long term (Scott, 1993) and temporary (Victor, 1992) homelessness are associated with an excess of mental disorder. The rising tide of homelessness may not be totally explicable on the basis of discharge from mental hospitals; other factors may include problems encountered in having mentally ill people admitted or readmitted to hospital (Lamb, 1993; Lamb, 1996) and the disappearance of affordable rented accommodation.(Leff, 1993) Homelessness does not appear to cause antisocial personality disorder, rather they have this profile before becoming homeless.(North ea, 1993) Caton ea (1994) found that drug abuse among seriously mentally ill men accounted for homelessness.

Dublin (Holohan, 2000)

29% of a homeless sample (only 64% of the known total of 780; 85% males) drank alcohol in excess of recommended limits, which compares favourably with general population (27% for males, 21% for females); majority of both homeless sexes were <45 years of age; 37% reported previous diagnosis of 2 psychiatric problems (32.5% depression, 27.6% anxiety) compared to 34% in a Sheffield (George ea, 1991) sample

Finnish study (Sourander ea, 2010) found that both cyberbullying and cybervictimisation are associated with psychiatric and psychosomatic problems.

⁵⁵⁰ Under the Irish *Housing (Miscellaneous Provisions) Act 2002* local authorities must provide housing to people in their area who require it.

Montreal (Roy ea, 2004)

Follow up of homeless aged 14-25 years; found standardised mortality ratio of 11.4; causes of death were suicide, overdose, unintentional injury, fulminant hepatitis A, and cardiac disease; predictors of mortality were HIV infection, alcohol use previous month, drug injection or homelessness in previous 6 months, and being male

San Diego County (Folsom ea, 2005)

Homelessness in patients treated for serious mental illness associated with male sex, being Black⁵⁵¹, substance misuse, lack of Medicaid, schizophrenia, bipolar disorder, and poor functioning

London (Abdul-Hamid ea, 2010)

Homeless men living in hostels require psychiatric and social assessments and alcohol and drug services; psychotic cases have high levels of unmet needs

Many psychiatric patients living rough fail to apply for their benefit entitlements.(Weller, 1989) Having been born in 1950s America, community psychiatry has arrived on the backs of a pharmaceutical revolution, hoped-for monetary savings,(Wildavsky, 1970) and the effects of social pressures born of an awareness of the poor condition of many Victorian institutions. Care in the community is universally hailed in principle but often condemned in practice. We are now in the era of bed shortages, high readmission rates, and revolving doors.(Appleby ea, 1993; Commander & Odell, 1998) Short inpatient stays in psychiatric hospitals are associated with high readmission rates.(Kammerling & O'Connor, 1993) Resettlement means moving patients from one place to another, such as from hospital to the community, whereas rehabilitation aims at minimising handicaps. Public hostility to community placement of mentally ill patients is quite common, at least initially, especially if placement is local and if adequate preparation of patients and the public is neglected. Some people have no objection to the 'insane' being deinstitutionalised as long as they are placed somewhere far from them, the NIMBY (not in my backyard) syndrome.(Sussman, 1997) Lamb (1996) was in favour of compulsory outpatient treatment and believed that Americans may be focusing excessively on liberty for patients 'at any costs'. Burns and Priebe (1999) warn that unless psychiatrists are proactive in advising governments about services we may be outvoted by more vocal groups whose proposals, whilst well meaning, may not be feasible or of practical utility. However, people usually want doctors when they are sick, but may avoid doctors when planning health care delivery.(Persaud, 2000) A novel idea is the use of negotiated joint crisis plans developed by patients and mental health staff that may include advance agreement on treatment preferences in case the patient later loses insight. There is some evidence that they may reduce involuntary admissions whilst not altering duration of hospital stay.(Henderson ea, 2004) However, Thomas and Cahill (2004) comment that 'the idea that we can soothe the pain of greater compulsion with the balm of advance statements is simplistic'. Patients' views about their involuntary admission (Priebe ea, 2010) varies with county studied, may become slightly more positive after a lapse of time, and may be more negative for females, people living alone, and if there is a diagnosis of schizophrenia.

See Change⁵⁵² (www.seechange.ie) was founded in Ireland in 2010 to tackle stigma associated with mental health problems.

Concern has been raised about direct advertising to consumer by the pharmaceutical industry⁵⁵³ aimed at the consumer and the potential for increasing costs⁵⁵⁴.(Bonaccorso & Sturchio, 2002; Gøtzsche, 2002; Mintzes 2002; Moynihan ea, 2002; Gilbody ea, 2004; Lenzer, 2005a,b; Anonymous, 2007a; Brown, 2007; Burton, 2008; Day, 2008; Dobson, 2008; Watson, 2009; Tanne, 2009a) Such direct advertising is currently prohibited in Europe but there is pressure to change this.(Moynihan, 2007; Toop & Mangin, 2007;

⁵⁵¹ Black Americans are relatively infrequent users of mental health services.(Neighbors ea, 2007)

⁵⁵² See Change works through the National Stigma Reduction Partnership, 38 Blessington Street, Dublin 7.

⁵⁵³ The most costly drugs to the Irish General Medical Services (GMS) scheme in 2002 were omeprazole (Losec), pravastatin (Lipostat), olanzapine (Zyprexa) – first to third respectively – and paroxetine (Seroxat), and risperidone (Risperdal) – ninth and tenth respectively.(Barry, 2002)

⁵⁵⁴ Drugs advertised in this way vary from antidepressants to drugs used for erectile dysfunction.(Rosenthal ea, 2002) Australia bans such practice and New Zealand was thinking of doing likewise in 2004.(Burton, 2004) Drugs may be portrayed in an unrealistically positive manner and doctors may be pressured to prescribe by patients and others.(Anonymous, 2005a; Kmietowicz, 2009) The US Congress has criticised drugs industry advertisements for overstating effectiveness and minimising risks.(Gottlieb, 2002) However, there are constitutional arguments favouring direct advertising (why not medication if alcohol can be advertised, etc?).(Shuchman, 2007)

Anonymous, 2008d, 2009; Watson, 2009) Whilst Canada also bans direct advertising of prescription drugs Canadians are influenced by TV and magazine advertisements from the US.(Mintzes, 2008) Doctors have become dependent on the pharmaceutical industry for funding research and declaration of interest may not always be forthcoming.(Editorial, 2002)

Informal carer stress⁵⁵⁵ (stress among relatives or friends who look after mentally ill people) is a newly recognised field for research. Women are the most common carers of sick relatives. Lauriello and Keith (1997) warn against families being asked to become the new 'back wards' of the community.⁵⁵⁶ Factors reported as being stressful include male sex of the patient, carers of high social class, difficult behaviour, negative symptoms, longer duration of illness, prior dependency on the ill person, and close relationship with the patient.(Olin ea, 1996; Tenakoon ea, 2000) Distress among carers can be persistent and may worsen over time.(Cooper ea, 2010) In a study conducted by Chessick ea (2009) increasing suicidal ideation had more negative subjective effects on the health of those caring for bipolar disorder patients than did static or declining suicidal ideation. Factors that were reported not to correlate with carer stress/distress include relationship of informant to patient.(Grad & Sainsbury, 1963; Mors ea, 1992) In a review of the literature, Fadden ea (1987) concluded that negative symptoms of mental illness, such as lack of conversation and non-performance of roles, are often a particular burden on relatives, that relatives do have a heavy burden to carry, that relatives complain very little and receive little support or advice, and that professional help has not improved much since the drive towards community care started. Indeed, voluntary befriending does not seem to help carers of people with dementia.(Charlesworth ea, 2008) Compared with control subjects, wounds in female carers of demented charges take longer to heal and their peripheral blood leucocytes produce significantly less interleukin-1beta mRNA in response to lipopolysaccharide stimulation.(Kiecolt-Glaser ea, 1995) Voluntary organisations tend to consider psychiatric interest in their endeavours in a poor light, although there much variation in this opinion.(O'Shea, 1989, 1992, 1994)

The UK Department of Health (2008) produced *Carers at the Heart of 21st-century Families and Communities* in which it was declared that carers would, by 2018, be respected as expert care partners and have access to integrated and personalised services to help them carry out their role; a life of their own alongside the carer role; have support to prevent being forced into financial hardship by the caring role; and have support to stay mentally and physically well and be treated with dignity. Children and young people will be protected from inappropriate caring and receive help to experience positive childhoods.

Patient self-advocacy is a very late twentieth century phenomenon. Patient groups such as 'Survivors Speak Out' in the UK are expressing views on the kind of service that they want.

There are numerous self-help groups.⁵⁵⁷ 'Recovery', for example, was started by the psychiatrist Abraham A Low. It employs a cognitive system for managing temperamental behaviour and changing attitudes towards nervousness and fears. Recovery groups do not discuss diagnoses or treatments and insist on members co-operating with physicians. It is a useful adjunct to professional care, helping clients to cope between consultations and during aftercare.

A family may use the anger engendered by a chronic illness in a relative to found a support group or increase public awareness. They may become depressed, withdraw from one another, or engage in bickering among themselves. Elder abuse may be a symptom of carer stress.

We live in an ageing population.(Falvey & O'Shea, 1983) In 1991 and 1996 respectively, Ireland had 403,000 and 411,000 people over 65 years of age. One projection for the year 2026 gives a figure of 692,000. Put another way, 11.4% of people were at least 65 years old in 1996, the projection for 2031 being 18%. These figures make planning for the future an urgent necessity.

Euthanasia (mercy killing) is illegal in the USA but physician-assisted suicide is not illegal in Oregon (since 1997) and Washington⁵⁵⁸ states in the US, Switzerland, the Netherlands⁵⁵⁹ Belgium⁵⁶⁰ (Charatan,

⁵⁵⁵ The *Carers Act 2000* in the UK entitles carers to their own separate assessments.

⁵⁵⁶ Time spent looking after patients by carers would contravene the European Working Time Directive were it carried out by paid employees.(Doran ea, 2003)

⁵⁵⁷ See Anonymous(1997b) and telephone directory for Irish contact addresses and numbers.

⁵⁵⁸ *Initiative 1000* in the state of Washington legalised physician-assisted suicide in 2008. Votes for the legislation were 58% for and 42% against.(Steinbrook, 2008) State residents with less than 6 months to live must wait 15 days then request again in writing and by word; possible depression warrants mental health referral; 2 doctors must approve the request; and the patient has to administer the lethal drug (usually a barbiturate in Oregon) him/herself!(Dyer C, 2008) In both states (Washington and Oregon) the doctor can supply the prescription for the lethal dose of medication but he/she cannot administer it.

2000; O'Shea, 2004, 2005; Onwuteaka-Philipsen ea, 2005; O'Shea ea, 2009), and Luxembourg (from April 1, 2009) and, according to a Constitutional Court ruling in 1997, not illegal in Columbia, is the direct taking of a suffering individual's life by another person in order to reduce such suffering or avoid disability. The Australian Northwest Territory legalised euthanasia under the *Rights of the Terminally Ill Act 1995* but this was voided, after three deaths had occurred, by the *Commonwealth to the Northern Territory (Self-Government) Act 1978*. Physician-assisted suicide (PAS), long used synonymously with 'euthanasia' (*Lancet*, Feb. 25 1899, p. 532; Branthwaite, 2005; George ea, 2005; Sommerville, 2005; Tännsjö, 2005), is the indirect help given by a doctor to achieve death, as, for example, when supplying a lethal dose of tablets (incl. in neonates and infants: Feudtner, 2005; Provoost ea, 2005; Vrakking ea, 2005; Sheldon, 2005; Costeloe, 2007). It is legal in Oregon (Steinbrook, 2002) under its *Death With Dignity Act* (1994 & 1997), despite attempts by the US attorney general to outlaw it under US 1970 *Controlled Substances Act*⁵⁶¹. (Charatan, 2004) The *Death With Dignity Act* allows mentally competent terminally ill people (confirmed by 2 doctors) with less than six months to live to ask for a lethal dose of drugs. PAS accounts for about 1 in 1,000 deaths per year in Oregon, a frequency that remained fairly steady for the first nine years since the *Death With Dignity Act*. (Quill, 2007) The high court in Colombia⁵⁶² ruled in 1997 that euthanasia was not a criminal act if the person had a terminal illness, wanted to die, and no medical treatment existed, leading to a legal no-man's-land where the practice was not prohibited but wasn't entirely legal. (Ceaser, 2008) The ruling Socialist Party in Spain is considering paving the way for assisted suicide (Villaneuva, 2008a) and Spanish law was changed in 2010 to allow abortion on demand up to 14 weeks gestation (de Lago, 2010a) and without parental consent. However, appeals have lodged with the Spanish Constitutional Court. (de Lago, 2010b) Portugal's medical ethical code condemned both abortion⁵⁶³ and euthanasia but, since 2008, it simply demands respect for life from the time of conception. (Villaneuva, 2008b)

Some doctors practice euthanasia/ physician-assisted suicide (E/PAS) in some form or other outside the law, (Mitchell & Owens, 2003; van der Heide ea, 2003; Turone, 2007; Dyer O, 2008) and not necessarily accompanied by an explicit patient request. (van der Heide ea, 2004, 2007) Courts have accepted testimony of third parties that it was a person's wish to die⁵⁶⁴. (Grayling, 2005) In November 2001, the British House of Lords refused a woman⁵⁶⁵ with motor neurone disease the right to choose her time of death and stated that her partner could be held legally accountable should he assist in achieving her demise.⁵⁶⁶ The English High Court granted a woman with cerebral ataxia the right to travel to Switzerland⁵⁶⁷ in 2004 where she terminated her life. In 2009, the Swiss government considered new laws to make it harder for foreigners to travel to Swiss clinics to get assistance to end their lives⁵⁶⁸. In 2004, the French National Assembly passed a law allowing conscious, terminally ill patients to refuse life-prolonging treatment. In 2007 Dr Laurence

⁵⁵⁹ The Dutch *Burial Act* was amended in 1993 to permit assisted suicide. The Dutch Foundation for Scientific Research into Careful Suicide provides advice on suicide at www.wozz.nl.

⁵⁶⁰ Belgian law acknowledges that mental suffering is a valid ground for euthanasia. (Naudts ea, 2006) Interestingly, Belgium legalised euthanasia despite having a very well developed palliative care system. (Bernheim ea, 2008)

⁵⁶¹ In *Gonzales v. Oregon* (2006), the US Supreme Court held that the US Attorney General could not use the *Controlled Substances Act* to stop Oregon doctors prescribing regulated drugs for use in PAS. The US Supreme Court (*Cruzan v. Director, Missouri Department of Health*, 1990) had previously held that the dying could refuse life-sustaining interventions.

⁵⁶² 95% Catholic population.

⁵⁶³ A referendum of 2007 led to abortion being allowed in registered centres up to tenth week of pregnancy. The ethical code only allows abortion if it is essential in order to save the mother's life.

⁵⁶⁴ In 2005, the Terri Schiavo case in Florida (brain damaged woman on life support) created great controversy.

⁵⁶⁵ Diane Pretty (d. 2002). In 2008, Debbie Purdy, a British woman with multiple sclerosis, won the right for a judicial review of whether her husband (Cuban violinist Omar Puente) would be held accountable if he brought her to Switzerland for PAS. The High Court refused her application and stated that only Parliament could change the law. In the same year, Daniel James (23, rugby injury, tetraplegia) was accompanied by his parents to Zurich for PAS but the director of public prosecutions (DPP) in England decided not to prosecute the parents because it would not be in the public interest. In 2009, Debbie Purdy (MS) received unanimous backing from the Lords for a policy statement from the DPP. The English DPP published guidance in early 2010 (Coggon, 2010) and listed factors for (e.g. victim < 18 years, lack of victim capacity, victim under doctor's care) and against (e.g. tried to dissuade victim or gave only minor encouragement) prosecuting with special relevance to medical personnel. In 2010 Tony Nicklinson (56) in the UK, a sufferer from locked-in syndrome following a stroke, asked the DPP (via his solicitors) if those carrying out mercy killing/voluntary euthanasia would be prosecuted.

⁵⁶⁶ The European Court of Human Rights upheld this refusal in 2002.

⁵⁶⁷ Zurich clinic run by *Dignitas* (founded 1998 by journalist and lawyer Ludwig Minelli).

⁵⁶⁸ The british conductor Sir Edward Downes (no terminal illness, aged 85) and his wife (Joan, had terminal illness) used *Dignitas* services in 2009.

Tramois of France received a one-year suspended sentence for a 2003 killing of a cancer patient.(Mullins, 2007) Under English law (*Suicide Act 1961*) assisted suicide carries a maximum prison sentence of 14 years⁵⁶⁹.(Huxtable, 2004; Dyer, 2007a) Whilst, at the beginning of 2005, the English Courts empathised sufficiently with the male survivor of a marital suicide pact to hand down a short suspended sentence, the UK House of Lords rejected a bill to legalise PAS in May 2006.(Dyer, 2006) In January 2007,(Dyer, 2007b) England's senior family judge ruled that life sustaining treatment could be withdrawn from a woman in a persistent vegetative state following brain haemorrhage. The conviction of Nicholas Reed, the former secretary of EXIT, for assisted suicide led that group to change its name to the Voluntary Euthanasia Society. Since 2000, Dutch law holds that only a medical doctor can consider a request for PAS and such request must stem from a physical or mental disorder, not an 'existential' (i.e. in the absence of a physical or mental disorder) source.(de Vries, 2003) A problem arises when a patient wants to die but the (Dutch) physician does not think that the patient's suffering is 'unbearable'!(Pasman ea, 2009) Onwuteaka-Philipsen ea (2003) found that the demand for PAS had not risen among Dutch physicians and patients since 1995; the authors deducted that the Dutch 'seem to have become somewhat more reluctant in their attitude towards this practice'. In fact, euthanasia and PAS declined modestly from 2001-5, perhaps replaced by other options such as 'palliative sedation'⁵⁷⁰.(van der Heide ea, 2007; Mullins, 2008; Rietjens ea, 2008) Dutch physicians usually refuse requests for PAS in the absence of severe disease, but most patients persist in their request.(Rurup ea, 2005) Dutch medical mercy killing of severely ill newborn babies does not seem to have become common, probably this is because of abortion, fear of litigation, and lack of knowledge of what is involved.(Sheldon, 2009) According to Swarte ea,(2003) the Dutch experience with cancer deaths is that the bereaved seem to cope better if death is due to euthanasia than if it occurs naturally. Advising a patient on the lethal dose of a drug does not appear to be illegal in the Netherlands.(Sheldon, 2007) Pain as a reason for requests for PAS to have decreased, probably because of improved pain management, to be replaced by deteriorating health and increased emphasis on 'self-esteem'.(Marquet ea, 2003) Hendin (1997) suggests that Dutch patients are subtly coerced by relatives and enthusiastic doctors to accept euthanasia. Switzerland has very liberal laws on assisted suicide: patients must persistently want to die, be of sound mind, have an incurable disease, and carry out the final act themselves. Technically, PAS is illegal in Switzerland, but to be guilty of an offence it must be shown that one acted selfishly⁵⁷¹.(Ziegler & Bosshard, 2007) Guidelines for PAS are now commonplace in Swiss hospitals.(Tuffs, 2007a) Prescribed barbiturates are the usual method in Swiss PAS. Lausanne University Hospital decided in 2006 to allow assisted suicide groups onto their premises to help terminally ill patients die.(Chapman, 2006) The wish to die is subject to great variation over time, and is influenced by many factors, especially depression.(Chochinov ea, 1995; Breitbart ea, 2000; O'Shea 2000a,b; Schuster, 2000; Blank ea, 2001; Kelly ea, 2003; Barnow ea, 2004; Marcoux ea, 2005; Ganzini ea, 2008; van der Lee, 2008) Depressed patients are more likely to refuse cardiopulmonary resuscitation (CPR).(Lifton & Kett, 2000) Fourteen percent of terminally ill cancer patients in various settings were found by Kelly ea (2003) to wish to hasten death and this wish was associated with depressive symptoms, hospice inpatient status, seeing oneself as a burden, low family cohesion/social support, high anxiety levels, and greater impact of physical symptoms. Hospice nurses and social workers in Oregon have viewed the chief reason for a request for PAS differently, placing a need to control the circumstances of death way ahead of depression, lack of social support, and fear of being a financial drain on the family.(Ganzini ea, 2002) States intending to legitimise PAS would do well to look first to the care already given to the dying (Ganzini & Block, 2002; Swarte ea, 2003) and the reasons why some people want it.(Mak ea, 2003) Peretti-Watel ea,(2003) reporting on a telephone survey in France, found that GPs and neurologists more than oncologists wanted euthanasia to be legalised; the authors suggested that a lack of knowledge about palliative care might explain this finding. Van den Block ea (2009) found that end of life decisions (including euthanasia/PAS) as reported by GPs in Belgium are not a reflection of lower resort to palliative care but 'often' (but see

⁵⁶⁹ The BMA in Britain has a tendency to swing to and fro on the issue.(Kmietowicz, 2006)

⁵⁷⁰ This term may be misleading as some authors contrast *palliative* (without the aim being death even if death occurs as a side-effect) with *terminal* (knowing the patient will die shortly) sedation.(Murray ea, 2008) In the Rietjens ea (2008) study, a nationwide questionnaire-based study of physicians, such continuous deep sedation increased from 5.6% to 7.1% of deaths between 2001 and 2005. Benzodiazepines were used in 83% of cases. 94% were sedated for > 1 week prior to death. 9% of those receiving sedation had unsuccessfully requested euthanasia. 9% of physicians had consulted an expert in palliative care. Cunningham (2008) has discussed the ethical use of sedation in the distressed dying.

⁵⁷¹ Article 115 of Swiss Penal Code.

Byock, 2009) occur in the context of multidisciplinary care. This study did not access hospital personnel and could not measure cause and effect. Blass and Ratan (2003) express worries about precipitating requests for PAS in patients by telling them that they have incipient Alzheimer's disease based on neuroimaging findings. In 2005, the Dutch euthanasia assessment committee reported that a doctor lawfully complied with a request for euthanasia from a patient with Alzheimer's disease. In fact, only 4 of 1886 cases of euthanasia/PAS in 2004 failed the Dutch legal requirements. The law requires that such cases be referred to the public prosecution service.

Palliation⁵⁷² is well within the Hippocratic tradition even though whilst it doesn't try to hasten death it doesn't seek to prevent it ('passive euthanasia'). (John Paul II, 1995; Keown, 2002) The ethical practitioner does not need to go to extraordinary lengths to preserve life but he/she should strive to minimise suffering. Beyond the death of the individual person and its immediate legal/moral implications, the major problem with active euthanasia is that its social acceptance removes any 'principled objection' to involuntary euthanasia. (Hughes & Baldwin, 2008, p. 726) The belief that all cases receiving PAS were 'terminal' may not be correct. (Koch, 2008) There is pressure in the Netherlands from *Uit Vrije Wil* (Of One's Own Free Will) to allow PAS for older people who are not dying but that feel their life is complete. (Sheldon, 2010) Also, not all dying people are free of fear. Dying people are vulnerable and are potentially open to exploitation. (Carlile, 2009) The increasing technological approach to medical practice should not divert practitioners from recognition of the fact that a person is dying and requires palliation and Livesley (2010) suggests that this has compromised our caring role to the extent that those who advocate assisted dying end up looking like the only people who care.

The relation between *religion* and risk for depression is complex and simple explanations may be misleading. (Maselko et al., 2009) Psychiatrists may be hostile to religion⁵⁷³ as a group (Dein et al., 2010), a

⁵⁷² A postal survey of UK medical practitioners (Seale, 2009) found that only 9% of doctors believed that they should be able to end the lives of people who had incurable and painful disorders compared to half of the general public who favoured physician-assisted death. The strongest opposition came from specialists in palliative care, followed by those charged with looking after the elderly.

⁵⁷³ *Religion* refers to socially based beliefs/traditions with/without ritual/ceremony. *Spirituality* is a strong sense of connection that enables a person to feel that his/her life contributes to a greater and valued whole, that we are not meaningless within the Universe. (Dein et al., 2010) Serious illness and death of a valued other may generate a crisis of meaning. A few notes on various **religions** in relation to healthcare issues will be made here (Mootoo, 2005; HSE, 2009). People who do not have religious beliefs may describe themselves as such or as humanist, agnostic or atheist. In-patients with this status should not be made to feel embarrassed during hospital-based religious services. Non-religious funeral ceremonies can be organised by the Humanist Association of Ireland (www.humanism.ie). Religious symbols (e.g. a plain cross in the case of Anglicans) should only be removed when essential (e.g. radiological study or cleaning the deceased) and should be replaced as soon as possible. Many religious and cultural groups have their own herbal remedies (which may interact with orthodox prescriptions) and washing rituals. Where medicines contain animal products forbidden by a particular religion the adherent will want to decide on whether to take them or not. Traditions requiring candles to be lit near the deceased should be accommodated if it is safe to do so. Those traditions mandating multiple visitors to the sickroom may be requested to rotate visitors or may be asked to leave a few visitors with the patient while others pray in a prayer room. Coroners should be advised where religion mandates early burial so that a Death Certificate is not unduly delayed. Some traditions have beliefs that may clash with those of the majority of the population but they must nevertheless be respected, e.g. some African Pentecostals may explain illness as being caused by unseen agencies and they may request that their pastor pray to God to intervene (although this does not normally cause problems with the simultaneous acceptance of medical intervention). There is some degree of pastoral cross-cover among the major non-Catholic Christian traditions but this will require clarification in each case. The tradition of the *Irish Traveller Community* (who are mostly Roman Catholic) held that pregnant women should avoid dead bodies and this practice may still pertain. The *Roma* (Lit. 'people') community may speak a Romani (this is nothing to do with Romanian) dialect and most members are Pentecostals with some being Roman Catholic or Orthodox Christians. Some traditional Roma women may want their menfolk to talk on their behalf but this cannot be assumed. The Roma often visit the sick in large numbers and they usually want to bring a deceased member's remains home as quickly as possible where the body will be displayed for two nights. Bereaved Roma wear black for one year and the men do not shave during this time. **(Roman) Catholics** will want a priest in attendance if a patient is close to death and newborn children who are dying should be baptised (by a Christian layperson if clergy are unavailable); the *Sacrament of the Anointing of the Sick* may be given to ill people or those facing major surgery and the *Viaticum* is given to those close to death. A dead infant cannot be baptised but can be named. Some Catholics are buried in a shroud. Baptism in the **Orthodox Church** is normally conducted when the baby is 40 days old, unless the baby is dying in which case the Orthodox priest or the parents can conduct the rite. Orthodox Christians believe that the deceased should be buried whole and undamaged. Sacred icons are an important part of the Orthodox tradition. In an emergency, **Church of Ireland** (*Anglican* or, in Scotland or US, *Episcopalian*) lay people can baptise an infant or child. **Baptists** do not baptise infants even when death is imminent; a minister of that faith may perform a *Naming Ceremony* if the child dies (including miscarriage/stillbirth) before it can be baptised. They may however hold a dedication service. **Lutherans** baptise during infancy and any Christian can perform this ritual in an emergency; a blessing may be offered in the case of miscarriage. **Methodists** do not have a formal death rite but they usually want a dying baby to be baptised. **Presbyterians** may want a minister of their faith to be called in cases of death in order to help them pray but the dead, including a child, are deemed to be in God's hands so a chaplain need not be called after death as such; non-ordained adherents may pray for and name a deceased newborn child but they cannot baptise the baby. **Pentecostals** (belonging to many different Churches) receive

phenomenon dated to Charcot and Freud.(Koenig, 2008) We must take our patients' religious and spiritual beliefs into account more than we have in the past.(Cook, 2010; King & Leavey, 2010) We may avoid doing so because we believe that religion is irrelevant generally or to psychiatry in particular, we do not see ourselves as theologians, or because we are fearful of such matters.(Sims, 1994; McClain et al, 2003) Religious patients may have difficulty confiding in a psychiatrist who they perceive as unbelievers or as disparaging of religion.(Dein et al, 2010) There are instances where involvement of a pastoral counsellor is relevant, where supporting religious belief is important, and, when we know our patients well, when confronting unhelpful beliefs may be indicated.(Koenig, 2008)

Sociobiology is the study of the biological basis of social behaviour. It integrates principles of evolution, genetics, ecology, and ethology. Important concepts in sociobiology include the following: *Fitness*, the highest measure of evolutionary success has been reached in that the best genes are passed down through the

baptism when an adherent is ready to receive this sacrament and infant baptism is not a requirement of this tradition. The **Religious Society of Friends** ('*Friends*', *Quakers*) have no clergy but may want a visit from a fellow adherent such as an elder during times of distress; baptism is not necessary for infants who are dying; funerals are silent apart from acknowledging manifestations of God's goodness in the deceased and requests for comfort for the bereaved. **Seventh-day Adventists**, who have the same Sabbath as do Jews, must not eat 'unclean' food. They may be vegetarians or vegans. Alcohol, including during *Holy Communion* (pure grape juice is allowed), is avoided. Baptism by full immersion only takes place when the 'age of accountability' is reached. **Church of Jesus Christ of Latter-day Saints** should be referred to as *Latter-day Saints* rather than as *Mormons*; *home teachers* visit their sick and *elders* perform religious ceremonies; blessing of the sick involves anointing with oil and laying on of hands; burial is preferred to cremation; and baptisms (normally conducted at age 8 years) of infants who are dying is not deemed to be necessary. **Jehovah's Witnesses** have Hospital Liaison Committees that provide support, mediation, and information when medical interventions are proposed; blood, blood cells and plasma (including in foods such as black pudding) are not allowed (adherents vary in relation to use of the patient's own blood or the use of albumin, clotting factors and immunoglobulins; organ donation/transplantation is based on personal choice); baptism of the newborn is not practiced (baptism occurs when the person understands its implications). **First Church of Christ, Scientist** (*Christian Science*) adherents may only be in hospital for childbirth, following an accident or secondary to family pressure and members should be allowed to discuss the level of care they will accept (children can be treated in accordance with State Law); a time to pray may be requested before a medical intervention; females should handle deceased female Christian Scientists; post-mortem examination requires compelling reasons; cremation is more common than burial; and baptism is not part of Christian Scientist ritual. **Bahá'í** adherents customarily put a ring on the finger of the deceased and this should never be removed. The Bahá'í forbid cremation and insist that the deceased is interred as near as possible to the place of death. **Judaism** (*Jews*) mandates dietary rules (*kosher*). The advice of a rabbi may be sought when major life questions arise. The Jewish Burial Society (*Chevre Kadish*: not available during *Sabbath*, i.e. sunset on Friday to nightfall on Saturday) will prepare the deceased, and the body, unwashed by healthcare workers and with tubes and dressings in place, should be left in the mortuary until the community arrives; mementos (e.g. a lock of hair) are not to be removed from the body; relatives may request that the body of the deceased be placed on the floor with feet pointing to the door and a window left open; burial (never cremation) is carried out as soon as possible after death and post-mortem examination should only be conducted if the law requires it; traditional mourning lasts for 7 days; and foetal losses after 3 months of pregnancy are given full Jewish ritual. Orthodox Jews do not use electrical appliances such as telephones on the Sabbath; neither do they travel during that period so visitors may need assistance with somewhere to rest; and women may want to light candles at the onset of Sabbath. Males over 13 years of age may wish to pray wearing religious garments such as a shawl. **Islam** (*Muslims*) is divided into the Sunni and Shi'a traditions; the left hand should where possible be left free for washing; when a child is born the parent, usually the father, recites a prayer into each ear in turn; patients should eat *halal* food (pork and alcohol are forbidden); during *Ramadan* food and liquid are avoided from dawn to dusk, although pregnant women, the ill and children are not subject to this rule; just before death the person should be turned toward Mecca; the body of the deceased should not be washed by healthcare staff and touching the body is a task for same-sexed staff; the dead, who should be modestly covered, are believed to retain awareness; essential post-mortems should end with restoration of removed organs; full ritual is carried out after death for foetuses that have developed; burial (in shroud and facing Mecca; cremation is forbidden) should be as soon as possible. **Hinduism** (*Hindus*) is often associated with *Ayurveda*, a traditional medical system involving herbs, exercise and diet. Beef (sometimes pork) and its derivatives are disallowed (if these are in prescription medicines the patient has a choice to make). Babies are blessed and named on the tenth day of life. Intra-uterine death from the third month onwards is treated as for infants. Family and/or husband involvement in decision making is very common. If family are not available then healthcare staff can clean and wash deceased Hindu adherents; a lighted candle is left near the head of the body; and cremation takes place within 24 hours of death with the ashes then scattered into a river, followed by 13 days of mourning. **Sikhs** have strict dietary practices and will want to know if medicines contain proscribed agents such as alcohol. They have a strict dress code (including a strapped miniature sword and a turban – when necessary for examination or treatment purposes, patients should be asked to remove their own turban). Deceased members should be washed by same-sex healthcare workers. A dead child should be wrapped in a clean white cloth before being handed over to the family. Do not remove a lock of hair as a memento for the family. If one has to cut hair then consent should be sought when possible. **Buddhists** believe that consciousness is retained for about 4 hours after death and they wish for a peaceful and private environment, unaffected by mind-altering medication, during their last hours so that the spirit (i.e. consciousness) can gently exit the body through the top of the head (sometimes assisted by tapping the head). The body should not be laid out for at least 4 hours, the head should remain untouched, and only essential cleaning (e.g. blood) should be undertaken by staff. Sacred symbols (*Prayer Mandalas*) may be placed on the deceased and these should be left *in situ*. Post-mortem examination should be delayed for a minimum of 4 hours and preferably for some days. Finally, some people practice ancient/traditional religions such **Druidry** and **Shamanism**. Patients should be asked if there are particular requirements in the context of medical treatment or if there are any observances in relation to death or dying, e.g. some women may want to bring the placenta home in order to dispose of it according to their particular belief system.

generations. *Inclusive fitness* is the sum of an individual fitness plus that of his relatives compared to the rest of the population. *Resource holding potential* (RHP) is an animal's ability to defend a disputed territory or resource, the greater the RHP the more successful is the animal. *Sexual dimorphism* means that female and male behaviour evolve differently to ensure maintenance of resources and reproduction. Finally, *altruism* is overtly unselfish behaviour that is really genetically selfish because it allows survival by another member of the population.

*Internet*⁵⁷⁴ *addiction* (Murali & George, 2007) affects a minority of users of the internet. It can be defined as excessive, maladaptive, or addictive use of the internet. There are many possible causes, e.g. operant conditioning, immediate reward, impulsivity, shyness, and introversion. This controversial 'entity' has a broad comorbidity ranging from ADHD to shyness. The excessive user may focus on cybersex, gambling, shopping⁵⁷⁵, database searching, or games. Adverse effects include reduced time spent in real-life relationships ('cyberwidow'), poor academic/occupational performance, loneliness/frustration/depression/suicidal ideation (Fu et al., 2010), and fatigue. Approaches to treatment include behavioural strategies (e.g. outdoor activities), support groups, and cognitive therapy.

Systems Theory

Everything is made up of a hierarchy of concrete systems that are made up of matter and energy. The parts of a system are interdependent and interact in the system. At a very low level of the hierarchy are atoms that contain sub-atomic particles. Further up the line are cells. Further up again are multicellular organisms, such as man. Beyond this are flocks of sheep, families of humans, armies, nations, international groups, et cetera.

External systems interact with any given system. Systems can be living or inanimate, and each has evolved methods of communication between its components and tended to become more complex over time.

Adaptation to external stresses and demands led to specialisation within organisms⁵⁷⁶.

Humans developed a capacity for symbolic language. (see box) Group efforts allow us to produce objects beyond the capacity of individual organisms, e.g. cities, hospitals, rockets, and the delivery of the mail. Despite this level of sophistication, we still can only survive within very narrow limits of, for example, temperature or acidity.

Systems contain subsystems that carry out certain processes, e.g. heart muscle, excretion, and so on.

Suprasystems are above the system; e.g. the individual person belongs to his family. Reproduction allows the continuance of the type to which a system belongs. Homeostasis allows the human system to survive despite fluctuations in the external or internal environments. If such changes prove extreme the system is strained. Excessive strain leads to pathological change. Systems have in-built positive and negative feedback mechanisms to enable fine adjustments to be made, e.g. the output of thyroid hormones.

Language

Discourse analysis: that aspect of pragmatics seeking to establish why texts are coherent

Linguistics: refers to the systematic and objective study of language

Metaphonology: rules governing permitted phonemic combination and subtleties of pronunciation

Phoneme: constituent speech sounds

Phonological receptivity: an ability that is at its height during infancy and fades until before adolescence; deterioration in this ability makes learning a new language difficult after the early childhood years

Phonology: study of sound patterns morphology and syntax, study of word and sentence structure

Pragmatics: use of language for interpersonal communication; use of language in natural settings, i.e. conversation; tone may be employed to convey feeling; familiarity with the listener or the context of the discussion leads to variation in what is said and how it is said

Prosody: rhythm and melody of speech

Psycholinguistics: studies the relationship between language and mind; must be taken into account in cross-cultural studies

⁵⁷⁴ See Perecherla (2009) for an introduction to internet matters, including 'telepsychiatry' (provision of services to remote areas).

⁵⁷⁵ DSM-IV-TR impulse-control disorders not otherwise specified include pathological shopping or spending, compulsive sexual behaviour or face-picking, and repetitive self-mutilation. **Compulsive or pathological shopping** (*mall mania*) may share some characteristics with substance use disorders, OCD, affective disorders, or anxiety.

⁵⁷⁶ E.g. some cells became able to contract very well, others to secrete specific substances in large quantities, and others to carry messages.

Semantics: study of meaning

Sociolinguistics: relationship between language and social groups

Syntax: grammar and word order, i.e. language rules on how to combine words to produce phrases/sentences

Information processing within the human system is highly complex and subject to pathological change in various ways. Psychoanalysts recognised that the psyche contained a number of homeostatic mechanisms, known as defence mechanisms, which guard against overwhelming anxiety or psychosis.

Group dynamics can be understood in terms of systems theory. In order to understand why something is happening to a person we must understand the system(s) within which he exists, the suprasystems(s), the subsystems, and the interplay of information to and from that person and all of the above. (Lipowski, 1975; Browne, 1988).

According to systems theory, intrafamilial interactions are multidirectional, homeostasis is desired and threatened by change, and scapegoating may be used to regain equilibrium, the scapegoat being presented as the 'patient'. The family therapist focuses on family interactions (e.g. communication patterns, unspoken rules and games, authority structure) and attempts to alter these.

Minuchin developed *structural therapy*. The family consists of a hierarchy of subsystems (spouses, parents, and siblings) with clear but semipermeable boundaries between them. Dysfunction may occur because of excessively rigid (*disengagement*) or diffuse (*enmeshment*) boundaries. Disruption may be due to overprotection, rigid behaviour, poor conflict resolution, or the involvement of offspring in marital conflict. Therapy aims to restructure appropriate subsystems.

Crisis Theory and Therapy

A crisis is a response to a hazardous event and is experienced as a painful state. If reactions are appropriate, then normal functioning resumes. The person learns more about adaptation because of the experience, and psychological growth may follow. Maladaptive reactions make matters worse and can cause psychiatric symptoms leading to neurotic behavior and poor function. Responses may be extreme, even including suicide.

In a crisis the anxiety level rises leading to attempts to solve the problem. The outcome depends on the effectiveness of the response. The person devotes all his energy into resolving the present crisis. He may seek outside assistance. Hopefully, he learns how to foretell, resolve or prevent such events in the future. The therapist, when faced with a patient of limited resources, aims at shoring up existing defences using supportive measures. In the case of people who are basically sound, but who from time to time experience neurotic breakdowns, and who are able to handle anxiety, he may indulge in dynamic psychotherapies which tend to provoke further anxiety. Supportive techniques include explanation, reassurance, advice, medication, environmental manipulation, and, if necessary, brief periods in hospital. Brief psychotherapy may be conducted in individual (therapist and patient only) or group (e.g. couple, family, large groups) settings. Anxiety-provoking techniques are only suitable for those clients who are highly motivated to understand themselves better and who are highly desirous of change. In dynamic therapies the therapist focuses on the crisis itself, the client works actively with the therapist in a therapeutic alliance, transference reactions are made use of (ignored in supportive cases), and the hope is that this turns out to be a true learning experience. Sifneos (1979) discusses short-term dynamic psychotherapy

Concepts or models of Disease⁵⁷⁷

How can we capture the essence of disease when health, often defined by the absence of disease, is itself difficult to put into words? Psychiatric disorders are symptom-dependent and the symptoms themselves are hard to describe. (McKenna, 2007, p. 81) What is regarded as illness, including a legitimate illness, may vary with time and the prevailing predominant culture. (Shorter, 1995; McCabe & Priebe, 2004) It may also vary with governmental policy, e.g. the UK government's 1999 declaration that it intended to introduce legislation for the 'compulsory and potentially indefinite' detention of persons with 'dangerous severe personality disorder'. This rejuvenated the debate as to whether the personality disordered were ill *per*

⁵⁷⁷ According to Jager (1999), 'Prostitutes and lawyers may have clients. Psychiatrists have patients'.

se.(Kendell, 2002) *Drapetomania* referred to an 'excessive' desire on the part of Negro slaves in pre-Civil War America to escape!(Brown et al, 1998)

According to Kreitman (1989), the essential task for both the clinical psychiatrist and the researcher is to 'understand how social, somatic, and psychological processes interact and how they sometimes lead to feelings of distress...a secondary distinction may then be drawn identifying those types of distress that are appropriate for the medical profession, broadly defined, and those that are not.'

Some criticisms of the notion of 'psychiatric disease'

Thomas Szasz (1960) - it does not exist

Franco Basaglia (1970) - an expediency suiting the ruling authorities

R. Leifer (1971) - an ideology

Scheff and others – we are simply labelling people

Labelling (see Gould, 2005) may lead to 'secondary deviance', promoting or reinforcing socially deviant behaviour. Depending on the onlookers' viewpoint, the constant alterations in, and dissatisfaction with, current psychiatric classification may be viewed as evidence of ignorance or as a quest for better understanding.

Alternative 'explanations' for psychiatric problems include badness, social problems, clashes of personality, demonical forces, learning problems (neurological or inadequate or unhealthy role models or experiences), separation experiences at vulnerable developmental stages, communication problems, deficits in inferential reasoning,(Charlton, 1995, who advocates a computer model of the mind) low self-esteem, fixed patterns of attribution, genetic traits, acquired biological damage, or a mixed bio-psycho-social diathesis.(George Engel⁵⁷⁸, 1982) At one time, mental functions were thought to be localised in the same manner as motor and sensory functions; at other times a holistic view held sway, the brain being seen as an 'equipotential diffuse organ'.(Berrios, 1991)

Illness and related terms

Patient: Lat. *pati*, to suffer; *client*: Lat. *clinare*, to learn.

Illness refers to feeling or looking unwell⁵⁷⁹. *Disease* is more difficult to define. The Concise Oxford Dictionary is unhelpful, defining disease as an 'unhealthy' state of the body, mind, or part thereof.

Traditionally in medicine, when a cause is known the term disease is substituted for other labels. However, Minas and Silove (2007, p. 512) are correct when they say that while organ systems may suffer disease it is 'only a whole, sentient person' who can be ill. A *syndrome* refers to a collection of symptoms and/or signs that occur together with sufficient frequency to suggest shared aetiological or pathogenic roots; even when causes are thought to be multiple it is assumed that they act through a 'final common pathway'.

Schizophrenia and ischaemic heart disease (IHD) are complex (non-Mendelian) disorders that arise from the interaction of a number of factors; we know more about the pathogenesis (mechanisms) of the latter than we do of the former.

ICD 10 tries to avoid the terms disease and illness, opting for the inexact word 'disorder' to imply the presence of 'a clinically recognisable set of symptoms or behaviour associated in most cases with distress and with interference with personal functions'. It states that 'social deviance or conflict alone, without personal dysfunction, should not be included in mental disorder' as defined in ICD 10.

Scadding's (1967) *biological disadvantage* concept of disease may be qualified by saying that, in certain circumstances, the individual's disadvantage (e.g. sickle cell anaemia) carries advantages for the wider group (who carry the gene for sickle cell anaemia and are protected against malaria).

Foulds' hierarchy, after Graham Foulds, a psychologist, who described it (Fould, 1976), places neuroses and personality disorders at the base of a pyramid. At progressively higher levels we find anxiety, depression, schizophrenia, and dementia. Disorders at a given level can have features of all the disorders

⁵⁷⁸ George L Engel (1913-1999) at Rochester, New York State.

⁵⁷⁹ Marshall & Klein (2002) define illness as being involuntary, with obvious effects on function and well-being, resistant to self-instruction, and persistence despite clear negative implications for the sufferer.

below it but not of those above it. Once popular, this diagnostic approach and explanatory paradigm has been largely displaced by an era of multiple diagnoses, i.e. co-morbidity⁵⁸⁰. Not everyone agrees with its displacement.

Diagnoses are often critiqued as being over-simplifications of real dilemmas, mixtures of other diagnoses, pejorative (e.g. hysteria), and conveying a false sense of understanding of a 'condition'. Diagnoses are concepts whose usefulness may (and have been) replaced by other concepts. They do, however, describe real phenomena, with the possible exception of some esoterica such as 'multiple personality disorder'. The DSM system of classifying mental disorders borrows from Kraupl-Taylor (1971) with its emphasis on actual or increased risk of significant distress, disability, or loss of freedom. Kraupl-Taylor stated that the disorder must be abnormal by the standards of the population or the norms of the individual and associated with concern experienced by the sufferer, other people, or doctors. The use of antidepressants to treat minor mood fluctuations and psychological problems in general has been condemned by Lader. (1998) Wing & Morris (1981) define *impairment* as loss of normal function at the organ level, e.g. renal or cerebral impairment, poor sight, or low IQ. *Disability* occurs at the level of the person as a result of impairments, poor exercise tolerance due to compromised pulmonary function. Handicap refers to disadvantages due to impairment and disability, as when one person suffers more because he hoped to continue sprint running, despite equal lung damage to a second person. In schizophrenia, for example, contributions to disability and handicap may arise from psychiatric impairment, such as social withdrawal and delusions, social disadvantages, like poor education level or lack of social support, and adverse personal reactions (low self-esteem, social discrimination) to impairments and disadvantages.

A statistically significant positive correlation between certain variables is not synonymous necessarily with a common causation⁵⁸¹. It could be due to such factors as shared high frequencies.

A physical 'lesion' is something like a malignant tumour, a bruise, a torn ligament, atrophic or dysplastic tissue, or a thrombus. Philosophers argue among themselves about what terminology most suits the constellation of problems psychiatrists deal with. (Dubos, 1968; Steiner, 1969; Davies, 1974; Mahler, 1975; Sedgwick, 1982) Is a disease something which we can isolate from the human body (e.g. bacteria) which is known to be associated with bodily reactions (e.g. tumour, pneumonia)? Is it a malfunction of some organ or tissue regardless of whether the aetiology is known or not? Did pernicious anaemia only become a disease with the discovery of cyanocobalmin or intrinsic factor? Is disease a term applicable to suffering regardless of knowledge of aetiology? Is the mind a distinct entity from the brain? Is the mind synonymous with the soul? Can all three, or two, become ill or diseased. René Descartes separated mind from body and thought from feeling, with profound implications for psychiatric thinking.

Psychiatrists are sometimes accused of being too expansionist, taking over the management of problems of living, (Double, 2002) or of being too restrictive in the territory which they define as their own.

The *medical model*⁵⁸² (Macklin, 1973; Berrios & Marková, 2002) assumes that one day we will discover a physical cause or mechanism for most, if not all, psychological ills, or, more narrowly, for certain psychological problems, such as psychotic states. Craddock et al (2008) are critical of attempts to downgrade medical aspects of care, viewing it as disadvantaging patients. Psychoanalysts interpret the psychoses as the loss of firm ego boundaries with intrusion of repressed noxious material into consciousness. The pure organic psychiatrist might view psychological/ behavioural problems as manifestations of brain dysfunction, however subtle the latter may be. It could be argued that at least some psychiatric problems are simply a way of communicating distress⁵⁸³, avoiding painful stresses, or evading

⁵⁸⁰ In practice, patients often have symptoms of more than one disorder or fulfil criteria for multiple disorders. (McGuffin, 2002, p. 11)

⁵⁸¹ H T Buckle (1821-62) wrote that 'in all fields of inquiry there are a sufficient number of empirical coincidences to make a plausible case in favour of whatever view a man chooses to advocate. (Buckle, 1857, p. 162) Raymond Pearl (1879-1940) of Johns Hopkins University infected cancer patients with tubercle bacilli because he concluded that the two diseases rarely occurred together and must therefore antagonise one another! (Pyenson & Sheets-Pyenson, 1999, p. 283)

⁵⁸² René Descartes (Renatus Cartesius), 1596-1650, Jesuit-trained father of modern philosophy, was born at La Haye near Tours. Descartes's separation of mind from body and thought from feeling had major implications for psychiatric thinking. Unlike Freud, he asserted that mental processes are limited to conscious awareness.

⁵⁸³ Jacob (2009), for example, is justly critical of the DSM concept of major depression. There are serious shortcomings attached to diagnosing depression by employing severity criteria and a cross-sectional examination. Major depression is a loosely defined category that trumps adjustment disorder and dysthymia. Jacob (2009) pleads for an emphasis on context (stress, coping, and support), a return to older categories (melancholia, dysthymia, and adjustment disorder), and avoidance of medicalisation of distress.

responsibilities, or, bluntly, of 'milking the system'. We do not know many of the answers to such questions and it is likely that all the various theories are true to some extent in some people some of the time. What brings a person to a psychiatrist or other mental health professional is rarely simple. Diseases, disorders, or whatever do not occur in a vacuum. They are dependent on many variables for their expression, e.g. genetics, upbringing, nutrition, peer group influences, cultural mores, drug intake, socio-economic status, education, and age.

The terms endogenous and exogenous were introduced into medicine by the neurologist Mobius in 1893. Their usefulness, like so many other terms, has not been straightforward, and modern practice assumes contributions from biological, psychological and environmental sources. Johnstone, ea,(1988) could not distinguish between organic and DSM-III -diagnosed, matched 'functional' (schizophrenia, mania, depression) cases on the PSE.

Aetiology is rarely known in psychiatry, except for problems like grief or diseases like syphilis.⁵⁸⁴ We are describing syndromes. There is no other practical alternative at present, unless we are to become enslaved by theory.

No matter what the diagnosis or however chronic the illness, we must not regard patients as objects.(Hinshelwood, 1999)

Diagnostic levels (Stanga & Preskorn, 1997)

Symptom detection - most basic form⁵⁸⁵

Syndromic diagnoses – majority of psychiatric practice⁵⁸⁶

Pathophysiological diagnosis - even better

Aetiological diagnosis - the ideal

One can view mental experience from the point of view of either *form* or *function*. The former model sees people as animals subject to various diseases that present in certain ways. This approach attempts to apply scientific objectivity to the understanding of a dysfunctional nervous system. The latter model grants pre-eminence to empathising with the mental/psychological activity of independent human agents. As pointed out by McHugh and Slavney,(1986) the approach from form asks 'what' (is the patient suffering from) whereas the approach from function asks 'why' (is he feeling, thinking, or behaving in this way)? Some disorders lend themselves to one approach more than another when different questions are being asked, e.g. dementia lends itself to form when we are considering aetiology but less so when we are talking about individual reactions to the news that one is suffering from dementia. However, life is not simple and there are many perspectives that allow us to conceptualise suffering or dysfunction, e.g. spiritual, behavioural/learning, medical/disease/disorder/categorical, dimensions, and the individual life narrative. The idea that medical diagnoses are less value-laden than psychiatric ones is untrue.(Fulford, 1989) Finally, *animal models (AMs) of human disorders* are many. Human beings live for longer than lower animals and their brains are not as readily accessible as other species. This has led to a search for analogies between humans and lesser creatures. Certain theories about human development, such as that of John Bowlby⁵⁸⁷, drew on earlier animal work.(Shapiro & Hertzog, 2003) The *olfactory bulbectomised rat* was discovered coincidentally to lead to a state reminiscent of depression during the 1970s. This model also shows immune and endocrine abnormalities similar to those reported in human depressives.(Kelly ea, 1997) Such changes are reversed by antidepressants, and the fact that the 5-HT₂ antagonist metergoline can

⁵⁸⁴ The Latin phrase *post hoc ergo propter hoc* refers to the error of logic wherein sequence is confused with aetiology.

⁵⁸⁵ However, Murray (2002) would suggest that many normals experience hallucinations and delusions, and suggests that schizophrenia may be at one end of a spectrum with 'normality' occupying the other extreme. Van Os (2002; Verdoux & van Os, 2002) points out that 13% of the Dutch population experience a 'psychotic' episode but only a distressed 4% seek help – he says that normal people experience psychotic symptoms and that it is the attributions they attach to such experiences, perhaps based on childhood neuroticism, that leads to distress and hence to psychosis; also, clinicians diagnosed psychosis in 0.7% of cases compared to 28.4% with screening instruments. Wiles ea,(2006) in an 18-month British follow-up study, found that 4.4% of the general population reported incident psychotic symptoms, risk factors for which included rural abode, poor social support, adverse life events, smoking tobacco, neurotic symptoms, and harmful drinking.

⁵⁸⁶ Having the same syndrome usually infers that the same symptoms are shared, but not necessarily the same aetiology.

⁵⁸⁷ E.g. Bowlby described 3 main *attachment patterns*: *secure* (confident explorers), *anxious-resistant* (afraid of separation and is clingy and unwilling to explore), and *anxious-avoidant* (lacks confidence that care will be given – extreme cases are found in badly run institutions).

reverse the effects of antidepressants suggests that bulbectomy involves mainly serotonergic mechanisms. Willner and Mitchell (2002) consider the *chronic mild stress model* to be most valid AM of depression available, although it is difficult to implement reliably. Animals that are subordinate or have lost their place in a *social hierarchy* constitute another AM for depression. The naïve/subordinate male tree shrew (*Tupaia belangeri*, diurnal SE Asia) develops a number of changes when exposed to an experienced/dominant male of the same species that are reminiscent of depression in humans (decreased motoric behaviour and intake of food, decreased weight of body and gonads, decreased plasma testosterone, increase in adrenal weight and urinary cortisol, reduced slow-wave sleep, broken sleep, early morning wakening, down-regulation of glucocorticoid receptors, down-regulation of CRH receptors, down-regulation of 5-HT1A and alpha-2-adrenoceptors in certain brain regions, one-tenth decrease in volume of hippocampal formation, inhibition of dentate gyrus granule precursor cell proliferation, and pyramidal cell apical dendritic retraction in hippocampal CA3), although uniquely human attributes such as suicidal ideation are impossible to model in this paradigm. Clomipramine leads to a delayed recovery from these changes (Fuchs et al., 1996) whereas diazepam is ineffective in this AM. (Fuchs, 2004)

The *spontaneously hypertensive rat* has been used to model attention deficit hyperactivity disorder. Animals may be specially bred to mimic human conditions, e.g. Flinders Low Sensitive Line of rats (depression). *Transgenic mice* with an excess of CAG repeats in the Huntington's disease gene have been created: they demonstrate progressive motor and behaviour disturbance. (Reddy et al., 1998) AMs of schizophrenia, such as the *apomorphine-susceptible Wistar rat* (strong gnawing response to apomorphine) and the *heterozygous haploinsufficient reeler mouse* (expresses only half the brain reelin content [reelin⁵⁸⁸ is a serine protease of the extracellular matrix that is expressed in adult brain, especially cerebral cortex, and may be involved in synaptic plasticity] of wild⁵⁸⁹-type mice), are discussed by Ellenbroek and Cools (2002) and Lipska and Weinberger. (2003) The NMDA receptor may be hypofunctional in schizophrenia and transgenic mice with diminished expression of this receptor display behaviours reminiscent of schizophrenia. (Gainetdinov et al., 2001) Monkeys that have their dorsolateral prefrontal cortex lesioned in infancy may not demonstrate abnormal behaviour until they are mature, an observation that may be of assistance in understanding why a neurodevelopmental disorder such as schizophrenia does not usually become overt until at least the teenage years. (Weinberger, 1987) Escalating doses of amphetamine leads animals to develop attentional problems. Overexpression of D2 striatal receptors in transgenic mice may mimic some of the cognitive problems found in schizophrenia, e.g. working memory. (Kellendonk et al., 2006) During the acute phase attention is impaired and performance-associated ACh release is frozen; during remission (when attention is easily distracted) such animals produce excess cortical ACh in an attempt to boost performance; such deficits are modestly reduced by low doses of antipsychotic drugs; and the authors suggest that the deficits reflect impaired top-down control and abnormalities in fronto-mesolimbic-basal forebrain circuitry. (Sarter et al., 2008) Clozapine normalises dopaminergic turnover in monkey prefrontal cortex after dopamine turnover had been reduced with phencyclidine, which may explain, at least in part, the therapeutic actions of clozapine. (Elsworth et al., 2008) AMs of catatonia have been reviewed by Kaner (2004) and can be collectively referred to as *behavioural arrest* (induced immobility), e.g. spontaneous when generated by confrontation by a predator, manipulation-induced as when an animal is held immobile on its back, or drug-induced as with antipsychotic drugs⁵⁹⁰.

AMs of anxiety disorders are discussed by Graeff and Zangrossi. (2002) They divide these into those for generalised anxiety disorder (GAD: exposing a rat to a cat, time spent in the dark versus the light by mice, a startle response, and the tendency for rodents to bury an object that they are scared of), panic disorder

⁵⁸⁸ Protein derived from Reeler mouse mutant. Derived from Cajal-Retzius interneurons (may be GABA-ergic) that appear in layer I and interact during early development with the deeper Martinotti cells. Plays a role in formation of laminar patterns. It provides radially migrating cells with positional information. If reelin is absent (Reeler mouse or Kawasaki rat) the cortex forms in the wrong order, i.e. younger cells will settle in the wrong order by age (in normal corticogenesis neurons migrate outwards to form the preplate – the latter is populated by neurons where younger cells occupy positions beneath older cells). Homozygosity for the mutated reelin gene causes lissencephaly in humans: a 4-layered cortex with pyramidal cells occupying the incorrect layer. Reelin and GAD67 mRNA have been reported as decreased in (mainly) layer I in schizophrenia and bipolar disorder. (Impagnatiello et al., 1998)

⁵⁸⁹ Alleles can either (i) the normal or 'wild' type (found in the Wild) or (ii) the disease/mutant type.

⁵⁹⁰ High doses of antipsychotic drugs induce severe immobilisation (cataleptic state): a conscious animal crouches in a hunched position, will maintain an uncomfortable imposed posture for a number of minutes, and will move normally under extreme conditions (e.g. a cat is introduced into the mouse's cage) but such movement only lasts as long as the provocation lasts. Because such catalepsy is considered to be due to involvement of the basal ganglia (blockade of dopamine receptors) it is often employed as a model for drug-induced Parkinsonism.

(defensive behaviour of wild rats approached by a human, various forms of stimulation of the dorsal periaqueductal grey matter and dorso-medial hypothalamus), combined GAD and panic disorder (mouse flight following approach of rat, rat's fear of heights and openness [elevated T-maze]), specific phobias (e.g. cat odour test), and OCD (e.g. acral lick dermatitis). Quinpirole, a D2/D3 receptor agonist, causes rats to check excessively (Dvorkin ea, 2006), a putative model of OCD. Early blockade of serotonin transporters with fluoxetine in the mouse leads to anxious adult mice.(Ansorge ea, 2004) Memory consolidation depends on protein synthesis and preventing this might prevent PTSD. Rats given the protein synthesis inhibitor anisomycin (too toxic to give to humans) reduces conditioned fear responses.(Cohen ea, 2003)

AMs of eating disorders, such as the '*tubby mouse*' (a recessive mutation causing maturity-onset obesity, insulin resistance, and degeneration of retina and cochlea) are discussed by Johansen and Schalling.(2002) Among attempts to model aspects of personality disorder is the breeding of rats to be high or low responders to novelty, e.g. high responders show a greater increase in dopamine in the nucleus accumbens when stressed, a greater release of corticosteroids when stressed, and learn to self-administer stimulant drugs faster, than do low responders.(Cools & Ellenbroek, 2002) According to Mayfield ea (2003, p. 849), with few exceptions (e.g. LSD), drugs that animals will not learn to self-administer are not abused by humans. The LSD case has been explained by 'a peculiarly human urge to seek altered states of consciousness'. Nevertheless, the present author has been intrigued by the idiosyncratic nature of some cases of drug abuse, e.g. a young woman who took large amounts of ampicillin on a regular basis. The so-called *clock mouse* has a genetic mutation affecting circadian rhythmicity. If this mouse is deprived of light it develops a prolonged (28 hour) period. It is one AM for sleep disorders.(Viaterna ea, 1994) A mutation in the so-called 'CLOCK' gene causes the mouse to become overactive, sleep less, and appear 'manic'.(Roybal ea, 2007)

One feline AM of mild head injury is induced by fluid-percussion under brief anaesthesia. The cats have no macroscopic brain lesions but do have extensive damage to axons. Photic induction of seizures in Senegalese baboons is used as one AM of human epilepsy and induction of seizures in rodents by electroshock or drugs⁵⁹¹ is employed to screen for anticonvulsant pharmaceuticals. One AM of Huntington's disease involves the mitochondrial toxin 3NP with possible NMDA-induced excitotoxicity.(Perez-De la Cruz & Santamaria, 2007) APP/PS1 transgenic mice have increased plasma clusterin⁵⁹², age-dependent increase in brain clusterin, and co-localised clusterin and amyloid in plaques whereas, in humans, excess clusterin is associated with various pathological indices of Alzheimer disease.(Thambisetty ea, 2010) In mice, preprohypocretin gene knockout or ataxin-3 driven hypocretin cell loss have been used to model narcolepsy.(Mignot ea, 2002)

Research & epidemiology⁵⁹³

'...when a disorder of unknown cause appears to be increasing in civilised countries, the effects of luxury, idleness, debauchery and town life were blamed'.(Hare, 1998)

'In our current state of development in psychiatry it is essential that we eschew long-established tendencies to theorise rather than experiment and to explain rather than correlate'.(Munro, 1999)

'The reasons why some researchers believe that a continuous number can issue out of the arithmetic addition of qualitative decisions is one of the mysteries of psychiatric psychometry'.(Berrios & Marková, 2002)

'The influence of the pharmaceutical industry on academic medicine is pervasive....Academic psychiatry is not for sale'.(Healy & Thase, 2003)

(In answer to the question: Do you think that psychiatry and psychiatric research are any further forward?) 'Not much, if at all; and, in clinical settings, there has been a deterioration'.(Wilkinson, 2003)

'Creating pseudo-entities such as 'major depression' for use as the principal 'diagnostic' measure increases the chance of non-differential results between interventions'.(Parker ea, 2003)

A researcher should carefully decide on what it is that it is hoped to prove or disprove (hypotheses) before embarking on the research itself. Otherwise p-values are meaningless! If one uses one statistical test at $p < 0.5$ there is a 5% chance of finding at least one false-positive result (*experiment-wise error rate*). If 10 tests are employed then this probability jumps to 41%!

⁵⁹¹ Pentylentetrazol, picrotoxin, bicuculline.

⁵⁹² Clusterin is involved in amyloid formation and clearance.

⁵⁹³ After decades of research most common psychiatric illness remains idiopathic. We have acres of correlations but little of concrete use in individual cases. The great majority of published research comes from wealthy countries.(Saxena ea, 2006)

Critical analysis of published research⁵⁹⁴ is now an established component of the MRCPsych II examination. (Greenhalgh, 1997; Lewis et al, 1997; Hotopf, 2000; Grimes & Schulz, 2002) Most research on drug treatments is too short and many employ a patient group that would be difficult to find in clinical practice, e.g. young⁵⁹⁵ non-female adults lacking comorbidity. Relatively healthy recruits (Geddes & Cipriani, 2004) and multi-site studies (Bridge et al, 2009) may account for very high placebo response rates. Selective publishing of trials may exaggerate positive results. (Turner et al, 2008) Drug research is largely funded by industry with non-commercial funding of trials being increasingly difficult to get. The RCPsych (2008) provides guidance on relationships with sponsors. Grunze (2009; Grunze et al, 2009) drew attention to 'sponsor bias' in relation to comparative efficacy of antipsychotic drugs.⁵⁹⁶ Ghost authorship (major contributor remains unmentioned, often a sponsoring company's statistician) is a worry. (Hargreaves, 2007) Research in psychotherapy is covered in the various chapters on individual disorders and in the chapter devoted to psychotherapy. Psychosocial therapies may be of such a high standard in research that the average busy service could not hope to emulate them.

Some fallacies

Ecological fallacy - erroneous attribution of causality to an observed ecological finding, e.g. because schizophrenia is more common in socio-economically deprived areas, then schizophrenia is due to socio-economic disadvantage, totally ignoring other possible explanations for the association, e.g. infection, childhood nutrition, some aspect of urban life, or downward social drift due to (fully or partially penetrant) illness

Berkson's bias (or *fallacy*) - making of false associations as a result of biased sampling (Berkson, 1949): classic example is the false assumption that institutionalised schizophrenics were immune from epilepsy and would therefore benefit from iatrogenic seizures, the original thinking behind convulsive therapy; since people with multiple disorders are more likely to seek treatment it should not surprise us to find high comorbidity in clinical (versus population-based) samples. (Bennett & Gjonbalaj-Morovic, 2007, p. 35)

Pilot studies are studies that are meant to test the water for bigger studies (although they often do not). They usually involve relatively small numbers and may last for relatively brief time periods. They may be used in negotiations for procuring finance for larger studies. An example of a pilot study is that by González-Isasi et al (2010) wherein patients with refractory bipolar disorder (BP) were randomised to usual medication or medication plus 'psychosocial treatment based on cognitive-behavioural' principles (adjuvant intervention). The authors found that the adjuvant group demonstrated improved functioning but the difference between the two groups did not reach statistical significance until 12 months had passed. Would this difference be maintained in a larger study and what about clinical significance (a major question when one considers the time and effort involved)? Also, how simply and seamlessly can the adjuvant intervention be employed (i.e. is the complete package required)?

Ecological studies involve scrutiny of a population as a whole. Outcomes are correlated with aggregate risk factor exposure. Such studies have low generalisability because we know little about the individuals involved and we lack temporal data.

*Case-control studies*⁵⁹⁷ are more appropriate for rare disorders like schizophrenia or for conditions that have very long latent periods. A random sample of cases of the disease under study is compared with a random sample of people who do not have the disease. Such studies are by their nature retrospective and subject to recall bias.

⁵⁹⁴ E.g. If the authors exclude the third of elderly medical inpatients who haven't the capacity to agree to be included in their study they cannot expect to detect disorders that reduce capacity in the remainder. (Holmes, 2008, p. 345)

⁵⁹⁵ The European Parliament approved legislation in 2006 (1901/2006) that insists on high quality research on drugs used for children. (Choonara, 2007)

⁵⁹⁶ Depending on the study: drug A > drug B > drug C > drug A, etc!

⁵⁹⁷ Case-control studies employ an *odds ratio* (approximate of relative incidence rates) to see if exposure or non-exposure to an event determines outcome.

*Self-controlled case series*⁵⁹⁸ (*case series method*) can be employed to examine the association between an acute event (e.g. stroke) and a (retrospectively ascertained) transient exposure (e.g. antipsychotic drugs) using cases only, i.e. no control subjects are required. There is implicit control of fixed multiplicative non-varying (over study period) confounders that act proportionally on baseline risk. This method is almost as efficient as the cohort method when periods of risk are brief relative to total period of observation. (e.g. Douglas & Smeeth, 2008)

The *nested case-control study* looks at cases with recent onset of the disorder of interest in an ongoing cohort study and compares these with suitable controls from the same cohort study for exposures that would be too costly or extremely difficult to have measured at the commencement of the study.

Cross-sectional surveys (point prevalence studies) look at defined total populations (all inpatients, all persons of a specified age group, etc) simultaneously (prognosis, risk factors, etc) and may be used to define the extent of a disorder, to compare findings with those in other groups, to plan services, or (if the study is repeated) to look for trends. Differences in outcome rates between those exposed to an event versus those not so exposed can be measured. Positive do not necessarily imply causality. Point prevalence rates are influenced by the rate at which an outcome develops and by the duration (chronicity) of the disorder.⁵⁹⁹ This type of research is not appropriate for the study of relatively rare phenomena (including major mental disorders).

Cohort studies compare the incidence of new cases of the disorder being studied in people who either have been exposed or not exposed to a theoretical risk factor: a *cohort study* is a longitudinal study of selected groups of individuals who are free of a disorder at the start of the study, and who differ in the level of exposure to a possible cause of the disorder. The association between outcome and exposure is expressed as relative risk (RR) which is the ratio between the incidence rates in those with the risk factor and the incidence rates in those without the risk factor. A *case register* is a local system that records the contacts with designated medical and social services for a defined geographical area.

Controlled trials may be open (patient and physician aware of drug taken), single-blind (doctors knows but patient does not know), double-blind (neither the doctor nor the patient is in the know), or triple-blind (patient, physician, and person evaluating outcome do not know). We work in the era of the *randomised controlled trial* (RCT⁶⁰⁰). An RCT is a cohort study where the researcher controls level of exposure and participants are randomly assigned to different exposures (e.g. a medication). 'Non-exposed' individuals might receive 'treatment as usual' or a placebo (as distinct from a *head-to head trial* where two supposed active treatments are the subject of randomisation). Randomisation increases the ability of researchers to invoke causation, e.g. drug X is an antidepressant because it was significantly superior to placebo on Y's depression scale. Blinding is not as easy as many researchers might hope, e.g. how does one conceal the fact that a patient is receiving psychoanalysis or not developing extrapyramidal side effects from a medication? Also, acceptable placebo conditions are not always easy to conjure up.

In a *crossover study* the intervention of interest (A) and the control intervention (B) are administered to two randomised groups, (a) and (b) respectively. Then, following a washout period⁶⁰¹, patients swap over so that B is given to a and A is given to b. This allows the researcher to measure the difference between A and B for each patient. This design is more useful for pharmacotherapy trials than for psychotherapeutic studies, the effects of drug treatments being more or less nullified by the washout.

Internal validity of a study infers that the researchers measured what they intended to measure. *External validity* means that one can generalise from a study's findings to the wider world of clinical practice.

Selection bias infers that groups being studied are not comparable. *Information bias* is the result of gathering information in a different way for the various groups that the researcher is trying to compare with one another.

⁵⁹⁸ Case series studies are an example of a *descriptive study*: description of health status of more than one person. No comparison subjects are included.

⁵⁹⁹ 6-month prevalence of bipolar affective disorder is not much lower than lifetime prevalence because the disorder lasts for life and is recurrent.

⁶⁰⁰ *Cluster RCTs* are employed where the unit of randomisation is an area or organisation (e.g. hospital or GP practice) rather than the patient. When a single patient is a member of a group (e.g. in a nursing home) an intervention will have knock-on effects on other residents. Large numbers are needed to show significant differences. (Ukoumunne et al, 1999)

⁶⁰¹ This means to wash out the effects of an intervention, e.g. to clear a drug from the body. How long this will require depends on the drug in question (half-life, lipid solubility, depot, etc).

Confounding variables⁶⁰² must be accounted for in research. When these cannot be controlled in the study design, they must be allowed for in the analysis. Overmatching is said to be present when inappropriate selection of control variables results in more being eliminated from a study than was intended by the researchers, including items that were hoped to be examined. Most controlled trials are too short in duration of follow up, too small in numbers of patients recruited, and poorly reported. (Thornley & Adams, 1998) *Efficacy* refers to the ability of an intervention to produce the observed or desired changes. *Effectiveness* asks whether the results can be generalised to clinical practice. *Efficiency* is the effectiveness of an intervention in relation to the resources it uses up⁶⁰³. *Effect size*⁶⁰⁴ in drug trials equals the mean response to a drug divided by its standard deviation,⁶⁰⁵ i.e. the clinical significance rather than the statistical significance. A large effect size favours a deduction of efficacy. (Harrison-Read & Tyrer, 1995) Statistical significance is not the same as clinical significance. (Meltzer & Fatemi, 1998) There is a world of clinical difference between a 'response' to a drug (e.g. a 50% drop in HAM-D scores) and the complete absence of symptoms. (Roose, 1997; Nierenberg et al., 2010) A remission is defined as a HAM-D score of 7 or less on HAM-D-17 or 3 or less on HAM-D-7 or 10 or less on MADRS.

In the *intention to treat* model in drug trials, all initially randomised patients are included in the analysis, no matter what happens to them thereafter. Ratings of dropouts are included in the final analysis and their last scores are usually carried through each assessment point. This approach may reduce active drug-placebo differences where poor toleration of side effects leads to early opting out from the study.

Official first admission rates are often markedly inflated because of ignorance on the part of compilers of prior admissions to institutions other than the one in question. (Kreitman, 1993) Healy (1991) warns us that 'simply achieving effects in clinical trials cannot be passed off as evidence of' imipramine equivalence.

Rigid dose regimens used in trials are not feasible in clinical practice.

One of the problems with genetic research into alcoholism is the tendency to view it as a single entity, rather than breaking it down into its component parts (alcohol consumption, dependence, and related problems) and investigating each one separately. (Marshall & Murray, 1991)

The literature paints a picture of depression being extremely widespread, on the increase over the years, being inseparable from but worse than normal unhappiness, classically affecting women who are poor or people out of work, showing a very similar clinical pattern and incidence worldwide, and perhaps being a product of industrialisation. Definitions, readiness or ability to recollect or admit depression, age effects, cross-sectional, prospective, retrospective, and different population groups, are only some of the confounders involved. (Kendell, 1993)

In a *catch-up prospective study* cases are identified at the commencement of the follow-up period. Because cases who do well tend to drop out, cases followed up tend to be chronic. A *follow-back design* involves a retrospective study with case identification at follow-up. This is rarely used in practice and also tends to miss drop-outs.

Lasagna's law

The rate of subjects for research will fall by at least half just as a study commences.

Equivalence trials try to determine if various treatments give similar benefits. Results are usually expressed as a *hazard ratio* (HR: ratio of response to treatment being studied to that of the comparator, the latter being a known effective intervention) with its 95% confidence intervals (CI). A HR circa unity and CI of 0.9-1.1 = probably equivalent; HR of 0.5 and CI = 0.3-0.7 = probably not equivalent; and HR 2.0 and CI = 1.7-2.3 = novel treatment probably inferior to comparator.

Reviews may be *traditional (narrative)* - a qualitative overview from a respected expert) or *systematic* (e.g. clear definition of why studies are accepted following by a meta-analysis). There are many sources of

⁶⁰² Distortion of a measure by exposure of subjects to factors other than the index factor.

⁶⁰³ E.g. cost-effectiveness or cost-benefit.

⁶⁰⁴ Effect sizes are essential to the computation of statistical power. They are the basis of meta-analysis. Effect sizes of 0.2, 0.5, and 0.8 would normally be considered as small, moderate, and large respectively.

⁶⁰⁵ Effect size = $\frac{\text{effect of experimental group} - \text{effect of control group}}{\text{SD of their differences}}$

studies for reviews, e.g. manual searches, conferences, *EMBASE*, *MEDLINE*, *PsycLIT*, and the *Cochrane Controlled Trials Register*. The latter is one of the services supplied by the Cochrane Collaboration (<http://hiru.mcmaster.ca/cochrane/default.htm>), an international, not-for-profit organisation named after Archie Cochrane, a British epidemiologist.

Michael Shepherd (1988) defined epidemiology as 'the mass aspects of disease'. A more conventional definition would be 'the population-based quantitative study of the distribution, determinants and control of disease'. (Lewis & Mann, 1992) Stromgren preferred the word *endemiology* because so many of the conditions studied are endemic to the population, rather than epidemic.

An *at-risk population* is a group of people within a population who are at risk of developing a particular disorder. This must be taken into account in epidemiological studies, e.g. in underdeveloped countries the percentage of the population under a certain age may be higher than in the West, which may influence the overall percentage of the population with diagnosable schizophrenia. There are 3 common indices of risk. *Absolute risk* is the incidence rate of the disease among people exposed to an agent, assuming that non-exposure does not increase risk. It is best to compare the risk of disorder among exposed persons under investigation with those not so exposed. *Relative risk* is the ratio of the incidence rate in the exposed group to that in the non-exposed group. This is sometimes expressed as a percentage. It measures the proportionate increase (decrease if agent is protective) in disorder/disease rates of the exposed group. Lastly, *attributable risk* is the difference between the incidence rates in the exposed and non-exposed groups, in other words the risk attributable to the factor being investigated.⁶⁰⁶

Certain considerations are necessary before attributing cause. Exposure to the putative cause must always precede onset⁶⁰⁷ of the disorder (time sequence consideration). The spatial distribution of the disorder should be similar to that of the suspected cause. The incidence of disorder should correlate with the amount and duration of exposure to the suggested cause. The same association with a suspected causal agent (SCA) should be found in studies of different populations. However, failure to find such consistency may be due to differences in study design. Also, this may be a tall order in a discipline characterised by multifactorial aetiologies. Biological plausibility means that the association between disorder and exposure to SCA should be consistent with the known biological activity of the SCA. The disease or disorder should be reproducible in experimental animal models. Control or removal of the SCA should reduce the incidence of the condition under study.

According to Marshall ea,(2000) people who devise new scales for their study are more likely to report statistically significant results than are those using scales that are already standardised and known.

A *risk factor* is not necessarily synonymous with a cause: it may be a marker of another causal process or a causal factor itself. Disorders, such as suicide, schizophrenia or arterial hypertension, are often associated with numerous risk factors. Multiple measures of outcome increase the likelihood of unearthing a statistically significant difference purely as a result of chance.

A *mediator* is a variable that accounts completely or in part for the statistical relation found between a risk factor and a disorder. A *moderator* reduces or enhances the effects of a risk factor, e.g. a warm relationship between parent and child may reduce the likelihood of someone subjected to early harsh discipline developing a conduct disorder (Rutter & Sroufe, 2000); in this case the relationship is a protective moderator or *buffer*.

Health services research is underdeveloped in Ireland.(Expert Group on Mental Health Policy, 2006, p. 210) The WHO (2001) suggests) four types of research that are needed in order to improve mental health delivery: **epidemiological data** is needed to prioritise and to design/evaluate interventions; research into **effectiveness** of interventions (as distinct from efficacy); policy/services research (training needs of professionals and understanding of impact of policy decisions; and **cost** of services.

Prevention in the community

The goals of prevention are to reduce the incidence (onset), prevalence (duration) and residual disability associated with a disorder.

⁶⁰⁶ Put another way, population attributable risk = proportion of a disorder that can be associated with exposure to a risk factor.(Caughlin ea, 1994)

⁶⁰⁷ It has been noted for many years that dating the onset of illness is at least difficult and sometimes 'dubious'.(Sanborn, 1894)

Prevention

Primary – preventing a disorder starting in the first place, e.g. teaching parenting skills, education about alcohol and substance misuse, enriching the environment of deprived children, crisis intervention following major life events, avoiding alcohol or giving folate periconceptually (this may not be working and fortification of food may be necessary: Ward ea, 2004; Walsh ea, 2007), diet for PKU, lead-free petrol, laws against child abuse, genetic counselling, and STD prevention

Secondary - reducing the duration of a disorder by early diagnosis and treatment, e.g. crisis intervention, public education, and child guidance clinics

Tertiary - decreasing the prevalence of residual defects and disabilities, enabling the person to reach the highest feasible level of function; psychiatric rehabilitation addresses the medical, psychiatric, and social needs of chronic patients; social needs include literacy, housing, employment, finance, and social and living skills

In summary: reduce incidence (primary), prevalence (secondary), and residual disability (tertiary).

The prevalence of mental illness is so high that the mental health workforce cannot help everyone. The focus tends to be on the more severe and chronic disorders. (Jorm, 2000) In some cases, this has meant a 'psychosis only' service. To date, efforts to improve public understanding lag behind those for other common illnesses. A void exists between beliefs about aetiology and management between doctors and the public at large that are greater than between 'primitive' healer and pre-scientific man. Most people believe that antidepressants are addictive and want counselling instead.⁶⁰⁸ Evidence for efficacy of counselling for depression is lacking. (Thompson, 1999; Baldwin, 2000)

Medical statistics⁶⁰⁹

'If you torture statistics, they'll confess to anything'. (Saying)

'Politicians, policymakers, and public-health professionals make complex decisions on the basis of estimates of disease burden from different sources, many of which are "marketed" by skilled advocates'. (Walker ea, 2007)

'We tend to search for or believe only those associations that fit in with our expectations'. (Simon, 2008)

The French physician Pierre Charles Alexandre Louis (1787-1872) was the first medical man to collect and numerically analyse data on patients⁶¹⁰. Statistics may refer to systematically collected numerical facts (e.g. vital or population statistics) or the science of collecting, classifying, and using data, particularly when these come in large quantities or numbers. (Hayslett, 1974; Pocock, 1980; Bourke ea, 1988; Altman, 1991; MacRae, 1992; McGuire, 1993) Statistical difference is not synonymous with clinical difference.

Investigators should seek advice on statistics at the study design stage and not when an amorphous mass of data has been collected! (Armitage ea, 2002)

Parametric statistics are those inferential statistics (assess meaning of data, e.g. the correlation coefficient or *Student's t test*⁶¹¹) that assume a normal distribution for data. The *power*⁶¹² of a study, in statistical jargon, refers to the probability that a type 2 error (Q.V.) will not be made, if indeed there is a real difference between 2 treatments. Power increases with the size of the study. *Non-parametric* statistics (e.g. χ^2 test), on the other hand, use material of non-normal distribution. Put another way, the methods of calculation power for categorical data (e.g. 'yes' or 'no' categories) are the non-parametric tests, whereas those for continuous data (e.g. graded tests for depression) are the parametric tests.

Prevalence means the total number of cases in a particular population at a given point in time (point prevalence) or over a period of time (period prevalence). A sample of prevalent cases will give an over-representation of chronic, poor prognosis cases. Factors associated with prevalent cases may lead to a poor

⁶⁰⁸ The author has noted (in 2010) that an Irish textbook designed for Junior Cert students warns about the 'addictive' nature of antidepressants!

⁶⁰⁹ See, e.g. Gonick and Smith (1993) for an introduction. *Statistics* derives from the German *Staat*, a State, because the State required information in order to guide policy.

⁶¹⁰ Louis distinguished typhus from typhoid and gave typhoid its name. He should not be confused with the French surgeon Antoine Louis (1723-1792) of Angle of Louis fame. The latter worked with Joseph Ignace Guillotin (1738-1814) on the guillotine.

⁶¹¹ The **t test (t-test)** is the optimal test to discover if the difference between means of 2 samples of subjects is likely the result of chance only. The **t test for dependent means** is the optimal test of significance for difference between means from 2 matched groups or treatment levels.

⁶¹² **Power** = probability of finding a true difference or relation between multiple measures with a given sample size.

prognosis without necessarily having a causative role. Retrospective and prospective studies may give wildly different prevalences⁶¹³ for common mental disorders for various reasons such as documentation issues and recall bias.

In order to seek causes one must study incident cases. *Incidence* refers to the number of new cases arising in a given period of time. A more precise measurement than incidence is the *inception rate* or the proportion of individuals in a population who are initially free of a disorder but who acquire it within a given interval of time. The term 'incidence' is often used loosely to mean the inception rate. *Cumulative incidence*⁶¹⁴ is the number of new cases divided by the total at-risk population over a specified period of time, say one year; this measure is useful in population numbers remain steady over the period in question. Epidemiologists often use *person-time* as the denominator⁶¹⁵, i.e. sum of time periods (such as person-years) of the observation for everyone in the population at risk: incidence rate = no. of new cases/person-years.

Statistical terms

*Analysis of covariance*⁶¹⁶ (ANCOVA): method used to determine if 2 or more related dependent variables that are exposed to 2 or more related variables differ significantly (more than chance), e.g. a researcher who is comparing a drug and exercise in order to determine their effects on the weight of obese patients will include pre-study weight⁶¹⁷ as a *covariate* (a covariate is a variable that the researcher believes may influence outcome [*dependent variable/endpoint*] and that needs to be adjusted for statistically).

Analysis of variance (ANOVA): test comparing mean values from at least 2 groups. Multivariate analysis of variance (MANOVA), a generalised form of ANOVA, may be used when multiple dependent variables are assessed at the same time.

Bias: a distorting influence that renders study results an inaccurate reflection of reality, e.g. 'selection bias' occurs when only acute patients enter one arm of a comparative study of two antidepressant drugs and chronic patients occupy the other arm.

Bivariate correlational analysis: provides a single number summarising the relationship between 2 variables.

Chi² test: assesses if a significant difference exists between an observed number of responses in any category and an expected number based on the null hypothesis.

Cluster analysis: a data reduction technique used to group subjects into subgroups based on how they are alike or different on a set of variables; it can produce clusters/categories (based on similarities or differences) but not dimensions. The idea of using clusters as a basis of classifying psychiatric disorders has been dismissed by Jablensky (2009) because of the likely necessity of increasing complexity in clinical thinking as we strive to incorporate new data into the way we work.

Clustering of disorders: statistically, the average GP should have 4 cases of the autosomal dominant disorder heterozygous familial hypercholesterolaemia (1 in 500 people) but the actual figure varies because of clustering within families; the geographical prevalence of Huntington's disease (autosomal dominant; 1 in 20,000) also varies for the same reason.

Confidence interval: measure of range of values within which true population value is believed to lie.

Confounding factor: something that explains a particular outcome in a study but has an independent relationship to another factor that does not exert a causal influence.

⁶¹³ A study (Moffitt et al., 2010) comparing a prospective New Zealand birth cohort that involved a 32-year follow-up with 96% retention (the percentage of original cases that could be studied throughout the duration of the study) gave prevalences for anxiety, depression, alcohol dependence, and cannabis dependence that were about double those reported in 2 US (retrospective) national comorbidity studies (NCS and NCS-R)!

⁶¹⁴ The specified time is written t_0 to t_1 . **Cumulative incidence** (CI) = Number of new cases, t_0 to t_1 /population at risk at T_0 , where the denominator = total number of persons at risk for the event at T_0 (the start of the time period). Do not include people at T_0 who have the disorder or experienced the event in question in the denominator. **Incidence density** (ID) is a superior measure of rate of occurrence of new events in unstable populations (where numbers change for any reason, such as assumption of 'caseness', demise, or uncontactability). ID = Number of new cases, t_0 to t_1 /total person-time of observation. The denominator includes the population at risk for the event in question and has to be adjusted due to drop-outs (e.g. death or loss to follow-up).

⁶¹⁵ For those who have forgotten the denominator is below the line, e.g. in $\frac{1}{2}$ the numerator = 1 and the denominator = 2.

⁶¹⁶ The Kruskal-Wallis test, which compares medians in at least 2 groups, is a non-parametric version of ANOVA.

⁶¹⁷ Or, e.g., when comparing the effects of two antidepressant drugs, baseline depression scores are a covariate.

Correlation coefficient (cc): measures relationship between 2 sets of variables without making any assumption about their dependence or independence: a cc of 1.0 means exact similarity, one of 0.0 infers no relationship.

Descriptive statistics: these simply summarise data, e.g. the mean that measures central tendency.

*Diagnostic test accuracy*⁶¹⁸: overall proportion of correct results when a test is applied to a sample or population.

Discriminant function analysis: used to statistically distinguish between at least 2 groups on the basis of discriminating variables.

Factor analysis: seeks smallest number of dimensions/variables that define a group; factors express the relationship between attributes, not between individuals; data reduction method used to reduce many variables to a smaller number of linear combinations of variables; sometimes attacked for showing anything that is sought by researchers! *Principal components analysis* resembles factor analysis and, like the latter, it requires continuous data; used where there is a need to reduce number of variables in an analysis but to explain the same amount of variance (factor analysis is employed where underlying unobserved factors/latent constructs are the focus of interest).

Funnel plot: bias in publication usually involves non-publication of small or negative studies; a funnel plot is used to plot study effect size against precision and can show up a void that small negative studies should occupy, i.e. funnel plot asymmetry.

Interquartile range(IQR): this provides an idea of the spread of values; numerical difference between values that are found a quarter way up from bottom of distribution and a quarter way down from top of distribution; used when values are not distributed evenly and when median value is known; the 2 values that define IQR encompass middle 50% off all the values in the distribution.

Kurtosis: a measure of peakedness or flatness of a curve.

Last observation carried forward was a traditional method of dealing with loss of patients to follow-up (missing data) in research. It has been replaced by so-called *principled methods*, e.g. multiple imputation.

Mann-Whitney U-test (Wilcoxon rank sum test): used to compare 2 groups of unmatched data (2 independent groups that are not normally distributed); the nonparametric equivalent of the t-test; it tests equality of medians only where distributions are of the same shape.

Mean: sum of scores divided by number of scores; it should be noted that the mean, mode, and median are synonymous in a normal distribution.

Median: the middle score, below, which half of the scores fall. The median is identified by ordering numbers according to size and then picking the middle one. If two values are the same (e.g. 100 and 102), then the median is the mean of these two values (i.e. 101 in this case).

Meta-analysis: statistical analysis of a large collection of analysis results from individual studies in order to integrate findings (to produce *summary statistic/s* – effect sizes from different studies are combined into a single estimate with associated confidence interval). When applied to controlled drug trials, the trials should be complete (i.e. include subjects with positive and negative results). The results of each trial are calculated in the form of an *odds ratio* based on comparing the number of patients in the experimental group reaching a defined end-point with the corresponding number in the control group. The odds ratio from each trial are then summarised using an appropriate test of statistical significance, and an estimate of the magnitude of the treatment effect⁶¹⁹ is made. This method overcomes the fact that the number of patients in individual trials is often small. One problem is that one does not always know how representative the patients are of those seen in clinical practice. Also, two meta-analyses of the same treatment do not necessarily reach the same conclusion!(Furukawa, 2004) *Cumulative meta-analysis* refers to the incorporation of new trials into the analysis. *Heterogeneity*, variations occurring between studies, may stem from statistics, methodology, or clinical variables, and may be sufficiently large make nonsense of meta-analysis. *Weighting* refers to the influence or weight that different studies may have on the results of meta-analysis, e.g. smaller numbers of participants in a study are given less weight than bigger numbers. When different studies employ different measures to assess the same outcome the statistician can combine the results using *standardised mean difference*⁶²⁰. The *forest plot* is a way of graphically summarising

⁶¹⁸ Patients with the disease and test positive + patients without the disease who test negative and divide total by the total sample and express result as a percentage.

⁶¹⁹ *Effect size* refers to group differences in standard deviation units on the normal distribution.

⁶²⁰ SMD = difference between mean results of treatment groups/pooled standard deviation.

results of a meta-analysis: the vertical line indicates equality between intervention of interest and control intervention and short horizontal lines show confidence intervals of outcomes of different studies with a square on such lines showing the weight of that study, and a diamond gives the overall summary statistic. A *mega-analysis* means that the raw data from different studies are employed as if they all belonged to one original study.

Minimisation: this is a way of allocating people to treatment groups in a study that does not use random allocation but, instead, uses means to deliberately reduce any imbalance between the groups that may be due to confounders, e.g. where one group has too many males you might add the next male to the other group.

Mode: most frequent score or most common value.

Multivariate analysis: method of examining the relation between 3 or more variables; techniques include multiple regression, discriminant analysis, canonical correlation, and factor analysis.

Multiple linear regression: used to predict a single continuous outcome variable from a set of continuous or dichotomous predictor variables.

Negative likelihood ratio: a measure of how much less likely than not a patient is to have the disorder in question if the test result is negative, i.e. $(1 - \text{sensitivity}) / \text{specificity}$.

Negative predictive value: the probability that a person has not got the disorder if the test result is negative.

Normal distribution: pattern for distribution for data set which follows a bell-shape curve; x-axis represents variables of interest (e.g. IQ or height) and y-axis represents number of people having a certain value of the variable; the curve decreases symmetrically either side of a peak, the latter representing the mean/middle variable.

Null hypothesis: the assumption that no difference exists (until one is shown to exist), i.e. that the difference between 2 groups is the result of chance or sampling error; a statistical strategy whereby it is assumed that there is no real difference between 2 variables, such as 2 treatments. The p-value is the probability that difference or association between variables is a result of chance (false positive). The threshold for statistical significance is arbitrarily set at 0.05 (meaning 5/100). If p equals or is less than this figure the null hypothesis (that there is no difference or association) is rejected. A p value of $P < 0.001$, by way of example, means that the odds of this difference between two rates happening by chance are less than one in a thousand, a highly significant statistical finding.

Number needed to treat (NNT): the number of cases that would have to be treated in a certain way in order to avoid one outcome event⁶²¹ $= 1 / \text{absolute risk reduction (AAR)}$, where AAR = control event rate minus experimental event rate (for an undesired outcome) expressed as a percentage. An NNT of > 10 usually denotes a good effect of the intervention/treatment.

Partial correlation analysis: a single number is provided to describe the relationship between certain variables, adjusting for the effect of other variables.

Population: entire collection of a set having the same definition.

Positive likelihood ratio: measure of how much more likely than not a patient is to have the disease if the test result is positive, i.e. $\text{sensitivity} / (1 - \text{specificity})$.

Positive predictive value: the proportion of true cases divided by the number scoring positive on the test, i.e. the probability that a person has the disorder if the test result is positive.

Range: measure of dispersion from lowest to highest score.

Rate: A figure determined by numerator (number of cases) divided by denominator (population at risk).

Reference range: this usually means the mean ± 1.96 standard deviations, where one expects to find the great majority of cases; it does not necessarily imply that values above or below the range are abnormal because they may simply be part of a continuum; extremely deviant findings (*outliers*), on the other hand, are likely to be discontinuous; interpretation of results often requires experience (age of patient, pregnancy, laboratory error, effects of disease or prescribed medications, factitious, comparison with previous findings, etc).

Regression: techniques used to develop complex models in order to examine role of one or several predictor variables on an outcome variable. *Logistic regression*: optimal technique to predict a binary outcome from a set of continuous or binary variables; gives probability value and odds ratio; used in research when outcome is either one thing or another, e.g. did the patient develop the illness or not?

⁶²¹ Or to obtain one success that would not be obtained with the control treatment. The number needed to harm (NNH) is another measure that would be useful to know.

Regression coefficient: measures relationship between 2 sets of variables, assuming one is dependent, the other independent; may be descriptive (summary of data) or inferential (assesses meaning of data).

Sample: subset of observations selected from a population.

Sample enrichment: method of narrowing down a sample so that it contains more of the variable being sought, e.g. picking a high-risk group for schizophrenia in order to study the pre-psychotic phase of that illness.

Skewness: measures deviation from normal distribution curve; non-symmetrical with one tail longer than the other at either side of the mean value.

Standard deviation (S.D.): square root of variance – 64% of scores in the normal distribution fall within one S.D. on either side of the mean.

Standard error: an estimate of discrepancy between the sample mean and the true population mean, or S.D. divided by square root of number of cases; this will shrink with an increase in sample size because bigger samples approach the characteristics of the population from which they are drawn.

Standard mortality ratio (SMR): observed number of deaths/expected number of deaths; the expected number is found by applying death rates of an external reference population to the age distribution of the study population. E.g., an SMR of, say, 5 means that the index group has a standard mortality rate five times that of the general population.

Standard (Z) score: the value-mean divided by the S.D.; specifies the position of a particular observation on the normal distribution.

Type 1 error: occurs when statistically significant result occurs by chance; a false positive; to regard a difference as significant when in fact it is not.⁶²²

Type 2 error: occurs when a real result is obscured by chance or random error; a false negative; a study fails to demonstrate a statistically significant effect that does in reality exist.

Variance: the squared S.D.

Wilcoxon signed-ranks test: used to compare 2 samples of matched data.

Neuroanatomy and neurophysiology

'As information is added to a computer, it gets slower, the exact opposite occurs with the brain'. (Trimble, 1996)

Nerve cells (neurones) and the interstitial cells (= neuroglia⁶²³ = oligodendrocytes and astrocytes) of the nervous system derive from ectoderm. Microglia (mesoglia) are of mesodermal origin. Glial cells, which possess almost the same receptors as are found on nerve cells, are likely to have neuromodulation and neurotransmission actions. They are not there simply to provide neuronal support. Nerve cells are born in proliferative zones around the ventricular lumen at a distance from their final locations. They must then migrate.

Neurones

CNS stem cells

Multipotent cells that can reproduce themselves or differentiate (so far) include:

⁶²² The usual approach used to balance the possibility of making type 1 or 2 errors is to set the value for P at less than or equal to 0.05.

⁶²³ Glia = glue (supportive and structural function). In multiple sclerosis there is an immune attack on myelin basic protein, the main protein in myelin, leading to failure of conduction of the action potential.

1. *Subventricular zone of lateral wall of lateral cerebral ventricle* – migrate to olfactory bulb and form interneurons – important for sense of smell
2. *Subgranular zone of dentate gyrus in hippocampal formation* – learning and memory functions

Glial cell types

Astrocytes (astroglia) – support (structure, nutrition, environment/ion concentration, maintenance of synaptic milieu, release of co-agonists needed for glutamate receptor function and transport of glutamate to end its action at synapse) the neurones and respond to nerve cell injury [fibroblast-like function leading to gliosis]; end-feet involved in blood-brain barrier; promote myelination by oligodendrocytes; may act as neural progenitor cells (Noctor et al., 2002); long-distance signalling between cells

Oligodendrocytes (oligodendroglia) – get their name from having few processes; myelin sheath formation
Microglia – immune function; rod-shaped when activated

Radial glial cells (RGCs) guide neurones during their migration and act as nerve cell progenitor cells in a number of brain areas. When the process of neurogenesis has finished, RGCs move from the zones of proliferation into the cortical mantle where they change into mature astrocytes. Astrocytes, the most common cell in the CNS, connect with nerve cells and blood vessels. The latter ‘perivascular foot’ forms the gliovascular membrane, one part of the blood-brain barrier. The capillary wall forms the other part of the blood-brain barrier. CNS capillary cells contain a transaminase that prevents GABA from entering the CNS by metabolising it. Nutrients and metabolites are exchanged between neurones and capillaries via a thick astrocytic process. Astrocytes enlarge following neuronal injury and move to the site of injury where they form a protective scar.

Oligodendrocytes⁶²⁴ in the CNS form myelin⁶²⁵. The manner in which each wrap themselves around axons differs, oligodendrocytes sending out processes to do so while Schwann cell bodies elongate themselves around axons. Specialised points along axons where the myelin sheath is thinned are called *nodes of Ranvier*. *Saltatory conduction* means that the nerve impulse jumps from one node of Ranvier to the next one, thus speeding up impulse propagation. The current travels in the intracellular fluid between the nodes and across the membrane at the nodes. Unmyelinated axons conduct (*continuous conduction*) more slowly and use more energy because they must utilise more Na^+/K^+ pumps in order to restore the resting membrane potential. Apart from myelin or the lack of it, the other factor determining speed of propagation of an action potential is axonal diameter: small and unmyelinated axons might conduct at half a metre per second whereas large and myelinated axons might conduct at 200 times that speed!

Microglia⁶²⁶ and cellular elements of cerebral blood vessels are the connective tissue of the nervous system. Microglia (thin, elongated cells with several thin processes) are phagocytic (scavenger) cells (‘macrophages of the brain’) that can travel long distances. They are the immune cells of the CNS. They remain dormant unless activated by insult to the brain.

⁶²⁴ Schwann cells (lemmocytes, neurilemma cells) in the peripheral nervous system.

⁶²⁵ 70% lipids [cholesterol and phospholipids] and 30% proteins. Central (e.g. MS) and peripheral (as in some polyneuropathies) inflammatory demyelinating disorders are different processes and are rarely combined in the same patient.

⁶²⁶ Astrocytes and oligodendrocytes are known as macroglia.

Neural tube development

The early nervous system is a (neural) tube in the midline of the embryonic dorsal surface. The tube's cavity gives rise to the cerebral ventricles and the central canal of the spinal cord. Later on, there are 3 cerebral swellings (vesicles) at the oral end of the tube (head end of embryo): forebrain or prosencephalon, midbrain or mesencephalon, and hindbrain or rhombencephalon, the latter continuing into the spinal cord. The midbrain (includes the colliculi, red nucleus, substantia nigra, and periaqueductal gray) will change very little thereafter. Two secondary swellings, collectively the telencephalon, grow out from the forebrain, precursors of the cerebral hemispheres. The latter include the olfactory bulbs and lobes (rhinencephalon or 'smell brain'), the pallium (cerebral cortex), and the basal ganglia or corpus striatum. It should be recalled that the olfactory pathway represents the only sensory modality having direct access to the cerebral cortex without passing through the thalamus ('marriage bed'). Part of the forebrain, the diencephalon, remains undivided in the midline and comprises the thalamus, hypothalamus, epithalamus, subthalamus, and optic vesicle.

Cerebral vesicles

The hindbrain divides into two secondary swellings, the metencephalon (pons, oral part of medulla oblongata, and cerebellum) and the myelencephalon (caudal medulla). Therefore, from rostral to caudal one can now see telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon (see diagram).

The dividing CNS during early gestation (rostral to caudal)

Primary (4th week)

PROSENCEPHALON

→

Secondary (5th week)

TELENCEPHALON + DIENCEPHALON

MESENCEPHALON

→

MESENCEPHALON

RHOMBENCEPHALON

→

METENCEPHALON + MYELENCEPHALON

The risk for neural tube defects is decreased by giving the mother folic acid supplements and by fortifying cereals. (Reece, 1991; Czeizel, 1993; McDonnell ea, 1999; De Wals ea, 2007) Similar prophylaxis may apply to orofacial clefts, although multiple vitamins may be required. (Shaw ea, 1995)

The cerebral cortex⁶²⁷ consists of a paleocortex or primary olfactory cortex, an archicortex or limbic formation, and a neocortex. The archicortex and the paleocortex have an allocortical structure, i.e. they are tri-layered and lack layers I-III.⁶²⁸ The neocortex (90% of the human cerebral cortex) is six-layered (isocortical).⁶²⁹ The limbic lobe consists of the hippocampal formation, mamillary nuclei⁶³⁰ and anterior thalamus, cingulate cortex and parahippocampal gyrus; confusingly, the 'limbic ('border') system' is often extended to include other structures such as the amygdala ('almond').⁶³¹ Functions of the limbic system are to heed somatic (interoceptive) sensations and to look for environmental threats (Jones ea, 2009), to integrate all this data, and then to determine threat magnitude and need for action, i.e. the system has a safety role.

The cerebellum is made up of the archicerebellum or nodulofloccular lobe, the paleocerebellum or anterior lobe, and the neocerebellum or posterior lobe, named in order of their phylogenetic appearance. The cerebellum (and indeed the basal ganglia, e.g. caudate atrophy in Huntington's disease) has a role in cognition, monitoring the temporal context of mentation.⁶³² It may also have a role in modulating emotion. (Leroi ea, 2002)

We can now look at some of these events from the point of view of their timing. After the third week in utero, the brain starts to form from the anterior neural tube. By 4 weeks, the forebrain, midbrain and hindbrain vesicles have formed. By the seventh week bulges will have appeared which go on developing to form the 2 cerebral hemispheres. The start of cerebellar growth is in the second month. In the latter half of pregnancy we see convolution of the cerebral hemispheres, dendritic growth, synapse⁶³³ formation, and axonal myelination. The volume of the newborn's brain is about one-tenth of what it will be at 20 years of age; it will reach 90% of its eventual volume at age 7 years. Brain weight doubles during the first year of life, and triples in 5 years, then being 90% of adult size. A mature man's brain weighs about 1,340 grams. Cortical neurones are formed in an inside-out fashion during neocortical development: the deepest layers are formed first and the neurones that form progressively outer layers must pass through earlier layers as they push into the cortical mantle, each wave travelling a longer distance than those preceding it. Essential to migration is intercellular signalling via cell-cell adhesion molecules (cross-talk between RGCs and travelling nerve cells). Other regulatory influences arise from neurotransmitters (via NMDA receptors) and reelin (see above).

The neuronal complement of the CNS⁶³⁴ is formed before birth but white matter, occupying one-half of the adult cerebral volume and consisting of axons invested with myelin, only begins to form during the middle trimester. By two years of age the process of forming white matter is nine-tenths complete, the remainder requiring many years and myelination may in fact extend to the end of the sixth decade. Myelination begins

⁶²⁷ The various parts of the cerebral cortex do not function as independent kingdoms. Instead they work in series with other cortical and subcortical areas and with larger circuitry. Cortical circuits have excitatory and inhibitory functions.

⁶²⁸ Numbered from brain's surface.

⁶²⁹ Liddle (2001, p. 44) has this classification wrong.

⁶³⁰ The mamillary bodies are classically affected in Korsakoff's syndrome.

⁶³¹ Murray (2004, p. 28) uses the term 'limbic music' to denote 'the existential, clinical, "raw feel" emanating from the patient, i.e. emotional body language. The 'paralimbic' regions include orbitofrontal cortex, temporal pole, insula, cingulate cortex, and parahippocampal cortex, wherein cognitive, emotional, and visceral inputs merge.

⁶³² Andreasen (2003) describes the **cerebellum** as a 'metron', monitoring/coordinating the sequencing of mental activities within the context of time. Lesions of the cerebellum (especially posterior cerebellum/vermis) lead to various cognitive and emotional problems that involve executive function, visuospatial discernment, personality, and language.

⁶³³ Term **synapse** (Gk. *syn*, with and *aptein*, to join – to join with [to clasp]) coined by London neurophysiologist Charles Scott Sherrington (1857-1952) in 1897. Golgi incorrectly opined that neurones were connected by a net or syncytium, whereas Ramon y Cajal correctly understood that they were separated by spaces (synapses). In fact, there are 2 types of synapse. In one type the pre- and post-synaptic cytoplasm is continuous (bridged junctions, e.g. in cardiac muscle) via connexions (resembling tubules) and allowing electrical transmission. In the other type (the chief CNS type) there is separation by a synaptic cleft (20-50 nm) and transmission is chemical.

⁶³⁴ Pyramidal cells migrate *radially* and form columns where each column contains cells from the same clone but interneurones derived from one cell (in the predecessor of the striatum, the ganglionic eminence) spread around the cortex by migrating *horizontally*. Apoptosis (programmed cell death) is important at all stages of brain formation.

caudally with the brain stem and cerebellum and proceeds in a rostral direction to include the diencephalon and cerebral hemispheres. (Filley, 2003)

Neurones grow in such a way that allows their dendrites to achieve very selective synaptic connections with neighbouring cells (*neural specificity*). Such specificity allows discrete and reliable information transfer between cells. *Neural plasticity* on the other hand is the ability to adapt synaptic connections according to use and disuse, a capability essential for memory and learning functions. This 'Hebbian' plasticity⁶³⁵ is based on the idea that several neurones receiving simultaneous stimulation will thereafter share extra synaptic connections; such increased connectivity is due to *long-term potentiation* (LTP)⁶³⁶ which is important in learning. The *critical period* concept states that some brain developmental tasks must occur during set periods of time; otherwise related abilities will be lost or diminished⁶³⁷. Apart from critical periods, the other major factor in LTP is *activity-dependent learning*: exposure to psychological and physical environmental stimulation leads to changes in the brain such as the way cells align themselves, increased spiny processes on dendrites, synaptogenesis, and variations in neurotransmitter concentrations. Neural plasticity therefore allows us to change in response to experiences during life and not to be a prisoner of our genetic inheritance or to become robotic clones of our parents.

The neuronal body⁶³⁸ contains neuroplasm and, in females, a paranuclear body, a nuclear satellite corresponding to the paired X-chromosomes. Neuroplasm also contains chromophilic Nissl substance, consisting of flattened membranous sacs to which ribosomes (RNA-containing granules) are attached. Nissl substance is also found in dendrites but not in the axon (axis cylinder or neurite) or axon hillock. The cell nucleus⁶³⁹ contains relatively little chromatin; it also contains a dense area called a nucleolus which contains protein and RNA. The main function of the nucleolus is the synthesis of ribosomal RNA (rRNA) and ribosomes.

Neuronal excitation

Potentials are measured in milliseconds (ms)

Graded potentials (GPs) – small changes in membrane potential, usually confined to a small part of the neuronal membrane and decreasing in magnitude from initiation site – may have local signalling role – if many stimuli arrive in close temporal association they may cause summation of GPs, which may lead to an action potential (AP: larger than a GP) – all cell membranes can transmit GPs but only excitable cells (e.g. neurones and muscle cells) can propagate an AP

Action potential (AP) – on being stimulated to a threshold level (about -55 mV) from baseline (about -70 mV or resting membrane potential [RMP]) an AP is generated which is propagated along the axon – a depolarising phase (to about +30 mV) is followed by a repolarising phase (to > -70 mV) – this latter after-hyperpolarising phase (AHP) eventually sees the return to the RMP of -70 mV – the depolarising and repolarising phases (to -55 mV) represent the absolute refractory period (no stimulus can produce another AP because voltage-gated Na⁺ channel activation gates are open during depolarisation and voltage-gated K⁺ channels are open and Na⁺ channels are inactivating during repolarisation⁶⁴⁰) whilst the AHP represents the relative refractory period (only particularly strong stimuli can lead to an AP because voltage-gated K⁺ channels remain open and voltage-gated Na⁺ channels are in a resting state)

Propagation of messages was thought to be in one direction only, from pre- to post-synaptic neurones (except for chemical feedback).⁶⁴¹ However it is now thought that action potentials propagate backwards

⁶³⁵ The Canadian psychologist, Donald Hebb introduced the idea in 1949.

⁶³⁶ The mechanism by which the size of a neuronal response increases after stimulation; enhanced by glutamate activation on NMDA receptors. Backward propagation of action potential into dendrites appears to be important in longterm potentiation.

⁶³⁷ E.g. stimulation of the visual system and, possibly, the acquisition of certain psychological capacities such as the notion of *constancy* (just because you cannot see you're mother/a ball does not mean that she/it is not present close by), an important factor in protecting the organism against excessive separation anxiety.

⁶³⁸ Neurocyte, soma, or perikaryon.

⁶³⁹ Mature red blood cells and platelets have no nucleus and hence no genome.

⁶⁴⁰ *Voltage-gated channels*: Membrane depolarisation causes Na⁺ channels to open quickly and then become inactivated. The K⁺ channels then open. Repolarisation causes Na⁺ and K⁺ channels to close.

⁶⁴¹ The terminal arborisation of the axon is known as the telodendrion, and the nerve terminals have swellings called *boutons terminaux*. The synaptic gap or cleft is about 200 Å wide. The presynaptic nerve ending contains mitochondria and vesicles, the latter being clear if they contain Ach and dense if containing monoamines.

into dendrites allowing postsynaptic depolarisation required for longterm potentiation. The postsynaptic⁶⁴² membrane is thicker than its presynaptic counterpart. Excitatory or inhibitory post-synaptic potentials (EPSP and IPSP respectively) generated at the postsynaptic membrane lead to membrane depolarisation or hyperpolarisation respectively. The cell leading, or not leading (depending on summation) to an action potential integrates EPSPs and IPSPs.

Specific membrane-bound proteins, such as synaptobrevin (neuronal) and synaptotagrin (vesicular), allow the vesicle to attach to the nerve cell membrane. Exocytosis is the process whereby the vesicle empties its contents into the synaptic gap. Exocytosis occurs in axon terminals at 'active zones' when calcium ions enter the neurone on arrival of the action potential. The vesicular membrane, recovered by endocytosis, is then reformed and the vesicle is available to be used again.

Many neurones within the CNS can generate their own activity pattern (endogenous activity involving specialised ion channels) without requiring synaptic input. There are two such patterns: pacemaker firing (regular firing) and burst firing (cluster firing).

Most neurotransmitters (NTs) are produced enzymatically within the presynaptic terminal. Neuropeptides, however, are made on ribosomes and put in vesicles in the nerve cell soma, the vesicles then being transported along the axon to the nerve terminal.

The DA system in the human brain arises in the ventral tegmental area (VTA) and substantia nigra and sends fibres along the nigrostriatal pathway (D1 + D2) to the basal ganglia, and D1 fibres (mainly) to the limbic system and then forwards and backwards over the prefrontal cortex. Fibres from the hypothalamus innervate the hypophysis (hypothalamico-pituitary tract). Psychosis might have its origins in the basal ganglia because of its richness in D2 receptors, and the ability to block D2 receptors correlates much more closely with antipsychotic drug actions than does D1 blockade. Even when medication is controlled for, the pituitary is often enlarged early in psychosis due to an increase in number and size of ACTH-producing cells. Such enlargement may precede psychosis by months in cases at very high risk for such disorders who eventually do become psychotic when compared with people at high risk who fail to progress to psychosis.(Garner ea, 2005)

In aminergic pathways⁶⁴³ the cell bodies are situated in the brainstem and these neurones have close connections with the limbic system. Their efferents are unusual in that they do not have the usual nerve endings; instead they have 'nodules' along their lengths, each nodule being rather akin to an atypical synapse. Each neurone can influence up to 140,000 other neurones and bathe the cortex in their transmitter.

Prefrontal cortex (PFC)

Crucially important for pursuit of goal-directed behaviour

Lesions to orbital part of the PFC cause euphoria, overactivity, and inappropriate social behaviour

Lesions of dorsolateral part (DLPFC) are associated with apathy (lack of feeling/interest/motivation), underactivity, and impaired cognition

DLPFC dysfunction is said to occur in schizophrenia

The temporal lobe can be divided into an outer neocortical part and an older medial part. The latter consists largely of the hippocampus⁶⁴⁴ and hippocampal gyrus on the inferomedial margins of the temporal lobes.

Hippocampal formation* (HF)

Folded sheet of tissue

Includes:

*Fimbria***

Dentate gyrus

Hippocampus

Subiculum

⁶⁴² Sometimes called subsynaptic.

⁶⁴³ 5-HT, noradrenaline – only a little adrenaline is made in the CNS because of a deficiency of the appropriate enzyme.

⁶⁴⁴ 'Seahorse', *cornu Ammonis* or Ammon's horn.

*The HF has the highest proportion of corticosteroid-binding sites in the brain.

** Contains hippocampal pyramidal cell axons that join behind the hippocampal commissure to form the fornix.

The hippocampus is divided into sectors (CA1-4) on the basis of cellular architecture⁶⁴⁵. The HF fold consists of three-layered old cortex that projects into the lateral ventricle; the HF is continuous with the six layers of the entorhinal neocortex. The change from 3 to 6 layers occurs at the subiculum. Entorhinal and perirhinal cortices meet anteriorly. The entorhinal cortex forms part of the parahippocampal gyrus posteriorly. A loop is completed as follows: dentate gyrus granule cells → CA3 pyramidal cells → CA1 pyramidal cells → subiculum → entorhinal cortex. Pyramidal and polymorphic cell axons form the alveus that runs along the ventricular hippocampal surface. These develop into fimbriae, crura of fornix, and body of fornix. The fornix ends in the hypothalamic mamillary bodies. The fornix, apart from cholinergic spino-hippocampal fibres, is an output system.

The HF processes incoming information and acts as a short-term memory store. The hippocampus is important for declarative memory, i.e. for remembering facts, experiences and information about events⁶⁴⁶. Long-term memory is mainly in the temporal lobe.

The medial temporal lobes

Right-sided damage/dysfunction – problems with acquisition of new **spatial** information

Left-sided damage/dysfunction - problems with learning and retaining new **verbal** information

The planum temporale is a triangular plane lying on the superior and posterior surface of the temporal lobe (just behind Heschl's gyrus) and, on the left side, forms part of the biological substrate for language⁶⁴⁷. The left planum temporale is bigger than the right one in two-thirds of all brains. Work on animals suggest that direct exposure to glucocorticoids may lead to loss of pyramidal neurones and dendritic branching in the hippocampus.(Woolley ea, 1990)

The dentate gyrus of the hippocampus produces new neurones from dividing progenitor cells in adult animals, including humans⁶⁴⁸. Psychological stress decreases the rate of neurone formation. Stress plus corticosteroids may cause cell death. Various antidepressant drugs, ECT, and lithium increase neurogenesis⁶⁴⁹ in rats.(e.g. Malberg ea, 2000) Tianeptine may preserve neurogenesis potential in face of stress, and ECT prevents steroid-induced reductions in new neurone formation in animals.(Steele & Reid, 2004)

The hippocampus in depression (Whale, 2008)

Hippocampal shrinkage occurs whilst depression remains untreated

Hippocampus is sensitive to BDNF⁶⁵⁰ – depression and stress decrease BDNF

Neurogenesis⁶⁵¹ is increased by BDNF, antidepressants, oestrogens, exercise, sexual activity, a stimulating environment

Neurogenesis is decreased by ageing, stress, corticosteroids, and NMDA (glutamate)

The occipitotemporal (fusiform) gyrus lies on the ventromedial surface of the temporal and occipital lobes. It is important for face recognition. It appears to be dysfunctional in prosopagnosia and perhaps in delusional misidentification syndromes. There is increasing evidence that patients with schizophrenia may have deficits in face processing, including those patients at first hospitalisation.(Lee ea, 2002)

⁶⁴⁵ The CA1 subfield may be differentially targeted in schizophrenia.(Schobel ea, 2009)

⁶⁴⁶ As distinct from procedural memory, memory for skills.

⁶⁴⁷ This area contains the auditory association cortex, i.e. Wernicke's area.

⁶⁴⁸ Apart from this, brain-injured patients may compensate for their difficulties when remaining cortex takes over from damaged areas. Magavi ea (2000), working with adult mice, found that hippocampal, subventricular, and even neocortical neurones could be induced to divide to produce daughter neurones and that these could then form connections with distant structures.

⁶⁴⁹ It is disputed as to whether neuro-regeneration of neurogenesis is the correct term. It now appears feasible to grow neurones from non-neuronal adult cells *in vitro*.

⁶⁵⁰ The gene for **BDNF** is at 11p14. 5-HT and norepinephrine increase BDNF synthesis via cAMP. **Neurokinins** (e.g. substance P) co-transmit with 5-HT and norepinephrine. There is a suggestion that NK1 antagonism is antidepressant. **Δ Fos B** is linked to learned helplessness in rats. There is evidence that life events must occur before increased cortisol occurs in depression.

⁶⁵¹ The adult brain can form new neurones only in the dentate component of the hippocampus and in part of the olfactory bulb.

Amygdala

A forebrain structure

Part of limbic system

On roof of temporal horn of lateral ventricle

At inferior end of caudate nucleus⁶⁵²

Adjacent to the uncus

Divided into various nuclei⁶⁵³

Entorhinal cortex and hippocampus have role in regulating responses of amygdala

Amygdala enhances storage of emotionally important memories in medial temporal lobe

Amygdala responses inhibited by medial prefrontal cortex when they cease to be relevant

Lesions of the amygdala may cause fearfulness and suspiciousness. Infusion of CRF into the amygdala of animals leads to behaviour reminiscent of anxiety, a response that may mimic stress-induced anxiety in the human. The CRH1/CRF1 receptor may modulate the anxiety-inducing effects of CRH (Holsboer, 1999) and a variant of the CRH1 receptor gene (TAT haplotype) might protect against the development of adult depression in women following childhood maltreatment. (Polanczyk et al., 2009) With the hippocampus, the amygdala is probably very important for learning and memory; it may also have a role in such activities as facial perception and recognition (as well as deciding how approachable/trustworthy a face appears to be)⁶⁵⁴, and the expression of aggression. Recognition of emotion in faces (especially fear and disgust⁶⁵⁵) is impaired in schizophrenia (no benefit accrued from increased emotional intensity), with a tendency to view neutral cues as negatively valenced. (Köhler et al., 2003) Paradiso et al., (2003) in a PET study, found that, unlike control subjects, when schizophrenics consciously evaluated unpleasant images they did not activate the amygdala, although they correctly rated them as unpleasant; also, they did not activate areas of the prefrontal cortex normally employed to recognise images as pleasant and were unable to recognise them as such; areas of reduced cerebral blood flow were widely distributed and included subcortical areas such as thalamus and cerebellum.

According to Parkin, (1987) amygdectomy alone does not cause amnesia. It is rare to find cases with discrete bilateral amygdala destruction, but it can occur, e.g. with lipoid proteinosis (Urbach-Wiethe disease, an autosomal recessive disorder involving skin, pharynx, and larynx). According to Liddle, (2001, p. 45) the amygdala responds to external imperatives by mobilising a fight or flight response at the expense of concurrent cognition, whereas the hippocampus is involved in a more reflective evaluation of current circumstances. According to Cras, (2002) the amygdala is important in the association of a particular emotion with a current experience. Contextual learning in rats seems to depend on an intact connection between amygdala and hippocampus.⁶⁵⁶ (Kim & Fanselow, 1992)

The *stria terminalis* is composed chiefly of fibres running from amygdala to hypothalamus and adjacent mesial basal forebrain. Scattered along the *stria terminalis* are patches of grey matter known as the *bed nucleus*, the largest part of which is in the mesial basal forebrain beside the lateral septal nuclei in the inferior septum pellucidum.

⁶⁵² The amygdala is found where the tail of the caudate nucleus meets the most anterior part of the hippocampus/parahippocampus.

⁶⁵³ Lateral, basolateral, basomedial, central (where vasopressin/oxytocin balance may influence set-point for anxiety response and activation of autonomic nervous system), medial, and cortical nuclei and amygdalocortical transition area.

⁶⁵⁴ A person with bilateral amygdala lesions can recognise who owns a face but not the **facial expression of fear**; this structure is therefore important in processing stimuli related to fear.

⁶⁵⁵ **Disgust** is taught by parents to ward off ingestion of contaminated materials but it may be involved in a number of psychiatric disorders. There may be impaired disgust recognition in schizophrenia and in Huntington's disease. Spider phobia is reported as being linked to disgust rather than fear. Disgust (leading to vasovagal syncope) is an important but not consistent finding in blood-injection-injury phobia. Other theoretical connections may be with contamination-based OCD, social phobia, eating disorders, sexual dysfunction, body dysmorphic disorder, coprophagia, and depression. (Phillips et al., 1998; Olatunji & McKay, 2007)

⁶⁵⁶ Normally tone + electric shock in a cage → associates cage with shock (i.e. fear occurs on being near cage: *contextual fear conditioning*), but after damage to amygdala tone only → fear (but not cage → fear).

Cavum septum pellucidum

Atypical space lying between the two layers of the septum pellucidum
Does not necessarily signify abnormal function

The Papez⁶⁵⁷ circuit can be described as follows. The mamillary body sends fibres via the mamillo-thalamic tract to anterior thalamic nuclei that then send fibres to the cingulate cortex and cingulum.⁶⁵⁸ The latter project to entorhinal (anterior part of parahippocampal gyrus with wart-like lumpy surface) and subicular cortices (medial temporal lobe). Entorhinal fibres pass via the perforant pathway to the dentate gyrus. Fibres from the latter project to hippocampal pyramidal cells. Hippocampal fibres and fibres running from the subicular cortex run in the fornix; they run backwards and upwards, arch up under the splenium and run forwards under the corpus callosum ('firm body' – connects homotypic regions of the two cerebral hemispheres), then turn downwards (as the columns of the fornix) to run through the hypothalamus, and end up in the mamillary body.⁶⁵⁹

Cerebral dominance is a too simplified notion. The hemispheres are functionally asymmetrical (lateralisation). Dominance refers to language and preferred hand, foot and eye use. The nondominant hemisphere is responsible for visuospatial function.

CNS control of visuospatial function

Information from visual cortex to temporal (ventral) or parietal (dorsal) cortex travels in 2 streams

*Ventral stream*⁶⁶⁰ – information linked to semantic data – 'what is it?'

*Dorsal stream*⁶⁶¹ – allows link between visual data and spatial position/orientation – 'where is it?'

Frontal eye fields – allows one to direct attention towards a target in the visual field

The thalamus⁶⁶², wherein sensory and motor information is relayed, consists of a number of nuclei,

Nuclei of thalamus

Dorsomedial (information received from [IF] the prefrontal cortex [PFC] and hypothalamus and sent to [ST] the PFC; a sense of dreadful foreboding follows stimulation)

Dorsolateral (IF cingulate gyrus and parietal cortex and ST the same areas)

Anterior (IF mammillothalamic tract and ST cingulate gyrus; a limbic structure)

Ventral anterior and ventral lateral (IF cerebellum and basal ganglia and ST premotor and motor cortices)

Posterolateral (IF occipital cortex and ST parietal cortex)

Medial and lateral ventroposterior (relays sensory information)

Intralaminar (part of reticular formation; IF from midbrain, PFC and motor area and ST basal ganglia)

Pulvinar (IF non-frontal cerebral cortex and ST to visual cortex)

Medial geniculate body (IF lateral lemniscus and ST primary auditory cortex)

Lateral geniculate body (IF optic tract and ST primary visual cortex)

⁶⁵⁷ The term *grand lobe limbique* (limbic lobe) was coined by Paul Broca in 1878. James W Papez of Cornell University wrote his paper in 1937. Papez's ideas were expanded on during the 1950s by the US physician and neuroscientist Paul MacLean (1913-2007) who considered that we had three 'brains' (*triune brain*): reptilian complex, limbic system, and neocortex. The list of constituents of the limbic system has not remained constant over the years.

⁶⁵⁸ The **cingulate** is 'an amplifier and filter, interconnecting the emotional and cognitive components' of mental life. (Devinsky et al, 1995) It has an important role in the emotional aspect of pain. The dorsal anterior cingulate cortex is involved in allocation of attention and monitoring for errors.

⁶⁵⁹ Put more simply, this circuit can be expressed thus: *mamillary body* → *ant. thalamus* → *cingulum* → *medial temporal lobe* → *dentate gyrus* → *hippocampus* → *fornix* → *mamillary body*.

⁶⁶⁰ This goes from occipital lobe to temporal lobe and especially allows recognition of people and objects.

⁶⁶¹ This goes from occipital lobe to parietal lobe and is important for visual guidance of action. Depressed patients show less engagement (as measured by magnetoencephalography and self-report) of this stream when watching pictures than do controls although, like controls, engagement is greater for emotional pictures than for neutral pictures. (Moratti et al, 2008) **Balint's syndrome** (bilateral dorsal stream lesioning) includes simultanagnosia (inability to discern > 1 item in visual scene simultaneously), optic ataxia (difficulty reaching for an object that is seen), and oculomotor dyspraxia (inaccurate directing of eye movements).

⁶⁶² Gk., inner chamber.

The thalamus acts as pacemaker by exerting rhythmic control over large groups of cortical neurones. Destruction of the thalamus abolishes rhythmic activity in the cortex. According to Andreasen, (2003) all experiences and perceptions flow into the thalamus which acts as a filter that allows suppression of irrelevancies and selection of important items. The pulvinar is important for connecting visual and auditory information.

The hypothalamus consists of preoptic (gonadotrophic hormone production; sleep generation), supraoptic (anterior, paraventricular, and suprachiasmatic components: parasympathetic nervous system; vasopressin [arginine vasopressin, AVP, antidiuretic hormone, ADH] and oxytocin production), mamillary (limbic area involved in memory), tuberal (ventromedial and dorsomedial components: the first component is involved in hunger and satiety, and the latter subnucleus is important for emotion such that rage occurs if it is destroyed), arcuate (fibres from here carry neurohormones to the adenohypophysis: the arcuate nucleus is outside the blood-brain barrier and has insulin, ghrelin and leptin receptors), and posterior (sympathetic nervous system) nuclei. The various hypothalamic releasing hormones either stimulate the release (e.g. corticotrophin [corticotropin⁶⁶³] releasing hormone [CRH] causes release of ACTH) or inhibits the release (e.g. somatostatin and dopamine inhibit growth hormone and prolactin release respectively) of hypophyseal hormones. However, hypothalamic peptides also act as neurotransmitters elsewhere in the brain, e.g. CRH has an activating effect on the locus coeruleus leading to noradrenaline release and this noradrenaline then activates CRH from the hypothalamus and the amygdala, a property (reciprocal stimulation) that may be important in the insomnia and anxiety associated with clinical depression.

The epithalamus is a collective term for the stria medullaris, the pineal gland, and the medial and lateral habenular nuclei. The habenular complex consists of relay nuclei that link limbic forebrain to midbrain and brain stem nuclei and may be reduced in size and neuronal cell number in depression. (Ranft et al, 2010)

The subthalamus⁶⁶⁴ is a complex set of nuclei important for motor function.

The striatum has a medial part (caudate) and lateral part (putamen) which are separated by perforating fibres of the internal capsule (see box).

Striatum consists of –

Caudate nucleus ('tail') and putamen ('stone')

Lentiform nucleus consists of –

Putamen and globus pallidus ('pale globe')

The C-shaped caudate nucleus is adjacent to the lateral ventricle and bounded by the internal capsule. It is divided into a head (in the frontal lobe), body, and tail (in the temporal lobe).

The pyramidal system (corticospinal tract) is important for the execution and control of skilled voluntary movements. The extrapyramidal system (with cerebellar inputs) is important for muscle tone distribution and posture maintenance. The cerebellum, in receipt of 'command' and 'response' information, compares both and corrects motor performance by its influence on the cortex via the basal ganglia or muscles via the reticular formation.

The anatomy of the stretch reflex is as follows. An intrafusal muscle fibre has two contractile ends and a central membranous, stretchable component. Ia afferent nerve fibres wind around the membranous part of the intrafusal muscle fibre. Impulses from these nerve fibres travel via their nerve cell bodies in the posterior root ganglia to synapse with the big alpha-motor neurones of the ventral horn of the spinal cord, the latter sending thick efferent fibres called A α fibres to motor endplates of striated muscle fibres. Smaller gamma-motor neuronal bodies lie close to the α -motor neuronal bodies in the cord and send thin A γ -fibres to the contractile ends of the intrafusal muscle fibre. Descending fibres from higher centres synapse with both alpha-motor neurones and gamma-motor neurones. Thus, nerve cells in higher brain centres influence the contractile state of muscle by acting on α -motor neurones or via the gamma loop. Put simply, gamma-motor neurones cause the ends of the muscle spindle to contract, thereby stretching the central membranous part; impulses then travel to the alpha-motor neurone via afferent nerve fibres.

⁶⁶³ CRH is also produced by the placenta during pregnancy (pCRH) and increased levels of pCRH in mid-pregnancy may be predictive of postpartum depression. (Yim et al, 2009) Cortisol suppresses hypothalamic CRH release but stimulates pCRH release.

⁶⁶⁴ Thalamus ventralis. A CVA (infarct or bleed) involving the subthalamic nucleus is associated with contralateral **hemiballismus** (wild swinging movements) which is treated with antipsychotic drugs. Hemiballismus usually resolves over some weeks.

That part of the cerebral cortex that is responsible for integrating information coming from many different sources is known as the association cortex, the sensory association cortex processing complex aspects of sensory stimuli and the multimodal association cortex integrating information from the different senses with motivations and goals.

Functional divisions of cerebral cortex

Primary – unimodal (sensory or motor)

Association – multimodal (receiving input from many areas) – frontal (executive, including impulse inhibition); limbic (memory, emotion); and sensory (integration of sensory input, including temporal, parietal, and occipital components) areas

OR

Idiotypic (primary) – such as primary visual, auditory, and motor areas

High-order (heteromodal) – such as motor association area and frontal eye fields

Modality-specific (unimodal) - such as visual association cortex

Paralimbic - orbitofrontal (ventromedial) cortex, temporal pole, insula, cingulate cortex, and parahippocampal cortex, (coming together of cognitive, emotional, and visceral inputs)

Cortical network regions

(Transmodal cortical areas that control different aspects of cognition)

Executive function/working memory – Lateral prefrontal and (?) inferior parietal cortex

Language – including Broca's and Wernicke's areas

Spatial awareness – frontal eye fields and posterior parietal area

Memory and emotion – amygdala and hippocampus/entorhinal area

Face/object recognition – temporal (polar and mid) cortex

*Fronto-subcortical networks*⁶⁶⁵

(Involved in cognition, behaviour, and movement)

Somatic motor – starts in supplementary motor area

Oculomotor – starts in frontal eye fields

Dorsolateral prefrontal – executive function

Orbitofrontal – joins the monitoring role of prefrontal cortex with limbic system

Anterior cingulate – concerns motivated behaviour

Executive function (EF) is not simply something that happens in the prefrontal cortex. Subcortical connections of the latter to basal ganglia (caudate, nucleus accumbens, globus pallidus), thalamus, and cerebellum are also part of the EF system and damage to any of them or their interconnections can interfere with EF.

The pathway allowing light signals to influence the pineal gland appears to be as follows: retina to suprachiasmatic nucleus, to paraventricular nucleus to synapses in the spinal cord, and then via sympathetic outflow to superior cervical ganglion, and thence via the *nervi canarii* to the pineal gland, i.e. a circuitous, multi-synaptic pathway.

Saccadic eye movements (i.e. visual search) involve a projection from the occipito-parietal cortex to the frontal eye fields (in the frontal lobe).

Gender differences in brain development have attracted increasing attention.(Castle & Murray, 2002)

Testosterone produced by the embryonic testis may slow brain development. It has been suggested that the male brain is slower than the female brain to lay down myelin and form connections between neurones.

The effect of such slowing may be chiefly left-sided. This may render male brains more vulnerable to insults, e.g. low birth weight may be more likely to lead to haemorrhage in the area of the cerebral ventricles if the sex is male, and 12-year-olds with minor neurological dysfunction are more often male and have suffered early environmental insult such as hypoxia. Male brains on average are larger than female

⁶⁶⁵ Frontal cortex → striatum → globus pallidus/substantia nigra → thalamus → frontal cortex. **Fronto-subcortical dementia** refers to the co-existence of frontal and subcortical symptoms due to disruption of fronto-subcortical circuits (e.g. in some cases of vascular dementia): dorsolateral prefrontal cortex-subcortex (executive dysfunction), orbitofrontal-subcortex (disinhibition), and medio-frontal/cingulate-subcortex (apathy and depression).

brains. Other differences include a larger preoptic nucleus (of the hypothalamus) and greater asymmetry of the planum temporale in males. Females may have greater bilateral representation of cortical functions than males. Ageing female brains may lose a greater amount of parietal, thalamic and hippocampal volumes than is the case in males, the opposite occurring in terms of whole-brain, frontal and temporal volumes. According to Andreasen,(2003) lose grey matter earlier and faster than do women. Males may have more D2 receptors to begin with but by mid-life end up with relatively less than females.

Kindling (Goddard & Morrell, 1971) is that process in which increasing behavioural or convulsive responses occur to repetition of the same stimulus over time. Carbamazepine is highly effective in inhibiting an amygdala-kindled compared to cortical-kindled focus. Goddard & Morrell,(1971) who described the phenomenon, indicated that limbic system structures, particularly the amygdala, were most susceptible to kindling. In animals, once seizures develop in response to repeated amygdala stimulation, they can again be evoked months to years later even in the absence of further stimulation. Cats who kill rats will cease to do this if they are amygdala-kindled. Pharmacological kindling can be performed with the local anaesthetic lidocaine. Repeated giving of lidocaine causes the development of seizures and abnormal behaviour that follow a kindling-like time course. Marked increases in irritability and aggression are seen in that animals show repeated lidocaine-induced limbic seizures. To distinguish it from 'electrophysiological kindling' (increased responsivity to repeated stimulation of the brain), when behavioural effects occur without seizures, the phenomenon is styled 'behavioural sensitisation'; e.g. increasing responsivity to repeated administration of the same dose of a stimulant such as cocaine. The latter is not as long lived as electrical kindling. Post (1992) has speculated on how environmental stress may induce genetic and other neurobiological changes, especially in the acute phase of affective illness, which might lead to a cascade of events that allows the illness to become autonomous of the 'mental' experiences of the individual. The idea that prolonged glucocorticoid secretion may cause memory and cognitive deficits by being toxic to hippocampal neurones is based mainly on animal work.(O'Brien, 1997) The concept of mass action or equipotentiality holds that learned behaviour is diffusely organised in the brain, and that it is the extent of a lesion rather than its site that determines loss of function, as applies to intellectual loss in dementia. Also, it should be noted, slowly expanding/spreading lesions/disorders are compatible with adaptive change and retention of ability, e.g. the very thin cortex of the child with hydrocephalus is still compatible with retention of premorbid IQ because of the slow progression of cortical thinning. Also, the functions of one cortical area may be undertaken by another area, and there is probably some cortical reserve that can be called on in the event of damage. There is evidence that dendritic growth continues into old age. There is also evidence that columns of cortical cells are functionally capable of independent and highly specialised function and action and can escape damage to independent and adjacent columns.

The chief consumer of body *glucose* is the brain – the brain of a 70 kg man needs 1 mg/kg bodyweight/minute (100 g/24 hrs). Half of all glucose made in the liver is consumed by the brain where the derived energy goes to make the ATP that is needed to guarantee the trans-axonal membrane potential difference. The brain's glucose uptake is obligatory and non-insulin dependent.

Neurochemistry, psychopharmacology and neuropharmacology

Doctors should consider stopping treatments that have not benefited the patient despite being taken for long enough and in adequate dosage.

Neuropharmacology is the study of the effect of drugs on nervous tissue, whereas psychopharmacology is the study of drug effects on behaviour.

The classical form of neurotransmission involves transmission of a message by chemical messenger (neurotransmitter) from one nerve cell (neurone⁶⁶⁶) to another across a cleft, potential space, or synapse. *Volume transmission*, on the other hand, is due to diffusion of a neurotransmitter (NT) to sites distant from the neurone. A small number of synapses do not use neurotransmitters but involve the direct flow of small molecules and ions from the cytoplasm of one cell to the adjacent cytoplasm of another cell through channels called *gap junctions*.

Receptors⁶⁶⁷ and enzymes are manufactured in the cell body (soma) and then transported to the cell periphery. The effect of activating a postsynaptic receptor largely depends on the location of where the

⁶⁶⁶ Neuron in USA.

⁶⁶⁷ Receptors are usually large protein or glycoprotein molecules in the cellular membrane, cytoplasm, or nucleus.

receptor is on the postsynaptic neurone. Activation of an ion channel-linked receptor located near the axon hillock, the site of generation of the action potential is generated, will have a far greater effect than activation of a similar receptor on a dendritic spine. In the latter case, activation of many receptors may be necessary to change the cell's activity. Because G-protein-linked receptors activate a cascade of second messengers, the effects of their activation is not so dependent on location.

Ion channels

These may be rested, activated, or inactivated

Rested = closed but can be opened if stimulated

Activated = open

Inactivated = closed and cannot be opened if stimulated

The majority of ion channels are inactivated and remain like this until they open when a specific signal dictates their opening – this phenomenon is called *gating*

Gating is governed by changes in the membrane environment

Voltage-gated ion channels: open in response to changes in membrane potential⁶⁶⁸

Ligand-gated ion channels: open in response to changes in concentration of a neurotransmitter molecule

Most receptors are in the cell's surface membrane and are divided into ionotropic (or ligand-gated ion) and metabotropic receptors. Intracellular receptors interact with chemicals like steroids⁶⁶⁹ and thyroid hormones.

Class I (ionotropic) receptors are ligand-gated ionic channels. Activation leads to a rapid and transient increase in membrane permeability and inhibition (e.g. GABA A receptors are inhibitory⁶⁷⁰) or activation (e.g. cholinergic nicotinic receptors) of the postsynaptic membrane. The receptor consists of a number of subunits surrounding a channel in the membrane. When an agonist binds to the receptor the channel opens. Normally, there is an excess and a deficit of potassium and sodium inside cells respectively. At excitatory ionotropic receptors neurotransmitter binding opens the ion channel and an opened channel allows potassium ions to move outward and sodium ions to move inward, with depolarisation of the transmembrane potential and the generation of excitatory postsynaptic potential (EPP). At inhibitory ionotropic receptors neurotransmitter binding causes the opening of chloride channels with the influx of chloride ions with membrane hyperpolarisation and the formation of an inhibitory postsynaptic potential (IPP).

Ionotropic receptors

- Neurotransmitter + excitatory receptor → K⁺ efflux + Na⁺ influx → depolarised membrane + EPP
- Neurotransmitter + inhibitory receptor → Cl⁻ influx → hyperpolarised membrane + IPP

The GABA A (GABA_A) complex consists of a ring of transmembrane proteins. The latter are arranged in 5 groups designated α , β , γ , δ , and ρ . Benzodiazepines (BZDs) are agonists at α subunits, GABA acting at β subunits. α , β , and γ act together to form the ω -1 or benzodiazepine receptor. Brain BZD receptors in the brain are divided into BZ1 (type 1, omega 1) and BZ2 (type 2, omega 2). Omega 3 receptors are common in the periphery. Zaleplon and zolpidem bind selectively to GABA A receptors containing alpha-1 subunits. GABA A receptors with alpha-1 subunits may mediate sedation, amnesia and anticonvulsant activity.

Those containing alpha-2 and alpha-3 subunits may mediate anxiolysis and muscle relaxation.

Class II (metabotropic) receptors give a slower response. G-proteins bind to the intracellular part of the receptor and are involved in second messenger activation (such a division of G-proteins is now known to be simplistic because G-proteins can interact with more than one effector system with varying results; also,

⁶⁶⁸ On arrival of an action potential at the nerve terminal voltage-gated Ca⁺⁺ channels are involved in the initial conversion of the electrical message into chemical transmission.

⁶⁶⁹ Ligands that are lipid soluble do not require secondary messengers. Once their receptors in the cytoplasm are activated they enter the nucleus, bind with DNA, and directly change gene expression.

⁶⁷⁰ However, GABA-A receptors are excitatory in (a) early development (because of high levels of chloride within cells) and (b) in some mature synapses (especially some projecting into initial segments of cortical pyramidal neurones). (Szabadics et al, 2006)

there are a number of families of G-proteins, each with a number of subunits with various tissue distributions, receptor agonists and known or unknown effectors; basically, G-proteins⁶⁷¹ have 3 different subunits – it is the α subunit that determines which receptor a G-protein complex interacts with and the type of effector system that will be modified; $G_{\alpha s}$ stimulates and $G_{\alpha i}$ inhibits adenylate cyclase – $G_{\alpha o}$ modulate voltage-sensitive calcium channels and phospholipase C whereas $G_{\alpha olf}$, found in the nasal mucosal neurones, are involved in transducing signals derived from olfactory receptors).

The receptor consists of long peptide chains with a number of subunits within the membrane and a long intracellular loop that binds the G-protein. Various second messengers may then be activated or inhibited, including adenylate cyclase (producing cAMP, leading to phosphorylation of other enzymes), activation of phosphoinositide turnover and calcium release, the conversion of arachidonic acids to prostaglandins, leukotrienes and other active compounds, and indirect activation of ion channels.

A neurotransmitter (NT), such as acetylcholine (ACh)⁶⁷², is a substance secreted by a neurone (nerve cell) that acts on a target neurone. A NT must be made in a neurone, be present in the presynaptic neurone, and be released on depolarisation in physiologically significant amounts. When given exogenously as a drug it should mimic the actions of the endogenous NT. Also, a mechanism should exist in the neurone or the synaptic cleft for its removal or deactivation.

The term neurohormone (e.g. CRF) refers to neuronal peptide⁶⁷³ secretions that directly enter the blood stream. These act on other neurones, as do neurotransmitters. A neuromodulator (e.g. steroids; CRF from lymphocytes) is a substance that influences neuronal activity and originates from non-synaptic sites. Neuromodulation refers to a situation whereby an NT's actions, among others, alter the responsiveness of postsynaptic cells to the effects of other synaptic inputs. Neuromodulatory NTs act, not by directly affecting neuronal firing, but by modifying neuronal excitability, so that responses to other NTs are altered (Cf. allosteric modulation below). An example is the action of BZDs on the GABA receptors (see below). (Dolan & Grasby, 1994) Neuromediators are postsynaptic compounds (e.g. cAMP) that participate in the generation of postsynaptic responses. Because of the difficulty in practice of fulfilling the criteria for neurotransmitter, neuromodulator and so on, a general term for all substances involved in chemical transmission has been proposed: neuroregulators. (Iritani, 2002)

In contrast to the classical but slower genomic (gene expression) mechanisms of steroid activity, neuroactive steroids⁶⁷⁴ regulate neuronal function by influencing neuronal excitability (non-genomic mechanisms via ligand-gated ion channel receptors). DHEA, which is metabolised to androstenedione (the latter is converted to androgens and oestrogens), may cause maculinisation, hirsutism, and changes in the voice. In humans, DHEA may improve mood⁶⁷⁵ and the symptoms of schizophrenia. Negative affect in healthy girls may relate to high testosterone and cortisol levels and low levels of DHEA. (Susman et al., 1991) *Allosteric*⁶⁷⁶ modulation refers to the situation where there are two sites on a receptor and only when a neurotransmitter (NT) acts on its site can another chemical cause an effect. In other words, the action is an indirect one. The allosteric modulator can block or amplify the actions of the primary NT. In the absence of the primary NT the second chemical will have no particular effect. An example is seen at the GABA receptor where benzodiazepines, barbiturates and anticonvulsants may act allosterically.

A different phenomenon is *co-transmission*. In this, each of 2 NTs work somewhat independently of each other, but can have additive effects if working together, e.g. glutamate and glycine at some glutamate receptors.

A *ligand* is a substance that binds with receptors. In research these are usually labelled with a radioactive isotope.

⁶⁷¹ Alfred Gilman and Martin Rodbell received Nobel Prize in 1994 for discovery of G-proteins.

⁶⁷² Discovered in ergot in 1914 by Henry Hallett Dale (1875-1961), a London physiologist. Called *Vagustoff* (vagus material) by Otto Loewi (1873-1961 – Nobel Prize, 1936), professor of pharmacology at Graz, after it was found in heart muscle in 1921. Eccrine sweat gland are innervated by cholinergic sympathetic fibres and those of the palms and soles are activated by emotion and this assists grip. In the CNS, **acetylcholine-containing (cholinergic) neurones** are found in the nucleus basalis of Meynert (which project diffusely to neocortex), septum and diagonal band of Broca (projecting to hippocampus, hypothalamus and amygdala), and (as interneurons) in the basal ganglia. Choline, the precursor of acetylcholine, is derived from recycled synaptic ACh and dietary phosphatidylcholine.

⁶⁷³ A peptide is a number of amino acids strung together by peptide bonds. A neuropeptide or neuroactive peptide is a peptide with neurophysiological activity.

⁶⁷⁴ E.g. dehydroepiandrosterone or DHEA and its sulphated form DHEA-S.

⁶⁷⁵ E.g. in elderly, those with SLE, dysthymics, major depression, and non-major depression in association with HIV/AIDS.

⁶⁷⁶ Allosterically simply means 'at another site'.

The number of putative NTs is increasing. The main NTs of importance to psychiatry are catecholamines (inhibitory at synapses, i.e. inhibit spontaneous firing of receptive cells; noradrenaline and dopamine – there is a benzene ring with two attached hydroxyl groups [catechol nucleus] and opposing side chain of ethylamine or one of its derivatives), indoleamines (inhibitory except for limbic cortex; 5-HT), neutral amino acids (inhibitory; GABA), peptides (inhibitory, except hippocampus; endorphins), choline esters (excitatory; Ach), and dicarboxylic amino acids (excitatory; l-glutamic acid). Other putative NTs include cholecystokinin⁶⁷⁷ (CCK, produced by mucosal endocrine cells of proximal small intestine), substance P, and vasoactive intestinal (poly-) peptide (VIP).

Pharmacological terms

Adverse drug reaction (ADR): a reaction that is harmful and unintended and occurs with doses used in man for prophylaxis, diagnosis or treatment of disease or modification of physiological function.

Agonist: compound acting on receptor to produce similar effects to natural ligand.

Agonist spectrum: if we imagine the antagonist, which has no intrinsic activity, in the centre, then the strength of agonist activity increases through partial agonist to (full) agonist, and the strength of inverse agonist (having effects opposite to an agonist) activity increases through partial inverse agonist to (full) inverse agonist. An antagonist reverses the actions of all 4 types of agonist. For example, in the case of a ligand-gated channel the resting state is one of partially opened channel, but full agonists open it fully. Partial agonists open it a little less fully, inverse agonists close it fully, partial inverse agonists almost close it, and the antagonist brings it back to its resting state in all cases. (Stahl, 2000) Partial agonists have low intrinsic activity but high affinity. They can therefore inhibit agonists with high intrinsic activity. Net effect is antagonism of agonists. One of aripiprazole's actions is as a partial DA agonist.

Amine: organic compound containing the amino group ($-NH_2$).

Antagonist: compound that blocks receptors, thereby preventing agonist or inverse agonist from eliciting a physiological response. It should have no biological activity of its own, e.g. flumazenil.

Anticholinergic load: the summed anticholinergic activity of all drugs being taken by a patient. Taking the anticholinergic strength of atropine as 1, the anticholinergic strength of the following drugs is instructive: propranolol, 0.00; ranitidine, 0.22; digoxin, 0.25; theophylline, 0.44; prednisolone, 0.55; and cimetidine, 0.86! (Tune et al, 1992) Even warfarin has anticholinergic effects. Serum anticholinergic load in schizophrenia may cause cognitive dysfunction and diminish the effects of cognitive training efforts. (Vinogradov et al, 2009)

Autoreceptor: a specific receptor on NT-producing cell bodies or presynaptic terminals, stimulation of which inhibits NT release, e.g. D2 and 5-HT₁ autoreceptors. In the central noradrenergic system, α -2-adrenoceptors act as autoreceptors. Agonists acting on 5-HT_{1A} (somatodendritic) receptors in the raphe nuclei inhibit raphe neurone firing, but agonists acting on hippocampal 5-HT_{1A} (postsynaptic) receptors produce serotonin-like effects. A common functional variant (C[-1019]G) variant in the human 5-HT_{1A} gene (HTR1A) was shown to be associated with significantly decreased threat-related amygdala reactivity. (Fakra et al, 2009)

Bioavailability (F): That fraction of an administered drug that reaches the systemic circulation. In the case of oral drugs bioavailability is the fractional absorption of oral compared to intravenous drug. Sublingual absorption (e.g. oro-dispersible olanzapine or risperidone) is rapid because first-pass metabolism is avoided since the mouth drains into the superior vena cava and thus avoids the liver.

Dale's law: a defunct belief that neurones only use one transmitter at all its terminals. (see neuropeptides)

Desmopressin (DDAVP): an analogue of antidiuretic hormone; used orally or as a nasal spray to treat enuresis, with onset of action measured in several days. It may cause nasal dryness or irritation and headache. Side effects are uncommon if electrolyte regulation is normal. As with TCAs, few patients become completely dry, and relapse follows DDAVP discontinuation. Desmopressin has become popular because of the potential toxicity of TCAs.

Dichlorodiphenyltrichloroethane (DDT): use of this highly fat-soluble disinfectant is restricted nowadays because of potential toxicity including facial palsy, dizziness, tremor, delirium, convulsions and, with

⁶⁷⁷ The effects of cholecystokinin, glucagon, TRH, and somatostatin on appetite (inhibition) are probably mediated by the vagus nerve. Bombesin, a gastric peptide, inhibits feeding independent of the vagus nerve. Calcitonin and gastrin-releasing peptide also inhibit feeding.

chronic exposure, e.g. in malaria-control workers, poor neurobehavioural function.(van Wendel *de Joode* et al, 2001)

Down-regulation: ‘desensitisation’ of receptors; after prolonged stimulation by agonists the cell becomes refractory to further stimulation; various explanations include chemical changes and hiding receptors from ligands by withdrawing them into the cell. (Cf. up-regulation) β -arrestins interfere in G protein receptor interaction leading to desensitisation of G protein-mediated receptor signalling, and β -arrestin-1 levels are elevated in rat brain by antidepressant drugs.(Avissar et al, 2004)

Elimination half-life: the time required for the blood concentration of a drug to decline by 50% - largely determined by rates of hepatic metabolism and renal excretion.

Flavonoids: grapefruit juice contains members of this chemical family, e.g. naringin and quercetin. They inhibit P450-dependent hepatic isoenzymes (CYP1A2 and CYP3A3/4/5), therefore, for example, increasing peak plasma midazolam levels by 56%. Intravenous midazolam levels are not affected because the liver is bypassed. This phenomenon has implications for other drugs (BZDs, SSRIs, antihistamines, carbamazepine, calcium channel blockers, certain anti-arrhythmics, erythromycin⁶⁷⁸, ketoconazole, cyclosporine) and hormonal agents (cortisol, ethinylloestradiol, tamoxifen) that are partly or completely metabolised by such enzymes. CYP1A2 is induced by cigarette smoke, modafinil and char grilled meat whereas CYP3A4 is induced by St John’s Wort, barbiturates and carbamazepine.

Half-life of a drug: time required for its concentration to fall in plasma by 50%; the quicker is metabolism and elimination, the shorter the half-life.

Heteroreceptor: Some presynaptic receptors are specific for a neurotransmitter (NT) other than the nerve cell’s own NT, allowing for modulation of release of one NT by another, e.g. serotonin acting on presynaptic 5-HT_{2A} receptors can inhibit DA release.

Inverse agonist: has opposite effect on receptor to the pure agonist, e.g. beta-carbolines in the case of the BZD receptor.

Kinetics: the relationship between the dose of a drug and its serum levels. Zero-order kinetics is the exponential relationship between the dose of a drug and its serum levels, e.g. in the case of phenytoin: because enzymes responsible for its destruction and excretion are saturated at levels required for its therapeutic effects.

Ligand: compound that specifically binds to a receptor.

Narcotic: redundant term first describing sleep-inducing drugs and later meaning morphine-like analgesics.

Non-substrate inhibitors: analogues that bind to the substrate site on a transporter but are not translocated into the cell, e.g. β -threo-benzyloxy-aspartate in the case of excitatory amino acid transporters I and II.

Nooceptive (nootropic): drugs that improve cognitive and memory functioning.

Opiate: drugs from juice of the poppy *Papaver somniferum*. During opiate withdrawal noradrenergic neurones are activated with increased release of NA. Opiates are found in compounds like Solpadeine (paracetamol, codeine phosphate, caffeine) and Solpadol (paracetamol, codeine phosphate), which renders the liable to being abused. Codeine is converted to morphine in the body and co-administration of paroxetine may prevent this conversion with resultant reduction in analgesia.

Opioid: any substance with morphine-like actions; use is often confined to synthetic narcotics not derived from *Papaver somniferum*. Opioids can be divided into μ (Mu) opioid agonists such as morphine and methadone, and mixed agonist-antagonists like pentazocine. The latter can induce withdrawals in people taking the former. Also, pentazocine can cause a psychotic state, including hallucinations. Levomethadyl acetate (LAAM) is a long-acting opioid agonist. Buprenorphine is a partial agonist at μ opioid receptors.

P450 (CYP) enzymes: These cytochrome enzymes⁶⁷⁹ are a loose group of mixed-function oxidases found mainly in the liver, but also in bowel and brain. The 450 refers to the 450 nm wavelength of the red pigment in the enzyme-containing vesicles. Classification (families and subfamilies) is based on amino acid sequence and this determines affinity for substrates (e.g. for CYP2D6: CYP = P450; 2 = family; D = subfamily; 6 = specific gene). The following enzymes are of most relevance to psychiatry⁶⁸⁰:

⁶⁷⁸ P450 enzymes became very important after erythromycin inhibited enzymatic breakdown of the antihistamine astemizole, accumulation of the latter leading to arrhythmias.

⁶⁷⁹ Also called microsomal enzymes after tiny vesicles of endoplasmic reticulum origin that contain the enzymes.

⁶⁸⁰ Only examples of inhibitors and substrates given here – for updates see relevant websites, e.g. www.drug-interactions.com. Therapeutic and toxic effects are a result of free (not bound) drug levels. Adverse effects may therefore arise despite having drug levels in the ‘therapeutic range’. Drug-drug interactions may lead to side effects and may or may not increase total serum levels (TSL)

- **CYP1A2** (inhibitors such as cimetidine, fluvoxamine, ketoconazole, grapefruit juice; inducers such as cigarette smoking, omeprazole; substrates such as amitriptyline, olanzapine, methadone, propranolol)
- **CYP2C9/10** (inhibitors such as cimetidine, fluoxetine, fluvoxamine, modafinil; inducers like rifampin; substrates such as phenytoin, warfarin)
- **CYP2C19** (inhibitors such as fluoxetine, fluvoxamine; substrates such as barbiturates, diazepam, divalproex)
- **CYP2D6** (inhibitors such as bupropion, cimetidine, fluoxetine, paroxetine, sertraline, ritonavir, phenothiazine drugs, quinidine; substrates such as codeine, donepezil, lipophilic beta-blockers, TCAs, type IC antiarrhythmic agents, trazodone, venlafaxine, most antipsychotic drugs; inducers like dexamethasone)
- **CYP3A3/4/5** (inhibitors such as diltiazem, fluvoxamine, grapefruit juice, ketoconazole, macrolides, protease inhibitor drugs, verapamil; inducers such as carbamazepine, modafinil, phenobarbital, phenytoin, ritonavir, St John's Wort; substrates such as alprazolam, anovulant pill, buspirone, calcium channel blocking drugs, donepezil, ethosuximide, lamotrigine, midazolam, paracetamol, protease inhibitor drugs, quinidine, statins, steroid drugs, tamoxifen, triazolam)

Together, P4502D6 and 3A4 account for 90% of clinical drug biotransformation.(Leonard, 2003, p. 469) Different races vary in the efficiency with which these enzymes metabolise drugs. For example, risperidone is metabolised by CYP2D6 and 5-10% of Caucasians and 2% of African Americans are slow metabolizers of risperidone. A number of mutations (genetic polymorphism due to alterations in genetic sequence) of the gene for CYP2D6 have been discovered. Such variations in enzymes may lead to inactive forms or failure to activate prodrugs (e.g. codeine conversion to morphine by CYP2D6).

According to a 'preliminary report on a pilot study', moving from Asia to Europe may slow the rate of metabolism of CYP1A2 substrates like clomipramine because of dietary changes.(Allen ea, 1977)

Partial agonist: defined either as (a) a drug that acts as an agonist at low concentrations but as an antagonist at higher concentrations, or (b) a drug whose intrinsic activity is somewhere between a full agonist and an antagonist; a partial agonist reduces the effect of a full agonist, although the former has the same qualitative action as the full agonist.

Pharmacodynamics: the mechanism of action of drugs, or what drugs do to the body, e.g. blocking receptors.

Pharmacogenetics: Also called pharmacogenomics, this discipline examines the influence of genetic variation on the success or failure of a drug treatment. The hope is to predict all drug effects.(Collier, 2002; Shurin & Nabel, 2008) For example, clozapine affects many receptors and differences (polymorphisms) in several of the genes encoding these receptors may exert effects on response to clozapine.(Arranz ea, 2000) However, failure to correct for multiple testing and failure of others to replicate these findings leaves such interesting potential leads without support. Some workers failed to find any association between serotonin receptor genes and treatment response.(e.g. Tsai ea, 2000) Barnes ea (2003, p. 496) suggested that 'the receptor affinities of [atypical antipsychotics] appear to concur closer to side-effects than response profile'. Sensitivity to side-effects of paroxetine seems to correlate with a variant of the 5-HT_{2A} receptor, i.e. HTR2A C/C genotype.(Murphy ea, 2003a) Response to mirtazapine among depressed elderly may be predicted by the APOE4 allele.(Murphy ea, 2003b) Patients in Taiwan with the short-form polymorphism of the MAO-A gene promoter had a greater response to mirtazapine than did those with long-form polymorphism.(Tzeng ea, 2009) A mutation involving CYP2D6 may be associated with adverse reactions to tricyclic antidepressants; a similar relationship exists between HLA-B*1502 and carbamazepine.(Ingelman-Sundberg, 2008) A meta-analysis conducted by Kato and Serretti (2008) found that TPH1 218C/C genotype was associated with improved antidepressant response as was the Met variant within the BDNF 66Val/Met polymorphism; a trend toward better antidepressant response in Asians was associated with variable number of tandem repeats polymorphism within intron 2 (STin2) 12/12 genotype; and 5-HTTLPR I and HTR2A-1438G/G modulated risk of side-effects of antidepressants, especially when SSRIs were employed. Other work (Licinio ea, 2009) suggests that the rs61888800 SNP region of the BDNF gene may be associated with antidepressant response in major depression. A region (rs10795189) on

of a drug. One drug may displace another, protein-bound drug. Most free drug levels represent 10% or less of TSL in serum, so that large displacement of bound drug may only slightly alter TSL. Lithium toxicity may follow addition of an NSAID or a thiazide diuretic.

chromosome 10p15 may influence the prophylactic action of lithium in bipolar disorder.(Perlis et al, 2009) Ising et al (2009), in a genomewide association study, found that multiple genetic factors combined with clinical features in predicting antidepressant drug treatment response. Another genomewide association study (Uher et al, 2010) found single-nucleotide polymorphisms in two intergenic regions containing copy number variants on chromosomes 1 and 10 that seem to be important in clinical response to escitalopram and nortriptyline.

The allele sequence associated with normal (i.e. 'extensive') enzyme function is coded by the wild-type gene and this is given the suffix '*1'. Following this, different genetic sequence polymorphisms are numbered in sequence: *2, *3. Multiple copies of a functional CYP enzyme can be found that leads to excess enzyme activity or there may be inactivating polymorphisms that decrease or nullify enzyme activity.

Drug metabolism CYP phenotypes are rather confusingly classified as:

Poor – absent active enzyme gene allele (AEGA); reduced metabolism is associated with increased medication levels and more side-effects at standard doses

Intermediate – 1 active and 1 inactive allele or 2 alleles with diminished activity

Extensive (normal) – possess the normal 2 copies of fully AEGAs for a given microsomal enzyme; associated with predictable response to usual doses of medication

Ultrarapid - multiple copies of AEGAs; increased metabolism leads to sub-therapeutic serum levels of medication

Variation between ethnic groups in allele frequencies is important, e.g. 4-10% and 1-3% of Caucasians and Black Americans and Chinese have no CYP2D6 enzyme. The tiny number of patients that lack AEGAs for both CYP2D6 and CYP2C19 will experience side-effects with most antidepressants and should probably be tried on drugs that are not substrates for CYP2D6 or CYP2C19 (e.g. mirtazapine and bupropion).(de Leon et al, 2006)

'Theranostics' (therapeutics-[diag-]nostics) refers to the development of ways of matching people to optimal drug treatments; immunoassay techniques have been developed to predict which hepatitis C virus genotype are more or less resistant to treatment; its application to psychiatry is in its infancy.

Pharmacokinetics: the drugs passage through the body, i.e. what the body does to a drug: absorption, distribution⁶⁸¹, metabolism, excretion.(Ashton & Harrison, 1994) Fractional absorption (the completeness of absorption) is measured as the 'area under the curve' or AUC when concentration in plasma is plotted against time. Oral drugs are mainly absorbed through the wall of stomach and small intestine. Absorption depends on drug ionization state which is in turn is dependent on pH. Psychotropics are highly ionized due to gastric acidity and so their movement across lipid cell membranes is blocked; they are therefore mostly absorbed via the small intestine. Some drugs are excreted with bile and reabsorbed in the distal small intestine (entero-hepatic circulation). Anticholinergic drugs may delay absorption of other drugs with the result that co-administered medication reaches higher concentrations in plasma. This matters little when drugs are administered over a prolonged period since a drug's steady state⁶⁸² is mainly dependent on metabolism (rather than absorption). *Clearance* (CL) is the rate of drug elimination (in litres/hour) = product of K_e (elimination rate constant) and volume of distribution (V_d , see elsewhere in text), i.e. $CL = K_e V_d$; if clearance remains constant the rate at which the body removes a drug is a function of the concentration of the drug.

Protein binding: The percentage of a drug bound to plasma proteins. Competition for binding sites are particularly important when the patient is taking warfarin or digoxin. The majority of psychotropic drugs are basic and bind mainly to albumin⁶⁸³. Most psychotropic drugs are highly protein bound and can displace warfarin⁶⁸⁴ or digoxin with potential complications.

⁶⁸¹ **Distribution of a drug**: When a drug reaches the systemic circulation it equilibrates between the blood compartment and the tissues, i.e. it distributes. Factors affecting distribution include the percentage of drug bound to plasma proteins and the tissues, solubility in lipid and water, size of the molecule, and pH partition. See *apparent volume of distribution* in main text. The use of the word 'apparent' here is because some drugs may have huge distribution values (e.g. hundreds of litres!).

⁶⁸² **Steady state**: when a drug is given a number of times (multiple dosing) the absorbed drug is added to that already in the system and plasma levels rise until a steady state occurs, i.e. when the availability of the drug is the same as the removal rate of the drug. This usually occurs after 4 to 5 drug half-lives. Apart from obvious allergy or overdose, the practitioner is generally in a position to consider tolerability (and to a lesser extent efficacy) when steady state is reached.

⁶⁸³ Acid drugs bind to α_1 -glycoprotein.

⁶⁸⁴ In a patient on warfarin, check the INR a few days after starting/stopping other drugs.

Psychodysleptic: any drug producing abnormal mental phenomena, especially cognitive and perceptual.
Regulation of receptors: the number of receptors, which are constantly being degraded, results from a balance between transcription of receptor RNA, leading to increased numbers, and receptor degradation. Receptors can be pulled inside the cell, as with G-protein-coupled receptors, following activation by NT, leading to down regulated by virtue of less receptor being available for further stimulation. Depending on the receptor, phosphorylation of certain amino acid residues by a kinase may increase or decrease receptor function. (Hamblin, 1997)

Steady-state equilibrium (steady-state): where amount of drug eliminated between doses equals the dose itself – reached after about 4-5 half-lives; the serum level reaches a steady plateau. This is discussed further in a footnote. When taking samples for plasma levels one should note how long it was since the last dose since apparent non-compliance (e.g. no drug detected) may be because of differing sampling times.

Tachyphylaxis: (a) rapid onset of tolerance to a drug, e.g. tolerance to sedation with BZDs can occur even as their plasma levels are rising; (b) loss of drug efficacy during long-term treatment; and (c) loss of drug efficacy after repeated drug exposures over time (e.g. Amsterdam et al [2009] found evidence for the third possibility with antidepressants in adults with bipolar II disorder with major depression).

Tricyclic: contains 3 rings in its structure. Examples are TCAs, cyproheptadine (Periactin, an appetite stimulant), and carbamazepine (anticonvulsant, mood stabiliser, and treatment for neuralgia).

Up-regulation: 'hypersensitivity' of receptors; often follows prolonged receptor blockade; possibly involves increased receptor synthesis.

V_{max}: maximum transport rate across membranes, as with 5-HT.

Volume of distribution: ratio between amount of drug in body and plasma concentration. *Apparent volume of distribution* or V_d = extent to which the drug equilibrates outside the blood compartment: small and large volumes indicate that the drug is mainly retained within the blood compartment or that a significant part is in the tissues respectively. Most psychoactive agents are very soluble in lipid and big volumes of distribution. Of course, lipid solubility is needed if the drug is to pass the blood-brain barrier. In this regard, it is important to note that there are no openings (fenestrations) between the endothelial cells of capillaries in the brain. A drug must therefore pass through the cell in order to access the brain.

Acetylcholine (ACh)

Acetylcholine is a quaternary amine. Acetyl coenzyme A (derived from glucose in neuronal mitochondria) plus choline (from the liver) in the presence of choline acetyltransferase (CAT) form ACh and a coenzyme. Giving choline because the enzyme is not fully saturated increases ACh synthesis. ACh can be hydrolysed by acetylcholinesterase or released into the synapse to act on its receptors. There are 2 main types of ACh receptor, nicotinic and muscarinic. Most of the brain's cholinergic receptors are muscarinic, and there are at least 5 subtypes, M1-M5. They are linked to G-proteins and a variety of second messengers.⁶⁸⁵ The cholinergic nicotinic receptor⁶⁸⁶ is a ligand-gated ion channel composed of 5 subunits which are encoded by different genes. The $\alpha 7$ -nicotinic receptor gene may be involved in the auditory sensory gating defect reported in schizophrenics. (Freedman et al, 1997)

Nucleus basalis of Meynert

⁶⁸⁵ Muscarinic receptors display the structural characteristics of 7 transmembrane proteins. M1 to M3 stimulate the hydrolysis of phosphoinositol and lead to increased intracellular calcium together with cAMP. M4 to M5 inhibit adenylyl cyclase. M1 receptors have a high affinity for the anti-muscarinic agent pirenzepine, while M2 receptors have a low affinity for this agent.

⁶⁸⁶ α [$\alpha 2-9$] and β [$\beta 2-4$] families.

In Alzheimer's disease, the cholinergic cell bodies in the basal forebrain nuclei (nucleus basalis of Meynert⁶⁸⁷ or nucleus gigantocellularis, septum, nuclei of diagonal band), that innervate the whole cortex, degenerate, a fact that is reflected in loss of cortical CAT and Ach. The balance between Ach and other transmitters in the striatum, such as dopamine, appears to be critical in both Parkinson's and Huntington's diseases in which anticholinergic drugs respectively improve and worsen the movement disorder. (Albin et al, 1989) CAT activity is unaffected in both Pick's disease and dementia of the frontal lobe type. (Procter, 1997)

The cholinergic system, which is very important for memory functions, originates in Meynert's nucleus (see above), the diagonal band of Broca, and the septal nucleus⁶⁸⁸. Meynert's nucleus projects throughout the cortex and to the hippocampus and amygdala, whereas the latter two centres project to the cingulate gyrus and the hippocampus. A third group of neurones provides local circuits to the basal ganglia.

There are 2 types of cholinesterase: acetylcholinesterase⁶⁸⁹ and pseudo-, butyl- or non-specific cholinesterase⁶⁹⁰. Outside the nervous system the 2 types are distributed differently.

Physostigmine⁶⁹¹, neostigmine and edrophonium inhibit acetylcholinesterase. Physostigmine, normally given intravenously for TCA (anticholinergic) poisoning has a very short duration of action, although an oral sustained-release preparation is being tested clinically. Physostigmine can cause nausea and vomiting. Another agent which has become available is galantamine (Reminyl), a component of snowdrops and daffodils, which is both a cholinesterase inhibitor and nicotine agonist, the latter action leading to Ach release.

Donepezil reversibly inhibits acetylcholinesterase but not pseudocholinesterase. Tacrine (Cognex), which is hepatotoxic, reversibly inhibits both types of cholinesterase; it also inhibits CYP450 1A2 and therefore tacrine levels are increased by co-administered cimetidine. Rivastigmine (Exelon) inhibits acetylcholinesterase only, but itself reverses this action over some hours, so-called pseudoreversibility.

Metrifonate, an antischistosomal agent, does not inhibit cholinesterase until metabolised to the organophosphate 2,2-dichlorovinyl dimethyl phosphate (DDVP), an irreversible inhibitor of both species of cholinesterase that has been associated with muscle weakness.

Botulinum toxin inhibits, and Black Widow spider venom facilitates, the release of Ach from the presynaptic neurone. Ach acts on nicotinic and muscarinic receptors. Nicotine acts agonistically, and d-tubocurarine, succinylcholine, decamethonium, hexamethonium, fuxamethonium and gallamine act antagonistically at cholinergic nicotinic receptors, while muscarinic receptors have their own agonists⁶⁹² and antagonists⁶⁹³. Muscarine and nicotine are mushroom and tobacco alkaloids respectively. Drugs like succinylcholine and decamethonium do not compete with Ach for the receptor site, instead causing prolonged depolarisation of the receptor rendering it insensitive to Ach. Low dose Ach is excitatory at nicotinic receptors in low doses, whereas in high doses it causes blockade by depolarisation; it is inhibitory at muscarinic receptors. Similarly, low doses of nicotine produce stimulation in the periphery, whilst high doses block nicotinic receptors with paralysis of the neuromuscular junction.

The effects of Ach on the peripheral autonomic system are muscarinic, whilst those on autonomic ganglia and the neuromuscular junction are nicotinic.

Cholinergic drugs or poisons, such as physostigmine and organophosphate fertilisers, can acutely cause a depressed, listless, fatigued, irritable state, with later seizures, myoclonus, and delirium.

Anticholinesterases such as physostigmine inhibit acetylcholinesterase, with accumulation of Ach at cholinergic synapses. Physostigmine does not reverse the cardiotoxic effects of TCAs but intravenous physostigmine may reverse transient psychosis secondary to antimuscarinic drugs.

Benztropine⁶⁹⁴, and to a lesser extent benzhexol⁶⁹⁵ and orphenadrine⁶⁹⁶, inhibit DA uptake as well as blocking cholinergic receptors.

⁶⁸⁷ Degeneration of the nucleus basalis of Meynert, a major source of cholinergic innervation (and efferents to the suprachiasmatic nucleus), could underlie sleep problems in dementia. (Klaffke & Staedt, 2006)

⁶⁸⁸ The **cholinergic basal forebrain** consists of the nucleus basalis of Meynert, the diagonal band of Broca, and the medial septum.

⁶⁸⁹ Mainly found in neurones in the brain and is the main enzyme for destroying Ach at cholinergic synapses.

⁶⁹⁰ Found mainly in glial cells in the brain, and it destroys Ach that diffuses to these cells.

⁶⁹¹ Physostigmine is found in Calabar bean (*Physostigma venenosum*).

⁶⁹² Muscarine, carbachol, pilocarpine, methacholine.

⁶⁹³ Atropine, bethtropine, procyclidine, hyoscine.

⁶⁹⁴ Not available from 2003.

⁶⁹⁵ Unavailable from 2002.

It has been suggested that, unlike atypical antipsychotics, typical antipsychotics do not release Ach in the medial prefrontal cortex and that this may account for adverse cognitive side-effects.(Meltzer, 2003)

*Catecholamines*⁶⁹⁷

Most noradrenergic cell bodies, which innervate the complete cortex, are found in the locus coeruleus, a dorsal pontine nucleus beside the fourth ventricle. Yohimbine, central α -2 adrenergic antagonist, increases locus coeruleus firing and hence noradrenaline release, causing anxiety in humans; the α -2 agonist clonidine reduces locus coeruleus firing, and has a modest anxiolytic effect.

Synthesis of catecholamines involves conversion of phenylalanine to tyrosine, which is converted to DOPA and this is changed to dopamine (DA); the latter can be converted to noradrenaline (NA; norepinephrine), from which adrenaline (epinephrine) is derived. NA can be broken down to (a) normetanephrine and then to 3, hydroxy 4 methoxy mandelic acid, or (b) 3,4-dihydroxy mandelic acid, or 3,4-dihydroxy phenyl glycol, the latter being degraded in turn to 3-hydroxy 4 methoxy phenyl glycol. The rate-limiting step in catecholamine synthesis is the conversion of tyrosine to DOPA by tyrosine hydroxylase. NA synthesis is blocked by α -methyl-para-tyrosine (AMPT) which inhibits tyrosine hydroxylase.

DA, in contrast to l-DOPA (levodopa), does not cross the blood-brain barrier. Clinically, l-DOPA is given with a peripherally acting inhibitor of DOPA decarboxylase such as carbidopa (in Sinemet) or benserazide (in Madopar). This ensures efficient delivery of l-DOPA into the CNS⁶⁹⁸. Once in the CNS, l-DOPA is converted to DA by l-amino acid decarboxylase.

All DA receptors, currently D1-5, are linked to G proteins. All 5 receptor subtypes are found postsynaptically, while D2 and D3 are also found presynaptically. D2 exists as two isoforms: D_{2short} and D_{2long}. D1 (dopamine 1) is linked to cyclic AMP (cAMP) and D2 is not linked to cAMP. The details of the distribution of their mRNAs can be summarised thus: D1 (caudate, putamen, olfactory tubercles, nucleus accumbens, amygdala, cortex), D2 (mainly basal ganglia), D3 (mainly limbic), D4 (mainly cortical fields), and D5 (parafascicular nucleus of thalamus, hippocampus, dentate nucleus, many cortical fields).(Mansour ea, 1998) D2 blockade seems to be responsible for antipsychotic effects. D2 antagonism from the strongest to the weakest can be illustrated as follows: haloperidol > risperidone > perphenazine > chlorpromazine > clozapine. Risperidone is strongly antagonistic at D2 receptors, antagonistic at 5-HT₂ receptors, and, in nanomolar doses, it has affinity for α -2 receptors. The benzamides sulpiride and remoxipride are specific D2 antagonists, while another benzamide, amisulpride (Solian) is highly selective for D2 and D3 receptors. The dibenzothiazepine quetiapine (Seroquel) has a greater affinity for 5-HT₂ receptors than for D2 receptors.

Remoxipride, in fact, has high selectivity and low affinity for D2 receptors. Ziprasidone acts on D1, D2, and D3, 5-HT_{2A}, 5-HT_{2C}, and 5-HT_{1D} receptors. However, its development was slowed by cardiac suppression (prolonged QT interval) with the risk of tachyarrhythmias.(Baldessarini, 1999)

Clozapine has low D2 affinity, equal affinity for D1 and D2, and high D4 affinity; low D2 and high D4 affinities may relate to enhanced efficacy in schizophrenia. It also blocks 5-HT₂ receptors and has high affinity for 5-HT₆ and 5-HT₇. Clozapine has relatively strong affinities for α -1 (postsynaptic) and α -2 receptors. Clozapine's affinity for D4 receptors is not unique among antipsychotic drugs. D3 receptors are expressed in the limbic system and have a possible role in schizophrenia. D3, D4, and D5 receptors are found in limbic and frontal areas. D3 and D4 receptors are subtypes of D2, and D5, which is found in the hippocampus, is a subtype of D1. DA is degraded to dihydroxy phenyl acetic acid and thence to homovanillic acid (HVA). During pregnancy oestrogen levels are raised, and they may have an antipsychotic action via DA receptors, with up-regulation of receptor numbers. After delivery, the fall in oestrogen levels leaves the receptors exposed.

Antipsychotic drugs acutely increase the dopaminergic neuronal firing rate, only later increasing DA metabolite levels. Very low doses appear to block autoreceptors selectively, leading to increased DA concentrations in the absence of postsynaptic blockade.(Wilcox ea, 1998)

⁶⁹⁶ Withdrawn, 1999.

⁶⁹⁷ In 1921, Cannon and Uridil used the name 'sympathin' for the substance released when sympathetic nerves were stimulated; this was later identified as noradrenaline by von Euler and shown to be present in brain by Holtz. Dopamine was discovered as a brain neurotransmitter by Arvid Carlsson in the late 1950s. Carlsson (Nobel Prize, 2000) suggested dopamine blockade as the mechanism of action of antipsychotic drugs.

⁶⁹⁸ It prevents levodopa metabolism in the GIT, diminishes GIT upset, and gives higher blood levels with smaller doses.

Chronic blockade of nigrostriatal D2 receptors by drugs may lead to upregulation of these receptors (increased sensitivity and/or numbers) in an attempt to overcome the blockade⁶⁹⁹. This is the 'dopamine supersensitivity' theory of tardive dyskinesia. The same theory has been used to explain schizophrenia itself.(McKenna, 2007, p. 149) A different theory for tardive dyskinesia implicates GABA deficiency, and is based on such findings as low CSF GABA levels in dyskinetic cases of schizophrenia.(Thaker ea, 1987) D2 occupancy can be measured using ¹¹C-raclopride as a ligand for PET and ¹²³I-iodobenzamide as ligand for SPECT. Typical antipsychotic drugs such as haloperidol bind tightly to D2 receptors and dissociate slowly, whereas clozapine (and quetiapine) binds loosely and dissociates rapidly; clozapine's occupancy of D2 receptors is transient. At doses of 5-20 mgs/day, olanzapine shows greater 5-HT₂ than D2 blockade, but at bigger doses 5-HT₂ occupancy approaches saturation and D2 occupancy still increases. The latter phenomenon parallels the increased likelihood of experiencing extrapyramidal side effects (EPS). Similar dose-related events have been demonstrated for risperidone. However, unlike clozapine and quetiapine, risperidone binds tightly to D2 receptors.(Kapur & Seeman, 2000)

Noradrenergic receptors are divided into α (alpha)⁷⁰⁰ and beta (β) subtypes. Alpha-1 and beta receptors are chiefly postsynaptic. Alpha-2 receptors are both pre- and post-synaptic. Beta (β) receptors are divided into β_1 , β_2 , and β_3 . All are linked to adenylate cyclase but sensitive to different antagonists. Beta-1 receptors are found in the heart where they are targeted by beta-blockers. Beta-2 receptors are found in lung⁷⁰¹, uterus and voluntary muscle. Beta-3 receptors are chiefly associated with adipose tissue where they are involved in energy metabolism and thermogenesis from fat, especially in response to NA. Sibutramine increases NA peripherally at beta-3 receptors, causing weight loss by heat production and increased consumption of oxygen.

NA is released by amphetamine, and phenylephrine acts as a noradrenergic receptor agonist. Clonidine, which has been known to cause depression, is a alpha-2-agonist, isoprenaline is a beta-agonist, and phentolamine and phenoxybenzamine are alpha-antagonists. Clonidine reduces anxiety levels by blocking presynaptic alpha-2-receptors, thereby producing downregulation. Beta-antagonists include propranolol, pindolol, and acebutalol.

Amitriptyline inhibits NA reuptake into the presynaptic neurone, whereas the MAOIs, phenelzine and tranylcypromine, inhibit degradation of NA by monoamine oxidase (MAO⁷⁰²). Venlafaxine (Efexor) is a serotonin and noradrenaline reuptake inhibitor or SNRI. Catecholamine reuptake inhibition may require higher doses of venlafaxine than those needed for 5-HT reuptake inhibition. Milnacipran (Ixel), a cyclopropane derivative, is another SNRI, although it is more potent for NA than for 5-HT. Duloxetine is a dual uptake inhibitor that is claimed to block NTs at starting and therapeutic doses. Amphetamine and amantidine facilitate DA release. Apomorphine act as an agonist at DA receptors, while the antipsychotic drugs haloperidol and chlorpromazine are classical examples of DA receptor antagonists. Nomifensine inhibits DA reuptake, and the MAOI (actually MAO-B inhibitor at low doses, e.g. 10 mg/day) L-deprenyl (selegiline) inhibits dopamine degradation by MAO. L-deprenyl, which is metabolised to methamphetamine and amphetamine, has antidepressant activity in high dosage (c 30 mg/day) and it may require the same dietary restrictions as classic MAOIs at such doses.

Bromocriptine (Parlodel) is an ergot alkaloid and mixed DA agonist-antagonist. At low doses it is an agonist at presynaptic D2 receptors, reducing DA release. At higher doses it has a direct agonist action on postsynaptic DA receptors. Its main uses are for Parkinson's disease, for antipsychotic-induced hyperprolactinaemia and galactorrhoea, and in neuroleptic malignant syndrome. Other claimed applications include alcohol or cocaine withdrawal amelioration, depression, drug-induced Parkinsonism, tardive dyskinesia, and anxiety disorders, including OCD. Side effects include nausea, headache, dizziness, vomiting, abdominal cramps, constipation, syncope, cardiac arrhythmias, worsening of angina, and, rarely, psychosis. Caution is necessary in the presence of hypertension and hepatic or cardiovascular disease. It should be avoided in pregnant or nursing mothers, and the contraceptive pill may interfere with its activity. The D2 agonist cabergoline (Cabaser, Dostinex) is related to bromocriptine.

⁶⁹⁹ By analogy with denervation sensitivity when ACh motor end plate receptors multiply following neuro-muscular disruption.

⁷⁰⁰ 1a-c and 2a-c.

⁷⁰¹ Target of bronchodilators.

⁷⁰² E. A. Zeller (1907-87) of Basel separated MAO from diamine oxidase in 1938; in 1952, in the US, he discovered that iproniazid inhibited MAO. MAO is found on the outer mitochondrial membrane.

Dopamine prevents prolactin secretion by pituitary lactotrophs. (McCollam & O'Shea, 2004) TRH, as well as causing TSH secretion, stimulates prolactin release: with reduced T4 one sees increased prolactin because of increased TRH. Drugs inhibiting DA secretion (methyldopa, reserpine, opiates, H2-receptor blockers) or inhibit DA action (neuroleptics, metoclopramide [a benzamide used as an antiemetic]) can cause hyperprolactinaemia. Oestrogens, including the contraceptive pill, cause lactotroph excess, and hence hyperprolactinaemia. Possession of the DRD2AI allele may lead to higher prolactin levels in patients exposed to antipsychotic drugs. (Young et al., 2004) The end result of hyperprolactinaemia is gynaecomastia in males and galactorrhoea and amenorrhoea in females. Pharmacological causes of gynaecomastia include alcohol, cannabis, cyproterone acetate, digitalis, oestrogen ingestion, and spironolactone.

After arising in cell bodies in the brainstem locus coeruleus, noradrenergic fibres project diffusely throughout the whole brain, including cortex, limbic lobe, brainstem, cerebellum and cord.

Dopaminergic cell bodies of the brainstem substantia nigra⁷⁰³ project to the caudate nucleus to synapse with cholinergic neurones that project to the putamen. Thence, GABAergic neurones descend to synapse with the dopaminergic cell bodies in substantia nigra. In other words, nigrostriatal DA axons connect with cholinergic caudate interneurons, and a striato-nigral feedback loop is set up that also involves GABAergic neurones.

There are, in fact, 4 main dopaminergic pathways in the brain. The *nigrostriatal pathway*, mentioned above, is part of the extrapyramidal system, and is therefore involved in movement control; as already stated, fibres project from the **substantia nigra** to the basal ganglia⁷⁰⁴ (corpus striatum – production of smooth/coordinated movement). The *mesolimbic pathway* arises in the ventral tegmental area (**VTA**) of the midbrain and projects fibres to limbic areas such as the nucleus accumbens (Cocaine blocks DA reuptake into presynaptic dopaminergic terminals, greatly elevating extracellular DA levels in the nucleus accumbens⁷⁰⁵, thereby activating the physiological 'reward system'). This pathway appears to be important for the experience of pleasure, the euphoric effects of drugs, and probably also for the positive symptoms of psychoses, such as delusions and hallucinations. The *mesocortical pathway*, also arising in the **VTA** but projecting mainly to limbic cortex, may play a role in the generation of the negative and cognitive symptoms of schizophrenia. One theory is that such clinical deficits are due to a primary DA deficiency in the prefrontal cortex (PFC). However, other possibilities are neuroleptic-induced D2 blockade and blockade of 5-HT_{2A} receptors by excess 5-HT (stimulation of rat brain 5-HT_{2A} receptors increase synthesis and release of DA and antagonists at this receptor decrease the stimulant effects of amphetamine; phencyclidine-induced decrease in the activity of rat frontal cortical dopaminergic terminals is reversed by antagonists at the 5-HT₂ receptor). Finally, the *tuberoinfundibular pathway* projects from the **arcuate nucleus** of the hypothalamus to the anterior pituitary, and controls prolactin release⁷⁰⁶.

In Alzheimer's disease, the cells of the locus coeruleus degenerate, with a reduction in concentrations of dopamine-β-hydroxylase. The restricted distribution of DA in the brain compared to other transmitter systems may explain why transmitter treatment has been more successful in Parkinson's disease than in other disorders. (Perry, 1991)

⁷⁰³ **Neuromelanin**, a product of catecholamine oxidation, is the dark pigment present in pigment bearing neurons of four deep brain nuclei: the substantia nigra pars compacta part, the locus coeruleus ("blue spot"), the dorsal motor nucleus of the vagus nerve, and the median raphe nucleus in the pons. In the human these nuclei are not pigmented at birth but become so during maturation.

⁷⁰⁴ Disease of the basal ganglia affects self-initiated actions more than actions cued by the environment.

⁷⁰⁵ 'Nucleus that lies beside'; the ventral striatum. (See e.g. Fladung et al. [2010] in relation to anorexia nervosa.) The nucleus accumbens lies below the ventral border of the internal capsule and merges with the caudate nucleus and putamen in humans.

⁷⁰⁶ The infundibulum, or median eminence, gives rise to the pituitary stalk at the base of the hypothalamus, i.e. in the floor of the third ventricle.

Substantia nigra

Many drugs and toxins are capable of causing *Parkinsonism*, e.g. alcohol withdrawal, alpha-methyl dopa, antipsychotic drugs, reserpine, carbon monoxide, cyanide, cytosine arabinoside, diazepam (in big doses), lithium, manganese, MAOIs, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine⁷⁰⁷, metoclopramide, organophosphates, reserpine, SSRIs, kava, captopril, cinnarizine, flunarizine, sodium valproate, phenytoin, and tetrabenazine. The list of disorders causing Parkinsonism is also lengthy, e.g. vascular disorders, degenerative disorders (e.g. progressive supranuclear palsy), infections (e.g. neurosyphilis), metabolic conditions (e.g. hypothyroidism), and other disorders (e.g. cerebral tumours and subdural haematoma).

*5-hydroxytryptamine (5-HT; serotonin)*⁷⁰⁸

5-HT, an indoleamine⁷⁰⁹ and phylogenetically the oldest of the neurotransmitters, is synthesised in the raphe nuclei. Tryptophan may be converted to indoleacetate via tryptamine and indoleacetaldehyde, or through 5-hydroxytryptophan to 5-HT⁷¹⁰, an indoleamine, and then to 5-hydroxy-indole acetaldehyde and 5-hydroxy-indoleacetate. The availability of tryptophan is probably the rate limiting function in 5-HT synthesis, rather than the enzyme tryptophan hydroxylase, which converts tryptophan to 5-hydroxytryptophan, although not all authors agree. (Mansour et al, 1998) Tryptophan hydroxylase is inhibited by para-chlorophenylalanine. L-tryptophan induces the hepatic enzyme tryptophan pyrrolase. The latter can be occupied by adding nicotinamide 1 gram daily.

There are an increasing number of classes of 5-HT receptor, especially 5-HT₁₋₇, 5-HT₁ being further subdivided into 5-HT_{1A-D}. However, the number of 5-HT receptors is expanding rapidly (at least 15 in 2007) and all such statements rapidly become dated. 5-HT₁, 1D, 2, 3, 6 and 7 may be particularly relevant in schizophrenia.

5-HT_{1A} receptors include autoreceptors that inhibit serotonergic cell firing, and postsynaptic receptors. Agonists include buspirone, a partial agonist at 5-HT_{1A} receptors pre- and postsynaptically. 5-HT_{1C} receptors are found mainly in the choroid plexus, and affect mood and appetite. To make life more complicated, 5-HT_{1C} is now thought to be the same receptor as 5-HT₂ (Musselman et al, 1998) and 5-HT₂ receptors are divided into A, B, and C subtypes. LSD activates 5-HT₂ receptors whilst a number of 'atypical' antipsychotic drugs inhibit these receptors. 5-HT_{1D} receptors are found on intracranial blood vessels, and cause vasoconstriction. LSD acts on serotonergic receptors. 5-HT is released by d-fenfluramine (causing prolactin release - halogen-containing amphetamine analogues like fenfluramine are more powerful at causing 5-HT release than are those lacking such atoms), reserpine, and tetrabenazine. LSD, mescaline, and methyltryptamine are agonists at dopamine receptors. Methysergide, cinnanserine, cyproheptadine, and metorgolide act as antagonists at that receptor. Clomipramine (chlorimipramine), nortriptyline, and fluoxetine act as serotonin reuptake blockers. MDMA ('ecstasy') blocks 5-HT uptake and induces its release from neurones, and clorgyline and tranylcypromine effect inhibition of 5-HT metabolism by MAOI.

Clomipramine inhibits 5-HT reuptake without inhibiting NA reuptake. However, its metabolite desmethylclomipramine is a strong NA reuptake inhibitor. The first really specific serotonin reuptake

⁷⁰⁷ MPTP, a toxic metabolite formed during synthesis of pethidine.

⁷⁰⁸ Brodie discovered a vasoconstrictor in the serum in 1900; Rapaport named it serotonin in 1948 and identified it as 5-HT; and 'enteramine', found in gut enterochromaffin cells, was shown to be 5-HT by Erspamer. Hamlin and Fisher synthesised 5-HT in 1951. Its presence in the brain was demonstrated by Twarog and Page. Perhaps reflecting its long history in evolutionary terms, 5-HT is involved in many different emotions and behaviours, a fact that may help to explain the broad range of applications for serotonergic antidepressant drugs. (Stein, 2003, p. 58)

⁷⁰⁹ Melatonin is also an indoleamine.

⁷¹⁰ The latter step being catalysed by aromatic amino acid decarboxylase.

inhibitor (SSRI) was zimeldine (Zelmid, now withdrawn from the market because of neurological sequelae).

The most selective SSRI is citalopram, but paroxetine is the most potent SSRI. Therefore, selectivity does not correlate with potency, citalopram being only one-tenth as potent as paroxetine in terms of serotonin transport blockade.

Ritanserin, a selective '5-HT₂ and 5-HT_{1C}' (but see above) antagonist, reduces the severity of negative symptoms in schizophrenia.(Duinkerke *et al*, 1993) Lithium might augment TCAs by sensitising postsynaptic 5-HT receptors. Tianeptine is an unusual tricyclic antidepressant that **increases** presynaptic 5-HT uptake.(Curzon & Widlöcher, 1992) However, tianeptine performed poorly in comparison to fluoxetine in one French primary care study of elderly depressives.(Guelfi *et al*, 1999)

The raphe nuclei are found in the region of the midbrain aqueduct and, like the noradrenergic system, they project widely. Areas innervated include all neocortical areas, temporal lobe, midbrain, hypothalamus, brainstem, cerebellum, and cord.

The therapeutic action of antidepressant drugs may ultimately depend on down regulation of postsynaptic adrenergic beta-1 receptors, or possibly of postsynaptic 5-HT₂ receptors as well.(*vide infra*) Nefazodone⁷¹¹, a relative of trazodone, blocks 5-HT₂ receptors and inhibits serotonin reuptake; 5-HT₂ receptors are downregulated with chronic nefazodone dosing. Increased beta and 5-HT₂ receptor density have been reported in the brains of suicides at post-mortem.(Kendell, 1993)

Weight gain due to psychotropic drugs may relate to antihistaminic and 5-HT_{2C} antagonism.

The 5-HT₃ antagonists ondansetron and granisetron are antiemetics, being employed to counter the side effects of cancer chemotherapy, whereas the SSRI sumatriptan (Imgran) is used to treat migraine.

Olanzapine has a relatively high affinity for 5-HT₆ receptors and risperidone for 5-HT₇ receptors.(Roth *et al*, 1994)

In Alzheimer's disease, the cell bodies of the raphe nuclei degenerate with an accompanying decrease in 5-HT concentration throughout the cortex.

Regulation of serotonergic neurone

Some of the contents of this section will be a repeat of what has been written already. The surface of the cell body and dendrites of the 5-HT neurone have 5-HT_{1A} receptors that are somatodendritic autoreceptors. When serotonin acts here there is shutdown of outflow of 5-HT from the neurone. These neuronal parts also have α -1 receptors. When NA acts here there is increased release of 5-HT from the cell. The axon terminal has 5-HT_{1D} (terminal) autoreceptors that, when stimulated by 5-HT present in the synaptic cleft, blocks further 5-HT release from the cell. If a drug blocked a 5-HT_{1D} terminal autoreceptor it would reduce serotonin release. Also at the axon terminal is the α -2 heteroreceptor. NA from nearby noradrenergic neurones can diffuse to these receptors and turn off 5-HT release. I.e., 5-HT release can be inhibited by 5-HT or NA. It should be noted that α -2 receptors on noradrenergic neurones are called autoreceptors, but those on serotonergic neurones are called heteroreceptors. In summary, all these receptors, with the exception of α -1 receptors, reduce the effects of serotonin neurotransmission. Finally, the postsynaptic neuronal membrane has its own serotonin receptors: 5-HT_{1A}, 2A, 2C, 3, 4, etc.

The noradrenergic neurones of the locus coeruleus send axons to the raphe nuclei (to synapse with dendrites and soma of 5-HT cells) where they promote 5-HT release, and to the cortex (to synapse with axon terminals of 5-HT cells) where they inhibit 5-HT release.

Gamma aminobutyric acid (GABA)⁷¹²

GABA is formed from l-glutamic acid by the rate limiting enzyme glutamate decarboxylase (GAD)⁷¹³. This conversion depends on vitamin B6 as cofactor. GABA, which has no releaser, is, along with glycine, a major inhibitory NT. B6 deficiency can lead to deficiency of GABA and seizures. Also, picrotoxin (*vide infra*), like bicuculline and pentylentetrazol, blocks the GABA chloride channel with resultant seizures.

⁷¹¹ Dutonin – withdrawn 2003. Unlike trazodone, nefazodone does not antagonise alpha-1-adrenoceptors and is non-sedating. Like trazodone, it is metabolised to the anxiogenic 5-HT receptor agonist, m-CPP. It is also metabolised to hydroxynefazodone, which has similar actions to the parent compound. Krystal *et al*(1993) gave m-CPP to patients with schizophrenia and controls and reported an exacerbation of positive symptoms in the former and no effect in the latter. To them, this suggested a 'pro-psychotic' rather than a psychotogenic effect, perhaps indicating a role for serotonergic mechanisms in schizophrenia.

⁷¹² 55%, 25% and 1% of brain neurones are GABAergic, cholinergic, and noradrenergic respectively.

⁷¹³ The chief initial source of GABA is glucose which is converted in Krebs cycle into alpha-ketoglutarate and then to l-glutamate. GAD is confined to GABA-producing neurones.

Pre-treatment with bicuculline blocks the actions of BZDs.⁷¹⁴ GABA is removed from the synapse into presynaptic nerve terminals and the surrounding glial cells where it is broken down by alpha-oxoglutarate and further (downstream) products enter Krebs cycle.

There are 2 GABA receptors, A and B.⁷¹⁵ Benzodiazepines combine with the BZD receptor site. The latter forms part of the GABA receptor complex. The BZD-BZD receptor site combination increases the sensitivity of the GABA receptor for the inhibitory transmitter GABA. This is achieved by facilitation of GABA-mediated increase in chloride conductance, resulting in neuronal membrane hyperpolarisation and inhibition of action potential propagation. (Hoffman & Warren, 1993) BZDs require the presence of GABA to produce their effects. Barbiturates do not have this requirement because of their direct action on GABA receptors. Barbiturates act closely with the GABA A receptor to increase chloride ion conductance, thereby reducing neuronal membrane excitability. In higher doses, barbiturates block the effects of excitatory NTs and disrupt membrane function outside the synapse. (Nutt, 1993)

GABA receptors are found mainly in the septo-hippocampal part of the limbic system, and also in the spinal cord.

Flumazenil is a BZD receptor antagonist with little inherent pharmacological activity. It blocks the effects of other BZDs and can provoke acute BZD withdrawal. Only available for intravenous use, flumazenil is used to reverse acute BZD toxicity. β -carbolines are inverse agonists of BZD receptors with resultant anxiety and seizures.

Brain BZD receptors in the brain have been classified as either BZ1 (type 1, omega 1) or BZ2 (type 2, omega 2), while omega 3 receptors are abundant peripherally. Zapelon (Sonata), a novel hypnotic, is thought to bind selectively to BZ1 receptors.

Changes in prefrontal cortical neural circuitry involving GABA may be involved in cognitive dysfunction in schizophrenia. Inhibitory interneurons containing parvalbumin⁷¹⁶ may be reduced in number and there may be reduced expression of the GABA synthesising enzyme glutamic acid decarboxylase⁷¹⁷. These findings suggest a functional prefrontal cortical GABA deficit.

As with so many other NTs, the intrinsic cortical transmitters GABA and somatostatin are diminished in Alzheimer's disease.

Gamma-hydroxybutyrate (GHB, sodium oxybate)⁷¹⁸, an anaesthetic⁷¹⁹, anti-narcolepsy agent, abused drug, and catabolic derivative of GABA, causes nausea and vomiting, muscle stiffness, unconsciousness and seizures and is a drug of abuse.⁷²⁰ Its euphoriant and disinhibiting effects resemble those of alcohol. It may act at GABA_B receptors. GHB increases cerebral DA. It is synergistic with alcohol and may depress respiration. Some effects of GHB are reversed by naloxone in animals. (Jones & Volans, 1999) GHB is a schedule three drug under the *Misuse of Drugs Act*.

Glutamate (glutamic acid)

This NT, the main excitatory NT in the brain, is derived from the cortical pyramidal cells and the hippocampus. It is a non-essential amino acid that cannot cross cell membranes, including the blood-brain barrier. Glutamate is formed from glutamine or aspartate within neuronal terminals. Glutamate is mainly taken from the synapse by a sodium-dependent mechanism into astrocytic processes that surround the synapse wherein it is converted into glutamine by glutamine synthetase⁷²¹. Glutamine is then taken up by

⁷¹⁴ Pentylenetetrazol, which is also anxiogenic, was used to induce convulsive therapy before the advent of ECT.

⁷¹⁵ 3-aminopropane, sulphonic acid, and muscimol are agonists for GABA; picrotoxin and bicuculline are antagonists; nipecotic acid and 4-methyl-GABA are reuptake inhibitors; and gabaculine, amino-oxyacetate, and acetylenic GABA inhibit GABA breakdown. Baclofen (Lioresal), a synthetic analogue of GABA, is a central muscle relaxant which depresses polysynaptic but not monosynaptic (e.g. knee jerk) reflexes; it can cause nausea, sedation, confusion, impaired alertness, and muscle fatigue; it is a GABA B receptor agonist. The GABA A receptor is baclofen-insensitive.

⁷¹⁶ Parvalbumin, an allergen implicated in seafood allergy, is a calcium binding albumin found in muscle, endocrine and nervous tissue. It is found in GABA-ergic interneurons, e.g. cortical chandelier and basket cells. It is present in a variety of hippocampal cells.

⁷¹⁷ The density of chandelier neurone axon terminals immunoreactive for the GABA membrane transporter (GAT-1) is reduced in most patients with schizophrenia. There are two types of **parvalbumin cell: chandelier** (with axons targeting initial axon segments of neocortical pyramidal cells with limited coverage of its axons) and **wide arbour cells** (targeting cell bodies and proximal part of dendrites with its axons covering a *wide* area). Chandelier cells may regulate the timing of output of a column of pyramidal cells. Wide arbour cells may inhibit pyramidal cells in nearby columns. It is easy to see how loss of such coordinating functions could disrupt higher cognitive functions in someone with schizophrenia.

⁷¹⁸ 'Liquid ecstasy'; liquid, powder and capsule forms.

⁷¹⁹ Since early 1960s.

⁷²⁰ In Britain it is associated with the rave and dance club scene, is sold in sex shops or can be ordered in the post.

⁷²¹ Glutamine synthetase is not present in neurones.

neurones and converted back into glutamate by glutaminase. Glutamate appears to be neurotoxic if present in sufficient quantity, so-called *excitotoxicity*⁷²². Apart from being a NT, glutamate is involved in synaptic remodelling, learning, neuronal maintenance, and brain development. (Fearon et al., 2000) Depending on agonist preference, there are 4 types of glutamate receptors: NMDA⁷²³, AMPA⁷²⁴, kainate⁷²⁵, and the slower acting metabotropic. The first 3 are linked to ion channels⁷²⁶ whilst metabotropic receptors, of which there are a number of subtypes, are G-protein-linked, act through cAMP or phosphoinositide, and seem to be important in memory function via a mechanism called 'long-term potentiation'. Phencyclidine (PCP) blocks NMDA glutamate receptors causing an indirect inhibition of calcium influx.

In fact, **NMDA receptors** have sites for glutamate, glycine (**co-regulatory site** for the amino acids glycine⁷²⁷ or D-serine that has to be occupied in order for glutamate to open the channel), polyamine, zinc (Zn), magnesium (Mg), as well as PCP. The receptor for PCP is called the sigma-PCP receptor and resides in the ion channel of the NMDA receptor complex.

Normally, glutamatergic fibres from the caudate nucleus have an inhibitory effect on DA release by the globus pallidus. In Huntington's disease, with cell loss in the caudate⁷²⁸, there is excess DA release from the globus pallidus, leading to choreiform movements.

cAMP and PI second messenger systems

(a) cAMP (cyclic 3,5-adenosine monophosphate) second messenger system

Neurotransmitter + receptor → activated G protein → activation of adenylate cyclase causing ATP conversion to cAMP → cAMP activates protein kinase A → protein kinase A phosphorylates (i.e. activates) various intracellular proteins such as cAMP-responsive element-binding protein (CREB) → CREB causes DNA transcription – protein synthesis

(b) PI (phosphatidylinositol) second messenger system

PI (in the cell membrane) → PIP₂ (PI biphosphate) → neurotransmitter binds to receptor and activates a G protein → activation of phospholipase C which hydrolyses PIP₂ to produce IP₃ (inositol triphosphate) and DAG (diacylglycerol) → IP₃ releases calcium from stores leading to calcium-dependent activities (e.g. phosphorylation of proteins by calcium-dependent kinases) and DAG activates protein kinase C (PKC) which regulates various activities via protein phosphorylation

Excitotoxicity is postulated to account for several acute (e.g. stroke) and chronic (e.g. negative symptoms of schizophrenia) forms of brain malfunction. Excess glutamate activity allows too much calcium to enter the cell and activate enzymes that in turn produce free radicals that destroy membranes and organelles.

Attempts are afoot to prevent such pathological changes by using glutamate (especially NMDA) antagonists, free radical scavengers⁷²⁹, or enzyme blockers⁷³⁰. (Graham & Hickey, 2002) Memantine, an NMDA receptor antagonist, is advocated for moderate to severe Alzheimer's Disease.

Clozapine, and perhaps other atypical antipsychotics such as olanzapine, may exert part of its therapeutic effect by increasing activity at the NMDA receptor. It blocks the psychotropic effects of ketamine.

Ketamine can induce a schizophrenia-like reaction and exacerbate the symptoms of schizophrenia.

Raclopride binding to D2 receptors is diminished by ketamine, which raises the possibility that ketamine causes striatal DA release. (Breier et al., 1998)

Glycine

⁷²² Term coined by J W Olney in connection with selective neurodegeneration in newborn rodents given monosodium glutamate.

⁷²³ N-methyl-D-aspartate.

⁷²⁴ α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid.

⁷²⁵ **Kainic acid**, a glutamic acid analogue derived from seaweed, is a powerful convulsive chemical.

⁷²⁶ Ionotropic.

⁷²⁷ **Regulation of the NMDA receptor** is complex with many sites of allosteric modulation, such as the glycine site. Agonists at the glycine site may be full (glycine, D-serine, and D-alanine) or partial (D-cycloserine). Cycloserine is an agonist at low concentrations and an antagonist at high concentrations. High-dose cycloserine used to treat TB may cause psychosis.

⁷²⁸ Loss of long GABA neurones connecting caudate to globus pallidus.

⁷²⁹ E.g. vitamin E and the so-called 'lazaroids'. Free radical scavengers bind reactive oxygen species. The main free radical species in humans are the hydroxyl (OH) and superoxide (O₂⁻) radicals and nitric oxide (NO).

⁷³⁰ E.g. caspase inhibitors, enzymes said to be involved in apoptosis.

Apart from GABA, glycine is the other main amino acid inhibitory NT, and is found in highest concentration in the spinal cord. Milacemide is converted to glycine in the CNS.

Histamine

Histamine, derived from L-histidine⁷³¹, is released from mast cells and causes vasodilation and activation of smooth muscle as well as gastric acid secretion. It mediates itch and pain. Posterior thalamic histaminergic neurones project axons throughout the CNS and are involved in wakefulness, appetite, and metabolic control. Histamine H1-3 receptors are found in the CNS and peripherally whereas H4 receptors are only found peripherally. H1 blockers include diphenhydramine (Benadryl) which can be used to treat drug-induced Parkinsonism or acute dystonia, or it can be employed for its hypnotic and anti-motion sickness properties⁷³². Cyproheptadine (Periactin) blocks H1 receptors and is an antagonist at 5-HT receptors. It has been used to put on weight in anorexia nervosa and, given before sexual intercourse, for inhibited orgasm in either sex due to SSRIs. Diphenhydramine and hydroxyzine have some antimuscarinic activity. H2 blockers like cimetidine are used for peptic disorders. Sedation and weight gain from antipsychotic drugs and antidepressants (e.g. mirtazepine) are antihistaminic effects. Based on animal studies suggesting that depletion of histamine affects short-term memories, researchers are examining the possibility of using H3 autoreceptor antagonists in patients with memory problems.

Substance P⁷³³

Although the brain is rich in substance P, it is mainly associated with the pain-conveying sensory afferents to the substantia gelatinosa of the dorsal horn. Release of substance P, which is inhibited by opiates, is associated with intense pain. Capsaicin, found in chili peppers, depletes substance P in nerve sensory terminals.

Neuropeptides

There are small proteins consisting of anything from two to dozens of amino acids. The physiological actions of neuropeptides last minutes to hours (v seconds to minutes for many other NTs) and they are found in picomolar to femtomolar concentrations (v nanomolar to micromolar for classical NTs and millimolar for glutamate). Peptide NTs coexist with other NTs, e.g. 5-HT coexists in neurones with substance P and enkephalin. While biogenic amines (e.g. DA) and amino acids (e.g. glycine) are manufactured at nerve terminals using enzymes from the cell body, peptides must be synthesised in the cell body itself. They are only deactivated outside the cell (by proteolysis), and have a long duration of action, their effects often persisting after they are degraded.

These peptides include cholecystokinin (CCK), vasoactive intestinal polypeptide (VIP, a member of the glucagon-secretin family), oxytocin, vasopressin (9 amino acids), TRH (3 amino acids), substance P (11-amino acid neurokinin peptide), bradykinin, galanin (30-amino acid neuropeptide; originally purified from colon and pituitary) stimulates growth hormone release; discovered in 1983), insulin, leu-enkephalin, and neurotensin. (Palkovits, 2002; Meyer, 2002) The co-existence of neuropeptides and classical NTs like 5-HT within the same neurone may be important for varying the effect of released NT and may have significance for understanding the effects of psychiatric somatherapies and mental illness. For example, TRH might act synergistically with serotonin to generate an increase in postsynaptic potential, while substance P may block postsynaptic autoreceptors, thereby inhibiting 5-HT release. Release of such peptides with serotonin appears to depend on an increase in electrical stimulation. (Hökfelt et al, 1987)

Cholecystokinin (CCK)⁷³⁴ is found in various forms, cholecystokinin octapeptide (CCK-8) probably being the most common variety in the central nervous system (CNS). CCK-8 and various analogues may modulate (regulate) CNS transmission in those DA neurones projecting to cerebral cortex and limbic system, but not those headed for the basal ganglia. These chemicals have been studied as possible antipsychotic agents, although with inconsistent results. An infusion of the tetrapeptide CCK-4 causes marked panic symptoms. Not surprisingly, therefore, cholecystokinin antagonists have also been looked at as potential anxiolytics.

Production of cocaine- and amphetamine-regulated transcript (CART) peptides is increased following use of either drug. They may play a role in drug abuse, control of stress and feeding behaviour.

⁷³¹ L-histidine is converted to histamine by L-histidine decarboxylase and histamine is broken down via oxidation or methylation.

⁷³² However, not all experts approve of Diphenhydramine as an hypnotic, pointing out that it causes confusion and sedation.

⁷³³ Gaddum and Von Euler discovered this excitatory transmitter in 1931.

⁷³⁴ A 33-amino acid neuroactive peptide co-transmitter with a variety of peripheral and central actions.

The main hypothalamic NTs stimulating feeding are (pancreatic) neuropeptide Y⁷³⁵, NA, opioids, galanin, and growth hormone releasing factor. Those inhibiting feeding include PYY (YY₃₋₃₆, PYY₃₋₃₆), CRF, serotonin, neurotensin, and CCK. (Gilbey & Macrae, 1993) It has been suggested that cholecystokinin (see above) and neurotensin receptor antagonists might have some antipsychotic activity.

α -melanocyte-stimulating hormone⁷³⁶ reduced food intake and increases energy expenditure by reacting with MC4R, a melanocortin⁷³⁷ receptor within the hypothalamus.⁷³⁸

PYY is a peptide secreted⁷³⁹ after a meal by endocrine L cells lining the distal small bowel and colon. In animal studies PYY inhibits hypothalamic neuropeptide Y-expressing neurones and agouti-related protein-expressing neurones via neuropeptide Y2 receptors, thereby disinhibiting nearby proopiomelanocortin-expressing neurones and decreasing food intake. PYY reduces fasting ghrelin levels in humans. (Batterham et al, 2003)

Agouti-related peptide/protein (AgRP⁷⁴⁰)

This is produced in the arcuate nucleus of the hypothalamus. It increases appetite and reduces metabolism and energy loss.

Endogenous opioids (EOs)

These are peptide NTs. The precursor proopiomelanocortin (POMC) gives rise to ACTH, MSH, and β -endorphin. Proenkephalin gives rise to met-enkephalin and leu-enkephalin. Prodynorphin gives rise to β -neoendorphin and dynorphin. EOs act on 3 major receptors (μ , δ , κ) and are thought to be involved in the regulation of stress, pain and mood. Expression of the prodynorphin gene is controlled by a calcium-regulated transcription factor that binds to downstream regulatory element (DRE) of the gene and is known as DRE antagonistic modulator (DREAM).⁷⁴¹

Alpha-MSH (α -melanocyte stimulating hormone) is an anorectic peptide found in the arcuate nucleus. It decreases food intake. The mainly hypothalamic peptide melanin-concentrating hormone is important for feeding and energy balance because melanin-concentrating hormone knockout mice are thin, eat little and have increased rates of metabolic activity.

Purine receptors

Receptors for purines such as adenosine are divided into P1 and P2. P1 receptors are blocked by xanthines like caffeine and theophylline.

Monoamine oxidase

Monoamine oxidases, flavin-containing enzymes, occur as either MAO-A or MAO-B. MAO-A is found in brain⁷⁴², sympathetic nervous system, liver, and gut, whereas MAO-B is found in brain, liver, and platelets. MAO-A mainly acts on 5-HT and NA, but also on DA and tyramine. Tyramine may act as a false transmitter and displace NA from presynaptic storage granules. MAO-B mainly acts on phenylethylamine, but also on DA and tyramine. The classical MAOIs, such as tranylcypromine, irreversibly block MAO, whereas the reversible MAO-A inhibitors (RIMAs), like moclobemide, can be knocked off the enzyme by, for example, tyramine. SSRIs cannot be given for weeks⁷⁴³ after stopping a classical MAOI, but can be taken a week or so after stopping moclobemide.

MAO-B is inhibited irreversibly by selegiline, used with L-DOPA in the treatment of Parkinson's disease, with no dietary restrictions. At much higher doses selegiline inhibits both MAO A and B and has been used at such doses as an antidepressant. Selegiline is metabolised to a number of active compounds including

⁷³⁵ Often stated to be the most powerful stimulator for feeding, but **peptide YY** may be more powerful. (Halmi, 2003, p. 1002) Both arise in the pancreas. When injected into the paraventricular nucleus, **neuropeptide Y** increases intake of food and water.

⁷³⁶ Peptide carved from proopiomelanocortin.

⁷³⁷ Concerns have been raised about use of synthetic melanocortin analogues melanotan I and II (mimic α -MSH) which are reaching people without being subject to normal safety measures. (Evans-Brown et al, 2009) They are used to produce a skin tan or to produce an erection. Melanotan II can cause hypertension in some people. Needle-sharing is a significant concern.

⁷³⁸ Deletion of the mouse Mc4r gene leads to hyperphagia, obesity, hyperphagia, hyperinsulinaemia and reduced energy expenditure. Mutations of the MC4R gene are reported in 3-7% of humans with a BMI greater than 40 and severe obesity commencing before the tenth birthday.

⁷³⁹ Proportionate to caloric intake.

⁷⁴⁰ The agouti is a rodent. AgRP resembles a protein (agouti signalling peptide) that gives colour to the body coat.

⁷⁴¹ When DREAM binds to DRE it inhibits transcription of the prodynorphin gene. DREAM knockout mice have been used to study regulation of nociception: such mice have a diminished response in neuropathic and inflammatory models of chronic pain. (Vogt, 2002)

⁷⁴² A PET radiotracer is available for MAO-A.

⁷⁴³ Depending on the particular SSRI.

methamphetamine, levoamphetamine, and N-desmethylelegiline. Toxic interactions with SSRIs have been recorded, although it may be safe with TCAs. (Brown et al., 2000) Sudden cessation of selegiline intake can cause nausea, hallucinations, and confusion. (Krishnan, 1998)

Rasagiline is another MAO-B inhibitor.

Pethidine (meperidine) can cause hypertension, hyperpyrexia and death if combined with a MAOI. Fava beans, which contain DA, have similar effects to tyramine in the presence of MAOIs. Tyramine is formed in foodstuffs by decarboxylation of tyrosine during aging, ripening or decay. The food containing the highest tyramine content is spoiled pickled herring. Aged cheese contains a high level of tyramine.

Catechol-o-methyl transferase (COMT)

COMT is a magnesium ion-dependent enzyme that catalyses the transfer of methyl groups from S-adenosyl methionine to a hydroxyl group of a catecholamine. The gene for COMT is at 22q11. COMT is involved in extracellular breakdown of catecholamines. The peripheral COMT inhibitor entacapone (Comtess – 200 mg with each dose of levodopa) is used to treat Parkinson's disease.⁷⁴⁴ It reduces levodopa breakdown before it reaches the brain. The dose of levodopa may be reduced if the patient takes entacapone. Side effects are mainly due to increased brain dopamine levels and include dyskinesia and nausea that may respond to dosage adjustment. Uncommonly, it can cause abdominal pain and diarrhoea. Another COMT inhibitor, tolcapone (Tasmar), may cause serious liver damage.

Monoamine reuptake inhibitors (MARIs)

This group contains such agents as TCAs, mianserin, trazodone, and the SSRIs. Trazodone is an antagonist at 5-HT₂ receptors. It also blocks postsynaptic α -1-adrenoceptors. On the other hand, its active metabolite, m-chlorophenylpiperazine (m-CPP), is a 5-HT receptor agonist.⁷⁴⁵

Mode of action of antidepressants: a critique

We tend to apply rationale for how a drug works after its benefits are noticed. (Duffin, 2000) The points against reuptake inhibition being therapeutic are that it occurs within hours whereas improvement in mood requires weeks, not all reuptake inhibitors are true antidepressants (e.g. amphetamine), and some effective antidepressants, such as trimipramine and bupropion, have negligible reuptake disinhibitory properties. On the other hand, the time required for an antidepressant drug to induce beta-adrenergic receptor downregulation⁷⁴⁶ closely parallels the course of clinical improvement. Beta-receptors are downregulated by TCAs, MAOIs, and ECT. Some antidepressants do not have this property, such as mianserin, trazodone, paroxetine, citalopram and fluoxetine. Also, shortening the time to downregulation does not accelerate clinical response, and β -receptor agonists like clenbuterol cause downregulation but are poor antidepressants.

Presynaptic α -2-autoreceptors are activated by NA in the synaptic cleft, causing inhibition of further NA release due to increased potassium conductance and consequent cellular hyperpolarisation. (Nutt, 1993) Antidepressants given long-term, lithium and ECT reduce the sensitivity of α -2-autoreceptors in platelets. However, deductions concerning depression ignore the fact that α -2-autoreceptors are both pre- and post-synaptic in the brain. (Trimble, 1996)

SSRIs block the serotonin transporter⁷⁴⁷, an effect that only takes a few hours, the activity of the serotonergic neurone recovering over the next 2 weeks. (De Montigny & Blier, 1985) Chronic SSRI dosing desensitises 5-HT_{1A} autoreceptors, but not 5-HT_{1A} receptors on postsynaptic cells. 5-HT₂ receptors may be upregulated in depression and downregulated by antidepressant drugs like SSRIs and TCAs. However, both antipsychotic drugs and LSD also downregulate these receptors, and ECT upregulates them!

⁷⁴⁴ Leonard (2003, p. 67) is not enthusiastic about COMT inhibitors because 'at most only 10% of the monoamines released from the nerve terminal are catabolized by this enzyme'.

⁷⁴⁵ See nefazodone.

⁷⁴⁶ Decreased receptor number or sensitivity.

⁷⁴⁷ The **serotonin transporter** is a cell membrane protein (gene [SERT] on chromosome 17) involved in the recycling of 5-HT, thereby terminating the synaptic activity of serotonin. Polymorphisms (number of tandem repeats) may explain a connection between depression and anxiety. (Ohara et al., 1999) The long (L) variant of SERT contains a 44-bp sequence which the short (S) variant does not possess. The L-variant generates more mRNA and hence more protein and thereby increases synaptic transport so that duration and intensity of 5-HT neurotransmission are diminished. The S-variant is thought to be involved in the origin of depression and anxiety. It is important to note that the binding potential of the 5-HT transporter varies with the seasons – higher 5-HT transporter density is associated with lower synaptic 5-HT levels. (Praschak-Rieder et al., 2008) This fact may have explanatory power concerning seasonal changes in normal and abnormal behaviours.

All chronic antidepressant treatments appear to increase intracellular concentrations of cAMP response element binding (CREB) protein as well as cAMP-dependent protein kinases. CREB may be responsible for receptor protein up- and downregulation. Two to 3 weeks are required for induction of CREB, which fits with time to clinical response. (Musselman *et al.*, 1998)

Nitrous oxide (N₂O/laughing gas): this euphoriant can cause delirium acutely. Chronic exposure can lead to combined degeneration of the posterior and lateral columns of the spinal cord (similar to B12 deficiency).

*Nitric oxide (NO)*⁷⁴⁸

NO, known as 'endothelial relaxing factor' before elucidation of its true nature, is an NT without specific receptors. It is not stored, is manufactured on demand, and is released by simple diffusion. Penile neurones and other tissues, such as granule cells in the cerebellum and some other brain cells, contain nitric oxide synthetase (NOS) which makes NO from l-arginine, leaving l-citrulline as a by-product. NO then diffuses to adjacent neurones or smooth muscle and leads to the formation of cyclic guanosine monophosphate (cGMP) by activating guanylyl cyclase (GC). NO binds to the heme (iron) site on GC. Glutamate and calcium can trigger NOS to form NO.

cGMP relaxes smooth muscle, thereby opening blood vessels and leading to penile erection. cGMP is terminated by phosphodiesterases (PDEs), of which there are several forms, the one in the penis being type five (PDE V). NO is also involved in the smooth muscle of the heart's blood supply (mediating the action of nitroglycerin), in blood pressure control, in platelet aggregation, and in peristalsis. NO may act as a retrograde transmitter in the CNS, being part of the back talk from post- to pre-synaptic neurones. It may also have a role in memory, plasticity of nerve cells, and neurotoxicity (NO is a free radical and its combination with O₂ increases its toxicity).

Inhibiting PDE V with sildenafil (Viagra) can decrease the rate of destruction of cGMP. Sildenafil only produces an erection if one is mentally interested in having sex, unlike, for example, the prostaglandin alprostadil which also relaxes smooth muscle to produce an erection, but in this case irrespective of whether the individual is currently interested in having sex or not.

NO appears to have a diversity of roles in the body, e.g. learning and memory (longterm potentiation in the hippocampus) and it may inhibit maternal behaviour in rats by modulating oxytocin release.

Carbon monoxide

This is produced in the brain by haemeoxygenase-2, an enzyme present throughout the brain but particularly common in the olfactory system, cerebellar Purkinje cells, and hippocampal pyramidal cells. It is freely diffusible and, like NO, it activates guanylyl cyclase.

*Attention deficit disorder (ADD)*⁷⁴⁹

It is postulated that the poor attention skills may be due to underactivity in DA and NA pathways innervating the prefrontal cortex (PFC), whereas hyperactivity⁷⁵⁰/impulsivity may be mediated by the dopaminergic neurones of the nigrostriatal pathway.

Medications for attentional difficulties include pemoline⁷⁵¹, which has caused liver toxicity, sometimes fatal. (Cozza *et al.*, 2003, pp. 1405 & 1407) Amphetamines are more popular in America. L-amphetamine is the enantiomer (Leonard, 2004) of d-amphetamine. L-amphetamine releases both DA and NA, whereas d-amphetamines releases DA only. Low doses of amphetamine improve attention in such cases. Some cases may respond best to a mixture of l- and d-amphetamine. Methylphenidate, which increases DA availability, is also employed in treating this problem. It has a slower onset of action but lasts longer than amphetamine. Postsynaptic α -2 agonists, such as clonidine, may be beneficial. Bupropion, which is chemically related to amphetamine and can cause seizures in high doses, increases the availability of DA and NA, helps some cases.

In cases of hyperactivity/impulsivity, increasing DA levels may paradoxically produce a calming effect. It has been suggested that cortically derived glutamate reduces impulsivity by inhibitory actions in the striatum. Higher doses of stimulants are effective for hyperactivity/impulsivity than are needed for attentional problems.

⁷⁴⁸ This should not be confused with nitrous oxide.

⁷⁴⁹ This 'complex' of symptoms has had many names: hyperkinetic disorder, hyperactivity-ADD, and ADD depending on the symptoms expressed.

⁷⁵⁰ Hyperkinesis.

⁷⁵¹ Withdrawn in UK.

Concerns have been expressed about the scope of the diagnosis on the one hand and about missing the diagnosis in both children and adults. Since stimulants can lead to tolerance, escalating doses and abuse outside core ADD, great care is required on the part of physicians. These considerations do not appear to apply to the core group. DSM-IV demands that symptoms of ADD go back to before age 7 years. Cynics would say that the overlap between ADD and conduct disorder has led to pressure from relatives and solicitors to diagnose adult ADD where dissociality once reigned!

Ethyl alcohol

Alcohol is metabolised to CO₂ and H₂O in 3 main oxidative stages. Firstly, ethyl alcohol (C₂H₅OH) is converted to acetaldehyde (CH₃CHO) in the presence of alcohol dehydrogenase; then acetaldehyde is changed to acetic acid (CH₃COOH) by aldehyde dehydrogenase; and, finally, acetic acid, having been converted to acetyl coenzyme A, enters the tricarboxylic acid cycle to be degraded to CO₂ and H₂O. Disulfiram inhibits the action of aldehyde dehydrogenase with resultant acetaldehyde accumulation. Acetaldehyde causes histamine release. Interestingly, alcohol dependent people develop higher acetaldehyde levels than their non-dependent comparators when they drink. This acetaldehyde interacts with catecholamines to produce complexes called tetrahydroisoquinolines that bind to specific brain receptor sites. Since tetrahydroisoquinolines resemble morphine alkaloids in structure, the theory has arisen that this may be a mechanism that stimulates further drinking. Disulfiram also inhibits dopamine hydroxylase and may potentially exacerbate schizophrenia.

The active absorption of water-soluble forms of vitamin B1 by the intestine is inhibited by alcohol. It is therefore better to employ passively absorbed fat-soluble forms such as thiamine propyldisulphide. (Madden, 1985) Absorbed thiamine is converted to thiamine pyrophosphate, the active form. The latter is a coenzyme for transketolase (involved in hexose monophosphate shunt pathway). Some people inherit a form of transketolase that has less affinity for activated thiamine and may develop Wernicke's encephalopathy with relatively mild lack of B1.

Alcohol dehydrogenase is absent during early embryonic life, making the foetus more susceptible to alcohol's effects on cellular proliferation, an effect demonstrable in mice deficient in this enzyme. Alcohol increases inhibitory neurotransmission at GABA A receptors, reduces inhibitory neurotransmission at the NMDA subtype of glutamate receptors, and possibly also releases opiates and endocannabinoids. Acamprosate (calcium bisacetylmotaurinate; Campral EC), which reduces craving for alcohol, seems to act either by stimulating GABAergic inhibitory neurotransmission or by postsynaptic antagonism of excitatory amino acids, especially glutamic acid. The latter mechanism is favoured by Sass et al. (1996) Congeners are substances in alcohol other than ethyl alcohol, including other alcohols and acetaldehyde. They are thought to be psychoactive, although their clinical effects require clarification.

Cannabis

The brain has its own cannabinoid receptors: CB1 in CNS and peripheral nervous system (G-protein coupled and also modulates adenylate cyclase and ion channels) and CB2 (chiefly in the immune system). An endogenous cannabinoid system activates these receptors. Endocannabinoids⁷⁵² are manufactured in neurones and taken up and destroyed by both neurones and glia. THC mimics their actions.

Endocannabinoid actions at CB1 are antagonised by SR141716. The latter substance has been shown to block the acute psychological and physiological effects of smoked marijuana without altering THC pharmacokinetics. (Huestis et al, 2001) AM404 is an anandamide transporter inhibitor.

Anandamide activated vanilloid (resiniferatoxin) receptors within cells, which may explain its effects on pain transmission. (Mayfield et al, 2003, p. 847)

Gamma-glutamyl transferase (γ-GT)

Increased plasma activity of this microsomal enzyme is a sensitive index of hepatic abnormality. Causes of such increased activity include biliary obstruction (producing highest increase), parenchymal damage for any reason, and microsomal enzyme induction due to alcohol (a γ-GT normal level does not outweigh excess intake of alcohol), carbamazepine, phenytoin, primidone, barbiturates, glutethimide, meprobamate, rifampicin, or griseofulvin.

Growth factors

⁷⁵² Such as the ethanolamide fatty acid anandamide. (Sanskrit: *ananda*, bliss) Independent of cannabis use, levels of the endogenous cannabinoid anandamide were found to be elevated in the blood and CSF of patients with schizophrenia.

Peptide regulatory factors are important for nervous system development and in neurodegenerative disorders for restoring neural circuits and coordinating glial response to damage. The best known is nerve growth factor (NGF). NGF mediates the differentiation and survival of nerve cells. Cholinergic nerve cells in nucleus basalis of Meynert, the medial septum and the striatum express both NGF receptors⁷⁵³, i.e. tropomyosin-related kinase A (TrkA) and p75, and NGF may help to maintain the function of these nerve cells. CNS growth factors may prove useful in the future, such as in facilitating regeneration following trauma, and in retarding or reversing age- or disease-related neural degeneration.(Logan, 1990)

Leptin

Obesity may be related to leptin⁷⁵⁴ (an adipokine) resistance: leptin levels are chronically increased in obese humans⁷⁵⁵ and decreased during starvation.(Gomez ea, 2002) Leptin levels in plasma and CSF are significantly reduced in underweight patients with anorexia nervosa, rising to normal values with weight restoration.(Halmi, 2003, p. 1003) Leptin, a 146-amino acid protein that is one of the interleukin 6 cytokines, is produced by fat cells and reduces food intake, decreases insulin levels, and lowers blood glucose concentration in the ob/ob (obese – lacks functional leptin) mouse but not in the db/db (mutant diabetic – lacks leptin receptor) mouse.(Bray, 1996; Caro ea, 1996; Schwartz ea, 1996) Giving exogenous leptin will reduce food intake and weight whether endogenous leptin is normal or deficient. Leptin concentration is proportional to fat mass when energy balance is stable. Acute fasting causes a larger fall in leptin levels than would be expected from any change in fat mass and excessive food intake leads to enhanced rise in circulating leptin following the meal. A fall in leptin levels signal a smaller fat mass and this leads to an increase in appetite. Insulin exerts a delayed stimulatory action on leptin production in adipocytes. Leptin may exert its central effects by inhibiting activity of neurones containing neuropeptide Y and agouti-related peptide and stimulating MSH activity. It is thought that leptin levels increase during atypical antipsychotic drug treatment as a result of increased weight rather than by any direct effect of these drugs on leptin physiology.(Hua ea, 2008)

Ghrelin

Ghrelin⁷⁵⁶ stimulates feeding and produces obesity in rodents. Levels of ghrelin rise just before a meal and with restricted food intake (including starvation⁷⁵⁷) and fall quickly following a meal.(Cummings ea, 2002) Bulimic patients may have blunted ghrelin response to a meal.(Monteleone ea, 2003) It acts on the hypothalamus. An infusion of ghrelin causes a brief increase in hunger in humans. There is preliminary evidence that ghrelin levels increase during atypical antipsychotic drug treatment.(Hua ea, 2008) Because obesity is associated with decreased ghrelin levels, it is unlikely that ghrelin causes obesity. Weight loss following gastric bypass surgery, unlike dieting-induced weight loss, is associated with decreased ghrelin levels that do not rise before a meal. Much more work needs to be done before a role for ghrelin antagonists in the management of obesity can be clarified either way.

Ghrelin and leptin

Hypothalamus detects *ghrelin* from stomach → hunger

Hypothalamus detects *leptin* from adipose tissue → satiety

Adiponectin

This 244-amino acid protein is secreted exclusively by adipose tissue and levels are low in the obese, i.e. adiponectin levels in humans negatively correlate with body weight and insulin levels. It is important in regulation of glucose levels, the breakdown of fatty acids, and sensitivity to insulin.

Ginkgo biloba

Ginkgo biloba, an over the counter (OTC⁷⁵⁸) preparation, is made from the leaves of the ginkgo or maidenhair tree. An antioxidant effect has been suggested. Combination with drugs that increase the risk of

⁷⁵³ Neurotrophic factors (neurotrophins) activate Trk (A, B, and C subtypes) and p75 transmembrane (which binds mature and precursor molecules) receptors.

⁷⁵⁴ Gk. *leptos*, thin.

⁷⁵⁵ Leptin levels are increased in *obstructive sleep apnoea* over and above levels found in obese controls.(Ip ea, 2000)

⁷⁵⁶ A 28-amino acid peptide produced by oxyntic cells in the gastric fundus. It gets its name because one of its actions is to cause **growth hormone release**.

⁷⁵⁷ Ghrelin levels are increased in underweight patients with AN and then fall as weight increases. There is a negative correlation between BMI and ghrelin levels.

⁷⁵⁸ The popularity of OTC preparations has a long history.(Digby, 1999, p. 228)

bleeding may be dangerous as ginkgo antagonises platelet activating factor. Ginkgo can cause headache, gastrointestinal upset, and rashes. Claims for beneficial effects on normal memory or in preventing dementia in the elderly have not received scientific support.(Frankish, 2002; DeKosky ea, 2008)

Neurochemical/molecular biological terms

Amyloid in Alzheimer's disease (animal research): Changiz Geula and others injected fibrillar B amyloid into (especially older) primate (more than rat) brain leads to cell loss with an intense microglial reaction at the injection site. There is also induction of hyperphosphorylated tau, the protein forming neurofibrillary tangles in Alzheimer brains.(Berger, 1998) β -amyloid protein is produced by cleavage of the precursor protein by secretases. Gamma-secretase produces the carboxyl terminus of beta-amyloid protein, the length of this terminus influencing the pathogenic effects of the protein. Research aims at producing inhibitors of gamma-secretase.(de Deyn, 2002)

Apolipoprotein E (Apo E): 299 amino acid compound found in serum and CSF. Major component of circulating lipoproteins and important regulator of lipid metabolism. Has a crucial role in cholesterol metabolism. Exists in 3 major isoforms (E2, E3, the commonest, and E4) encoded by 3 alleles (E2, E3, and E4) of the apolipoprotein E gene. Two functional domains, one end binding to cholesterol and the other to cellular low-density lipoprotein (LDL) and other receptors for lipids, thereby facilitating endocytosis. Apo-E2 cannot bind LDL receptors and is important in coronary artery disease and strokes. Apo-E4 is important in the pathogenesis of late-onset Alzheimer's disease. In an autopsy study (Polvikoski ea, 1995) the E4 allele of apolipoprotein E was significantly associated with Alzheimer's disease. Dementia is latest in onset with no E4 allele, earlier with one E4 allele, and earlier still with two such alleles.(Devasenapathy & Hachinski, 1997) Even in elderly subjects without dementia, the apolipoprotein E genotype is related to the degree of deposition of β -amyloid protein in the cerebral cortex. The E4 allele of Apo E is on chromosome 19 [q13]. Apo E plasma levels were found to be significantly reduced in treatment-free patients with schizophrenia spectrum disorder and those with bipolar disorder, levels increasing with treatment in the bipolar patients.(Dean ea, 2008)

Cytoskeleton: This gives the neurone its shape and allows for the traffic of proteins and organelles within various parts of the neurone). There are three main fibrous components: microtubules (transport highways for organelles made up of tubulin subunits extending in bundles throughout the neurone to form a scaffold – stability is provided by microtubule-associated proteins [MAPs]), neurofilaments (very stable and abundant in axons, these form part of neurofibrillary tangles), and actin⁷⁵⁹ (a dense network beneath the neuronal membrane and, together with various binding proteins, is important for cell motility, synaptic specialisation, and axon and dendrite plasticity).

G-proteins: family of guanosine triphosphate binding proteins that play an obligatory role in the transduction of a wide range of extracellular, receptor-detected signals across cell membranes to intracellular effectors (NT + receptor + G-protein activate protein kinase); they couple receptors to effectors. Lithium may exert some of its therapeutic actions via G-proteins.

Imidazoline receptors: newly discovered; some of these, like $\alpha 2$ -receptors, have a presynaptic inhibitory effect on NA release; they might have a role in depression.

Myo-inositol: Precursor of phosphorylated inositols involved in phosphatidyl inositol⁷⁶⁰ intracellular signalling pathway. Dephosphorylation of inositol triphosphate yields myo-inositol, which becomes incorporated in phosphatidyl inositol. When a neurotransmitter binds to its receptor, phosphatidyl inositol is further phosphorylated to again yield inositol triphosphate.

Second messengers: these activate specific types of protein kinase that regulate the phosphorylation state of numerous substrate proteins (third messengers) which act as transcription factors regulating trans-synaptic gene expression.

Signal transduction: processes by which effects of NT binding to receptors produce alterations in neural functioning; G-proteins are examples of signal transducers.

Tau: one of a family of microtubule-associated proteins that functions to stabilise polymers of tubulin⁷⁶¹; 6 isoforms⁷⁶² (produced by differential splicing of the same gene) splicing of tau are known; abundant in

⁷⁵⁹ The same contractile protein as that found in muscle.

⁷⁶⁰ Inositol is a glucose isomer and myo-inositol (q.v.) is the most common inositol isomer in the mammalian CNS.

⁷⁶¹ Microtubules, polymers of tubulin, are involved during mitosis in transport within the cell and in guiding chromosomes to daughter cells, whereas after mitosis they have a transport function only.

neural tissue, predominantly in axons; decreased concentration of soluble tau protein occurs in old age, even in the absence of dementia.(Garruto & Brown, 1994) Exists in CNS as 6 isoforms generated from a single gene. Aberrant phosphorylation of tau protein is associated with paired helical filaments, the main structural element of neurofibrillary tangles. In other words, the central component of neurofibrillary tangles is a cytoskeletal protein called tau, modified by abnormal phosphorylation. Different neurodegenerative conditions associated with tau can be differentiated on Western blots, e.g. bands of 60 and 64 kDa phosphorylated tau in Pick's disease.

Tribulin: proposed name for an endogenous anxiolytic substance within the brain.(Sandler, 1983) This low molecular weight substance was isolated from human urine. It inhibits binding of the BZD to its receptor site. **Other proposed endogenous BZD receptor ligands** (*endozepines*) include nicotinamide, inosine, hypoxanthine (the latter three molecules may have mixed agonist-antagonist properties; the latter two may modulate BZD receptors by activating purinergic mechanisms), ethyl- β -carboline-3 carboxylate, nephten (large polypeptide, found in bile ducts and other peripheral tissues and to a lesser extent in brain – possibly gives rise to another chemical that acts on BZD receptor), diazepam-displacing activity in human CSF, and the anxiogenic diazepam-binding inhibitor (DBI; Leonard, 1997; an 86 amino acid peptide that can be spliced into biologically active fragments) which inhibits binding of tritiated diazepam (as well as antagonists and inverse agonists) to the BZD receptor. Leonard(2003, p. 234) emphasised the controversial nature of speculation in this area and informs us that BZDs may exist in plants (e.g. potato) and in the brains of mammals. 'Idiopathic recurring stupor'⁷⁶³ may be due to an excess of endozepines. It can be interrupted (quickly and temporarily) by flumazenil injections.(Rothstein et al, 1992)

Extrapyramidal side-effects (EPS)

Dopaminergic neurones projecting from the substantia nigra to the corpus striatum exert an inhibitory action on cholinergic striatal cells. The latter, in turn, inhibit striatal GABAergic neurones that are themselves inhibitory for the dopaminergic neurones of the substantia nigra, thus completing a circuit. If Ach and DA actions are blocked simultaneously, then the effects on the motor system are cancelled out. However, if the Ach system is freed from DA inhibition, then EPS emerge.

The TCA blocks D2 receptors and causes EPS.(Rudorfer & Potter, 1989) SSRIs can also cause EPS.

Inborn errors of metabolism

Most enzymes can have activity levels of less than half of normal without serious consequences, a fact that allows one to test for heterozygous carriers. When two heterozygous carriers of a recessive gene mate one in four offspring will be homozygous and manifest the associated disorder. Incestuous relationships and cousin marriages carry the highest risk of this happening.

Phenylalanine can be converted to σ tyrosine and thence to σ hydroxyphenylacetic acid, or to phenylpyruvate and NH_3 , the phenylpyruvate being metabolised to phenylacetate and phenyllactate, or to tyrosine by an hydroxylase enzyme (step A). Tyrosine can be converted to DOPA or to adrenaline via dopamine and noradrenaline, or it can be changed to p-hydroxyphenylpyruvate; the latter is changed to homogentisate by an oxidase enzyme (step B) and on to maleylacetoacetate by further oxidation (step C), and finally to fumarate and acetoacetate. Phenylketonuria⁷⁶⁴, tyrosinosis and alcaptonuria result from enzymatic defects at steps A, B and C respectively. The metabolites σ hydroxyphenylacetic acid, phenylacetate and phenyllactate are excreted in phenylketonuria.

Regarding the sulphur-containing amino acids, homocysteine can be converted into or from homocystine and methionine, or can be changed into cystathionine (a normal brain constituent; step 1) and thence cysteine (step 2). A defect at step 1 leads to homocystinuria,⁷⁶⁵ while one at step 2 leads to cystathionuria.

⁷⁶² These isoforms may have 3 (= 3R, found mainly in Pick's disease) or 4 (= 4R, found in corticobasal degeneration and progressive supranuclear palsy) or zero microtubule-binding domains. They may have 1 or 2 N-terminal inserts.

⁷⁶³ Frequent or infrequent attacks of stupor/coma lasting hours/days with diffuse 13-18 Hz activity on EEG and excess endozepine 4 in blood and CSF, mainly in males, average age of onset being in late 40s.

⁷⁶⁴ **Phenylketonuria (PKU)**: The incidence of PKU is 1 in 20,000. There is phenylalanine hydroxylase deficiency and phenylpyruvate and its derivatives are excreted in the urine. Cerebral damage is associated with intellectual disability and epilepsy. PKU is managed by avoiding phenylalanine in the diet (especially in the first months of life) and by giving tyrosine supplements.

⁷⁶⁵ **Homocystinuria** is an autosomal recessive disorder with lack of hepatic cystathione synthetases due to mutations in the cystathione-beta-synthetase gene at 21q22.3. Ectopia lentis, enlarged joints, hair that is fine and fair, skeletal abnormalities, cardiovascular disease (thrombo-embolism), emotional instability, with or without intellectual disability. Treat by restricting methionine intake.

Homocysteine, a simple amino acid, is said to be a risk factor for atherosclerotic disease, and possibly dementia as well. There is some evidence for a role for low and high homocysteine levels in depression⁷⁶⁶ and schizophrenia, respectively. (Sachdev *et al.*, 2005; Neeman *et al.*, 2005; Kim *et al.*, 2008) Levels increase with age. It is a central metabolic intermediate in the metabolism of sulphur-containing amino acids, and⁷⁶⁷ it can be converted to either methionine or cysteine. Elevated plasma levels of homocysteine increases the risk of disease in coronary, carotid and peripheral blood vessels. Homocysteine might cause oxidative damage to vessel walls, proliferation of vascular cells, and promote the development of a prothrombotic state. There are a number of ways in which homocysteine might lead to dementia: cerebral micro-angiopathy, endothelial dysfunction, oxidative stress, and enhancement of beta-amyloid peptide-dependent neurotoxicity and neuronal apoptosis. Elevated plasma homocysteine levels have reported in young male patients with chronic schizophrenia. (Levine *et al.*, 2002) Homocysteic acid, a metabolite of homocysteine, can cause neuronal excitotoxicity by stimulating NMDA receptors. Taking a normal diet and large doses of folate, vitamin B12 or betaine will usually reduce plasma homocysteine levels. Deficiency of folate or B12 causes reduced activity of methionine synthetase with an increase in homocysteine and a reduction in the formation of S-adenosyl methionine. There is some evidence that deficiency of these vitamins may be associated with a poor response to treatment for depression⁷⁶⁸ and that correction of such deficiencies may improve responsiveness. (Gottfries & Karlsson, 1997, p. 22)

Regarding those inborn errors of metabolism involving the Krebs-Henseleit cycle (which converts ammonia to urea), defects may occur at the points of conversion of carbonyl aspartate to citrulline (hyperammonaemia), the metabolism of citrulline to argininosuccinate in the presence of aspartate (citrullinaemia), and when argininosuccinate is changed to fumarate and arginine (argininosuccinic aciduria), all leading to disorders characterised by intellectual disability, cerebellar ataxia, poor muscle co-ordination, and, in some cases, seizures.

Psychopharmacology

'Psychopharmacology is a mixture of science and marketing, and the onus is on clinicians to be thoughtfully skeptical'. (Ghaemi, 2003, p. 123)

The *therapeutic index* (relative safety) of a drug refers to the gap between the therapeutic and toxic doses of that drug. A narrow index (as with lithium) suggests that careful prescribing and regular monitoring of levels in appropriate body fluids is required. ED₅₀ is the drug dose producing the wanted effect in half the subjects receiving the drug while the LD₅₀ is the dose that will kill 50% of people who receive the same drug. LD₅₀/ED₅₀ = therapeutic index.

Various markers of vulnerability to depression have been described: a possible increase in platelet MAO B, a decrease in CSF 5-HIAA, reduced platelet ³H-imipramine binding, possibly increased platelet α -2 adrenergic density, decreased platelet ³H 5-HT uptake, increased lymphocyte beta-adrenoreceptor density, diminished platelet 5-HT induced aggregation, increased 5-HT₂ receptor density, and delayed induction of early REM sleep phase by the muscarinic agent arecholine.⁷⁶⁹

Antidepressants are actually system stabilisers and require time to carry out their wanted actions. They may exert their effects presynaptically⁷⁷⁰ or postsynaptically⁷⁷¹.

Schizophrenia and lipid metabolism

Two polyunsaturated fatty acids (PUFAs) are essential in humans: linoleic and α -linolenic acids.⁷⁷² Levels of arachidonic acid in the frontal lobes, platelet conversion of arachidonic acid to prostaglandins, red cell

⁷⁶⁶ Perhaps high levels of homocysteine cause cerebrovascular disease and neurotransmitter deficiency, leading to depressed mood. (Folstein *et al.*, 2007)

⁷⁶⁷ At the intersection of the re-methylation and trans-sulphuration pathways.

⁷⁶⁸ Jacka *et al.* (2010), in a study of women, found that a traditional (wholesome) diet was associated with a lower likelihood of anxiety and depression than was a 'western' (fried/refined/sugary and beer) diet but direction of causality makes interpretation difficult.

⁷⁶⁹ Arecholine is contained in the betel nut [*Areca catechu*] which is commonly chewed by schizophrenic patients in developing countries, with some claims for a beneficial effect on positive and negative symptoms, but it is a factor in the development of oropharyngeal carcinoma. (Kuruppuarachchi & Williams, 2003)

⁷⁷⁰ Synthesis, release, metabolism or uptake of NTs.

⁷⁷¹ Recognition sites/receptors; transducers: G-proteins that couple a receptor to a secondary messenger; secondary messengers, such as cyclases and the PI system; function, such as at ion channels.

⁷⁷² PUFAs are stored in membrane phospholipids, are released by phospholipase A2 and related enzymes and act as precursors for a variety of chemicals such as prostaglandins.

membrane arachidonic acid and docosahexaenoic acid, and platelet membrane PUFA are reduced in schizophrenia. Brain phosphodiester concentration is increased in first episode cases, which may relate to increased breakdown of phospholipase A2. Phosphomonoesters are less plentiful, possibly due to decreased synthesis of phospholipids.

Phospholipase A2 is the rate-limiting enzyme in prostaglandin synthesis. It catalyses the release of PUFAs from phospholipids and is involved in synaptic outgrowth. Calcium-independent phospholipase A2 activity is increased in schizophrenia, whereas calcium-dependent activity is normal. In late childhood/early adolescence a normal pruning in synaptic density occurs. It is possible that increased phospholipase A2 activity could cause this process to fail. Furthermore, an abnormal gene in schizophrenia for phospholipase A2 has been postulated.

Lipid peroxidase and vitamin E concentrations are increased in schizophrenia, more so if patients smoke. In cancer, endogenous reactive oxygen species released during normal respiration damage nucleic acids and lipids. Because of this, it has been speculated that PUFA and antioxidant supplements might be beneficial in schizophrenia, perhaps in the form of eicosapentaenoic acid. However, supplementation with this last omega-3 fatty acid⁷⁷³ (Miyamoto et al., 2002, p. 795) was ineffective in a trial conducted by Fenton et al. (2001). Nevertheless, Amminger et al. (2010) reported that long-chain omega-3 fatty acids⁷⁷⁴ may prevent the development of full-blown psychosis in young people with subthreshold psychotic states.

Polymeropoulos et al. (2009) studied the expression profile of over 12 thousand human genes in a cell treated with various antipsychotic drugs and compared the results to a library of other compounds employed in the treatment of other conditions. There was a common effect of antipsychotics on biosynthesis and regulation of fatty acids and cholesterol leading the authors to wonder if changes in lipid homeostasis might underlie the pathogenesis of schizophrenia: antipsychotics not only activated genes involved in lipid homeostasis but they did so preferentially from all other genes. Polymeropoulos et al. (2009) suggested that antipsychotics alter the ratio of polyunsaturated to saturated fatty acids and cholesterol content, which modulates fluidity of neuronal membranes and the membranes of surrounding cells. The end result could be changes in neuronal connectivity.

There is some preliminary evidence that eicosapentaenoic acid may augment antidepressant efficacy in major depression, (Nemets et al., 2002) although dosage may be crucial. (Peet & Horrobin, 2002) Marangell et al. (2003a) found no significant effect for docosahexaenoic acid in subjects with major depression. According to Stoll et al. (1999) omega-3 fatty acids may have greater antidepressant than antimanic effects in bipolar disorder, and Noaghiul and Hibbeln (2003) suggest that greater seafood consumption reduces the prevalence of bipolar disorder. Frangou et al. (2006) reported the effective use of adjunctive ethyl-eicosapentaenoic acid in bipolar depression. Seafood and fish are rich dietary sources of eicosapentaenoic acid and docosahexaenoic acid. Miyake et al. (2006) failed to find a clear effect of dietary fish in preventing postpartum depression. Hallahan et al. (2007) reported a reduction in surrogate markers of suicidal behaviour and increased well-being in repetitive self-harmers receiving the long-chain omega-3 essential fatty acids eicosapentaenoic acid (EPA) plus docosahexaenoic acid (DHA). Anonymous (2007b) concluded that omega-3 fatty acids should not be used on their own for treating depression⁷⁷⁵, but they *might* be helpful when added to existing antidepressant medication.

Breast milk, but not formula feeds, contains eicosapentaenoic and docosahexaenoic acids, leading Walker et al. (1999) to suggest improving nutrition in pregnancy and breast-feeding of the child. However, the association between breast-feeding and schizophrenia is tenuous. (O'Shea, 1997)⁷⁷⁶

Some factors involved in ageing

Genetic factors

⁷⁷³ Thought to be anti-inflammatory and perhaps to promote neurogenesis.

⁷⁷⁴ Given as concentrated marine fish oil.

⁷⁷⁵ Depressed patients were noted to have relatively low tissue concentrations of different components of the omega-3 pathway. There is some evidence to suggest that EPA may be the more effective agent in depression: DHA used alone may be ineffective and EPA is incorporated into body tissue quicker than is DHA. (Coryell, 2008, p. 518)

⁷⁷⁶ Similarly, breast-feeding does not improve intelligence in children. (Der et al., 2006)

Contribute 25-33% of variance in human longevity (Bittles, 2008, p. 3)

Cell ageing

The Hayflick limit refers to the fact that cultured fibroblasts stop dividing after a certain number of divisions. The message to do so may be sited at the telomeric end of the chromosome, the latter region shortening each time a cell divides until a crucial length is reached.

Leucocyte telomeric length shortening may be reduced in patients with coronary artery disease by giving omega-3 fatty acids (Farzaneh-Far et al, 2010)

Oxidative stress

Free radicals (reactive oxygen species) overcome antioxidants leading to DNA mutations/deletions, affecting mitochondrial more than nuclear DNA⁷⁷⁷. Hastened by oxidative stress, protein and sugar react to produce glycosylation (protein glycation) with functional and structural damage to the protein.

Olive oil

The Mediterranean diet involves abundant use of olive oil, a rich source of monounsaturated fatty acids. There is some preliminary evidence that such a diet may help to prevent depression. (Sánchez-Villegas et al, 2009) One major limitation with this type of research is failure to control for a variable that might lead to both low depression levels and high consumption of certain culinary items (fish, olive oil, etc), e.g. active extended family networks.

Evening primrose oil

This treatment for premenstrual dysphoric disorder contains gamma-linolenic acid, an essential fatty acid precursor of prostaglandin E1 (PGE1). PGE1 is thought to decrease the effects of prolactin, the latter being one possible mechanism for premenstrual dysphoric disorder. Evidence of efficacy from randomised controlled trials have been negative. (Steiner & Yonkers, 1998, p. 15)

Some neuropathological phenomena

Necrosis follows acute ischaemia or trauma. Free radicals and excitotoxins⁷⁷⁸ are released.

*Apoptosis*⁷⁷⁹ is a normal regulatory mechanism but can be pathological (physiological v aberrant apoptosis). Acute cases occur around an area of necrosis (the penumbra). It affects individual cells that are removed by macrophages and adjacent cells. The apoptotic cell is small, round, and may be surrounded by a halo that separates it from other cells; the cytoplasm is eosinophilic and the nucleus contains condensed chromatin. Programmed cell death⁷⁸⁰ is an analogous process that occurs in developing organisms and can be illustrated by the removal of webs between the digits. Caspases⁷⁸¹, cysteine-dependent, aspartate-specific proteases, are involved in apoptosis. These enzymes, which exist as procaspases (latent precursors) before activation, cleave other proteins, e.g. caspase 3 targets cytoskeletal proteins, DNA repair proteins, etc. Neuronal apoptosis is induced by beta-amyloid and mutated presenilins in Alzheimer's disease. Mutant huntingtin protein can cause neuronal apoptosis in Huntington's disease⁷⁸². The role of apoptosis in conditions such as schizophrenia⁷⁸³ requires further research. (Gaffney, 2002; Friedlander, 2003) BCL-2 is the human proto-oncogene on chromosome 18, the translocated locus in **B-cell** leukaemia. Bcl-2 proteins are involved in the response to apoptosis. Chronic lithium treatment increases Bcl-2 levels in rat brain and may be neuroprotective. (see Kessing et al, 2008)

Diaschisis is the idea that a lesion may influence brain regions far from the damaged area.

⁷⁷⁷ Numbers of mitochondria and their genomes vary with the tissue looked at, being high in muscle because of its high respiratory demand. There is an increase in random deletion of mtDNA with age. Voluntary muscle fibres have more mitochondrial electron transport problems as the organism ages. (Bittles, 2008, p. 10)

⁷⁷⁸ Glutamate, calcium, cytotoxic cytokines, etc.

⁷⁷⁹ Gk. dropping off of petals.

⁷⁸⁰ If cells didn't die in multicellular organisms tissue accumulation would reach astounding proportions! Apoptosis (shrinkage of cells), necrosis (swelling of cells), and possibly autophagy (starving cells eat their constituents) are the known modes of cellular demise. (Hotchkiss et al, 2009)

⁷⁸¹ Cysteine-requiring **aspartate** protease.

⁷⁸² Huntingtin is a protein associated with synaptic vesicles. It may trigger NMDA receptor-mediated excitotoxicity. Excitotoxicity is involved since injected excitatory amino acids mimic the pathology of Huntington's disease.

⁷⁸³ Reduced levels of the anti-apoptotic Bcl-2 family of proteins in schizophrenia and their increased levels with neuroleptic therapy.

Focal cortical dysplasia (FCD) consists of collections of large, bizarre neurones and ‘grotesque’ cells in cortex and underlying white matter. Clinical severity varies, the mildest degree consisting of microdysgenesis (neuronal heterotopias⁷⁸⁴, undulating cortical layers, or collections of nerve cells). Common manifestations of FCD are developmental delay, low IQ, seizures, and focal neurological deficits. *Hemimegalencephaly* is an abnormally big and dysplastic cerebral hemisphere, the opposite hemisphere being compressed. The affected hemisphere shows an enlarged and abnormally shaped lateral ventricle, hypertrophic white matter, and cortical dysgenesis. The cause is unknown but some cases have abnormal expression of L1CAM (L1 neural cell adhesion molecule), the latter having a regulatory role in neuroblast migration and the development of axons. Classical cases have developmental delay, hemiparesis, and intractable partial seizures from birth or infancy. Hemispherectomy may provide seizure control. Other manifestations include neurofibromata, hypomelanosis of Ito, epiloia, and linear nevus syndrome. *Hirano bodies* are small, eosinophilic rod- or carrot-shaped bodies that may be found in or close to pyramidal nerve cells of the hippocampus. They contain the microfilament protein actin and are numerous in Alzheimer’s disease. *Holoprosencephaly*⁷⁸⁵ may involve non-separation of the cerebral hemispheres, a single midline eye, one nostril, and similar defects. Severe cases do not survive but mild cases may be represented by hypertelorism or a single incisor tooth occupying the midline. All degrees of intellectual disability have been reported. The majority of cases are due to chromosomal abnormalities. A number of genetic mutations have been described as underlying sporadic cases.⁷⁸⁶

Lewy body

Lewy bodies are laminated intracytoplasmic inclusion bodies in melanin containing neurones of the substantia nigra derived from the neuronal cytoskeleton. They are often seen in the remaining cells of the substantia nigra in Parkinson’s disease. They can also be found in the pigmented cells of the locus coeruleus, dorsal vagal nucleus and reticular formation. On haematoxylin and eosin staining, substantia nigra Lewy bodies are pink, often with concentric rings and a surrounding colourless halo. Outside pigmented nuclei⁷⁸⁷ they may be amorphous. With the development of the concept of Lewy body dementia,(Q.V.) it has become clear that these eosinophilic intraneuronal inclusion bodies have a core of phosphorylated and non-phosphorylated neurofilament protein, microtubule protein, the protein ubiquitin⁷⁸⁸ and tau protein and can be found in cerebral cortex⁷⁸⁹. Antibodies to ubiquitin and α -synuclein⁷⁹⁰ can be used in postmortem tissue as a method of detecting Lewy bodies. The first genetic cause of Parkinson’s disease was reported in 1997: a mis-sense mutation altering the fifty-third amino acid of the α -synuclein protein (A53T). Shortly thereafter, α -synuclein was found in Lewy bodies. Discovery of another mutation (A30P) followed. Genetic triplication⁷⁹¹ is associated with onset of Parkinson’s disease and dementia with Lewy bodies in the mid-thirties. Genetic duplication⁷⁹² also leads to disease in some European families. Triplication is far more likely to be associated with dementia than is duplication.(Singleton & Gwinn-Hardy, 2004)

⁷⁸⁴ The neurones are not in their correct position.

⁷⁸⁵ Prosencephalon = forebrain.

⁷⁸⁶ E.g. sonic hedgehog or SHH gene (chromosome 7q.36).

⁷⁸⁷ Substantia nigra and locus coeruleus.

⁷⁸⁸ This is tagged on to other proteins so that they become degradation targets.

⁷⁸⁹ Temporal, hippocampal, cingulate, limbic and neocortical areas.

⁷⁹⁰ α -synuclein is normally present presynaptically and appears to be important for memory and learning.

⁷⁹¹ 3 copies of α -synuclein gene on one chromosome 4 and one copy on the other chromosome 4 = 4 genes.

⁷⁹² One extra copy of the α -synuclein gene = 3 genes.

Lissencephaly (a smooth brain: pachygyria and agyria⁷⁹³ and less cortical layers than normal) is a result of early disruption in cortical neuroblast generation. The severest cases involve the complete cortex with associated severe intellectual disability, paralysis, seizures, and cortical blindness. Mild cases involve small areas of cortex and may account for a significant proportion of childhood epilepsy. Mutation in the LIS1 gene⁷⁹⁴ is associated with Miller-Dicker syndrome⁷⁹⁵. Another form of lissencephaly is X-linked⁷⁹⁶, usually sporadic, sometimes familial, mainly affecting males (mild in females), with an inverted cortical neuronal lamination. Mutation of the RELN gene⁷⁹⁷ is found in the lissencephaly/cerebellar hypoplasia syndrome type-b.⁷⁹⁸

Necrosis is a response to noxae that kill adjacent tissues via inflammation and cicatrization.

Neurofibrillary tangles (NT) appear as coils of argentophilic⁷⁹⁹ tangled bundles. On electronmicroscopy, they are made up of paired helical filaments. The tangle is formed from tau protein itself derived from microtubules. Tau protein in Alzheimer's disease is abnormally phosphorylated by protein kinases, less soluble than normal, and unable to bind to microtubules. Glycogen synthase kinase-3 (GSK-3) is an important enzyme in this phosphorylation process. (Lovestone, 1997) Such abnormal phosphorylation of tau causes the neurofilaments to become cross linked and hence form insoluble complexes. (McKeith, 1997) Heavily phosphorylated tau does not bind to microtubules, leading the latter to collapse. Many affected neurones die and disappear in the latter stages of Alzheimer's disease, leaving *ghost/tombstone tangles*⁸⁰⁰. NTs are usually confined to the hippocampi in normal ageing, whereas in dementia they are more widespread and prevalent. NTs are found in almost every person surviving to the tenth decade.

NTs in Alzheimer brains abnormally express a fetal brain protein antigen known as Alz-50.

In association with NTs, the axonal processes emerging from neuronal soma contain neural thread protein that may be important in the repair and regeneration of neurones.

Periventricular nodular heterotopia consists of groups of cells in the wrong part of the correct tissue, in this case in the periventricular and subcortical white matter. There seems to be a failure of neurones to migrate to the cerebral cortex. There may or may not be other brain or other system anomalies. Females are affected more than males. Mutations in the FLNA gene on Xq have been reported⁸⁰¹. Seizures are the most common complication, and IQ is most often normal or somewhat lower than that.

Pick bodies are rounded, perinuclear condensations of straight (contrasting with helical Alzheimer) filaments found in cortical neurones. They contain cytoskeletal elements that bind polyclonal antibodies against neurotubules and a monoclonal antibody against neurofilaments.

Pick cells are cortical neurones that have been expanded and enlarged (ballooned) by argyrophilic bundles of neurofilaments.

Polymicrogyria consists of a cerebral cortex with excessive microscopic gyration. There are abnormal lamination of cortex with excess folding and fusion of gyri. Both perisylvian regions are affected in the commonest type. Most cases have epilepsy. X-linked cases have been described. Non-genetic causes include congenital cytomegalovirus infection, hypoxia, or reduced perfusion of the brain. Sometimes polymicrogyria may be part of a wider disorder, e.g. velocardiofacial syndrome.

Schizencephaly (developmental cortical clefts⁸⁰²) can arise as a result of focal ischaemia in the second trimester, cytomegalovirus infection, or, possibly, genetic mutations. Cavities may be open- or closed- (apposed walls) lipped. Open cases have seizures or hydrocephalus. Closed cases have motor delay or hemiparesis. There may be no septum pellicidum. Cases occur with hypoplasia of the optic nerves.

Senile (neuritic) plaques: a group of abnormal argyrophilic neuritic processes together with reactive microglia and astrocytes arranged in roughly spherical formation, with (mature plaque) or without

⁷⁹³ Pachygyria = broad, simple gyri; agyria = no gyri.

⁷⁹⁴ Chromosome 17p13.3 – protein product binds tubulin.

⁷⁹⁵ Severe intellectual disability, thick upper lip, upturned nose, high forehead, and lissencephaly.

⁷⁹⁶ Mutation at DCX or Doublecortin gene at Xq22.3-q23, its protein product also binding tubulin.

⁷⁹⁷ Human version of reelin in mutant reeler mouse, the latter suffering from a movement disorder.

⁷⁹⁸ Thick cortex, pachygyria, abnormal hippocampus, and hypoplastic cerebellum.

⁷⁹⁹ Plaques and tangles were stained with silver impregnation techniques. Immunostaining (using antibodies against important abnormal proteins) is the more modern approach.

⁸⁰⁰ Tangles without a neurone: especially common in hippocampus.

⁸⁰¹ A few cases are associated with abnormal 5p. Some others have microcephaly and autosomal recessive inheritance with ARFGEF2 gene (chromosome 20) mutation.

⁸⁰² If there is white matter or gliosis (T2 signal) then the diagnosis is more likely to be **porencephaly** (CSF-filled cysts due to destructive processes, e.g. infection or stroke).

(immature plaque) a core of extracellular amyloid. This amyloid is amyloid β -protein (A β , 39 to 43 amino acids), derived from a membrane-bound precursor, amyloid precursor protein (APP). The gene for amyloid precursor protein (APP) is on chromosome 21.⁸⁰³ Amyloid β -protein is a normal physiological product. It is hypothesised that amyloid β -protein deposition leads to tau phosphorylation, tangle formation and cell death: the so-called 'amyloid cascade'. It has also been suggested that amyloid precursor protein gene mutations alone can account for all pathology found in Alzheimer's disease. Senile plaques are found in 75% of people who reach their ninetieth birthday.

Subcortical band heterotopia (SBH, subcortical laminar heterotopia or 'double cortex') consists of bilateral bands of grey matter (disorganised neurones, better organised small neurones, and deeper nodules) lying between normal cortex and lateral ventricle and visible on MRI. Mutations in the DCX (X chromosome) and LIS1 (at 17p) genes have been described⁸⁰⁴. It is much more common in females. Seizures and mild to moderate intellectual disability are the typical features.

Prescribing during pregnancy and breast-feeding (O'Shea, 2001; Burt ea, 2001; Kohen, 2004; Yonkers, 2007)

'There is rarely a valid reason to stop essential drug treatment during pregnancy'. (Kohen, 2004)

Maternal depression in early pregnancy is a risk factor for preterm delivery. (Li ea, 2008⁸⁰⁵) Webb ea (2008) examined a Danish population-based cohort and found a higher risk of fatal birth defect in the offspring of mothers (but not fathers) who had schizophrenia or affective disorder. This type of research does not say why this should be so: genes (and their interaction with environment), diet, smoking, alcohol, drugs (including medication), antenatal care issues, etc? King-Hele ea (2008) looked at live births and stillbirths over a 25-year period in Denmark. The offspring of mothers who had been admitted to hospital for mental illness at any time before the birth were at considerable risk of stillbirth and neonatal death; mothers with alcohol or substance dependence had an increased risk of stillbirth due to delivery complications; and women with affective disorders were more likely than comparison subjects to have stillborn babies with congenital abnormalities. Pregnant women in Taiwan with bipolar disorder are at increased risk for delivering low birth weight babies, preterm infants, and offspring who are 'small-for-dates' when compared with subjects who have no history of mental disorder. (Lee & Lin, 2010) Schizophrenia in either parent may be associated with increased likelihood of death of the baby. (Nilsson ea, 2008) In addition to the mother's behaviour, poor social and parenting circumstances seem to be important. The untreated mentally disordered pregnant woman may neglect her diet, smoke, drink alcohol, abuse illicit substances, neglect personal and domestic hygiene, rarely take exercise, miss antenatal appointments, self-harm, and otherwise put herself and her unborn child at risk. Unfortunately, this scenario is not confined to the mentally ill. (Mc Millan ea, 2006) Maternal obesity⁸⁰⁶ may increase the risk of preterm births. (McDonald ea, 2010) The pregnant state is associated with reduced motility in and reduced emptying of the stomach. Volume of distribution is enlarged. Liver metabolism increases.⁸⁰⁷ Albumen levels fall. Drug binding capacity is diminished. Finally, the glomerular filtration rate is increased. Higher than usual doses of SSRIs or TCAs may be required to achieve remission from depression during pregnancy. Hepatic function and plasma protein binding are relatively low in the foetus, whereas cardiac output and blood-brain barrier permeability are relatively high. (Kohen, 2004) Medications may be available to the unborn via the placenta, and perhaps via the amniotic fluid. (Loughhead ea, 2006) Immature liver enzymes in premature babies places them at increased risk for adverse effects when exposed to drugs in maternal milk.

Adverse effects on fetus

⁸⁰³ q21; By way of contrast the genes for presenilins 1 and 2 are on chromosomes 14 [q24] and 1 [q31-42] respectively; like amyloid precursor protein, these are associated with early onset Alzheimer's disease. Presenilins are gamma-secretases (aspartyl proteases) that cleave APP into the 42 amino acid version of amyloid peptide (A β 1-42).

⁸⁰⁴ Males with mutations in DCX often have lissencephaly but affected females will have SBH.

⁸⁰⁵ This prospective cohort study also found that greater severity of depression increased the risk of preterm delivery and that the risk was exacerbated by low educational level, a history of fertility problems, and the presence of obesity and stressful events.

⁸⁰⁶ Maternal smoking may be a confounder.

⁸⁰⁷ The volumes of plasma and blood increase during pregnancy. Hepatic blood flow is unchanged. Therefore there is a fall in the proportion of cardiac output reaching the liver. As a result, metabolism of drugs may be affected.

- **Teratogenic** – first trimester exposure
- **Neonatal toxic and abstinence syndrome** – third trimester exposure
- **Behavioural/developmental** – evident later in childhood

The two best known drugs to be prescribed during pregnancy were the hypnotic thalidomide⁸⁰⁸, withdrawn in 1961, and diethylstilbestrol (DES – used to prevent miscarriage and later, in the USA, as a morning-after pill – associated with vaginal adenocarcinoma in young adult female offspring⁸⁰⁹). (Porter, 2002, p. 107)

The association between DES and malignancy is now in doubt. (Hollingworth, 2005, p. 772) Thalidomide⁸¹⁰ came back in use for the treatment of leprosy,⁸¹¹ multiple myeloma,⁸¹² multiple sclerosis, and wasting and aphthous ulcers in AIDS. Phenytoin, carbamazepine, sodium valproate, lithium, warfarin (dysmorphia and abnormal bone growth), carbimazole (neonatal hypothyroidism), retinoids (multiple anomalies), ACE inhibitors or antagonists (oligohydramnios), and danazol are commonly used teratogens. On the other hand, metoclopramide may be safe during the first trimester of pregnancy. (Matok ea, 2009a)

Dual diagnosis⁸¹³ is common. Females with schizophrenia are more likely to get married than males with the disorder, but, once married, males may have more offspring than their female co-sufferers, thus ensuring transmission of the disorder. Older studies of reproduction rates showed decreased reproduction rates in schizophrenic patients, but these rates appear to have increased over time, perhaps in part due to communitisation and lack of contraceptive advice. Also, atypical antipsychotics are less likely to induce hyperprolactinaemia and are associated with improved social functioning, thereby increasing the probability of conceiving. Assortive mating is relatively common among the mentally ill. Clinicians will see pregnancies where at least one of the parents has schizophrenia.

About 1-3% of birth defects result from drug exposure in utero. The classic teratogenic period occurs during weeks 3 to 8 post-conception, during organogenesis. Before 3 weeks, drugs may have an all-or-none effect: survival or death⁸¹⁴. After 9 weeks drugs can affect growth or functional development. Apart from huge molecules, most drugs cross the placenta. Drug efficacy may be altered in pregnancy, e.g. increased metabolism or excretion necessitating increased dosage. Perhaps 50% of pregnancies are unplanned. At least one third of pregnant women in the UK are prescribed one course of drug treatment, and 50% of pregnant women prescribed medication do not take it⁸¹⁵. We have no large clinical trials to guide our prescribing habits during pregnancy. Such studies that are available are retrospective involving, for example, chart reviews or prescription monitoring.

Dosing requirements of antidepressants increase by a factor of about 1.6 times the non-pregnant dose during the second trimester of pregnancy. (Abel, 2007, p. 641)

The long-term consequences of being born preterm *per se* should be borne in mind when interpreting the literature. A Norwegian study (Moster ea, 2008) followed up survivors of preterm birth to adulthood.

Cerebral palsy affected 0.1% of term babies v 9.1% of those born at 23-27 weeks gestation; the prevalence of intellectual disability was 0.4% v 4.4%; and the prevalence of receiving a disability pension was 1.7% v 10.6%. Gestational age at birth among those lacking medical disabilities was associated education level,

⁸⁰⁸ About 12,000 children with limb deformities due to thalidomide were born. (Tuffs, 2007b) Major limb malformations affected about a third of exposed cases. (Paton, 2008)

⁸⁰⁹ DES is unlikely to cause later psychiatric disorders according to Verdoux ea. (2007)

⁸¹⁰ Lenalidomide, an analogue of thalidomide that should also be avoided in women of child-bearing age, has been used to treat early myelodysplasia with deleted chromosome 5q.

⁸¹¹ Thalidomide was found to reduce pain in leprosy in 1964. (Bynum ea, 2006, p. 396) Adverse effects include sedation, constipation and peripheral neuropathy. Thalidomide was used for type II lepra reaction (erythema nodosum leprosum) but the WHO no longer recommends its use because of associated teratogenicity.

⁸¹² Thalidomide has immunomodulatory actions and anti-angiogenic effects against blood vessels in neoplasms.

⁸¹³ Substance abuse plus mental disorder.

⁸¹⁴ Utero-placental circulation is not established for about a fortnight and home pregnancy tests can detect pregnancy as early as day 10. This raises the problem of sudden cessation of medication with attendant risks of abstinence symptoms and relapse of the syndrome being treated. Changing from one drug (e.g. valproate) to another should preferably be done slowly (with overlap) before conception but this may be impractical and ineffective after pregnancy is discovered. (Tomson, 2009)

⁸¹⁵ According to Daughters ea (2007, p. 224), women (compared to men) less often abuse substances and start such abuse relatively late but quickly become dependent and suffer severe and early consequences and have more co-morbid psychiatric problems (anxiety and mood); they are more likely to have a substance-abusing partner and tend to cope with relationship loss by resorting to drugs; they are less likely to enter treatment because, e.g. social attitudes and responsibilities for children.

income, receipt of social security payments, and establishing a family, but not with not having a job or being involved in criminal activity.

Benzodiazepines (BZDs), diazepam in particular, are widely prescribed during pregnancy. If a tranquilizer or hypnotic is considered necessary in pregnancy or in the puerperium, then only a BZD should be used. Earlier studies suggested that the latter could cause lip, palatal, and cardiac defects but these have not been upheld. At most there is a 0.7% risk for cleft palate with first trimester exposure. One meta-analysis of cohort trials found no evidence for a connection between BZDs and teratogenesis. Unsurprisingly, since BZDs and barbiturates cause drug dependence in the unborn, withdrawal symptoms have been described in infants. Large doses can cause drowsy, floppy babies with hypotonia, respiratory problems, suckling difficulties, agitation, and hypothermia. High-dose abuse throughout pregnancy has been associated with foetal alcohol-like syndrome⁸¹⁶, but confounding by alcohol abuse is a factor to consider. (Steiner & Yonkers, 1998, p. 41) Benzodiazepines enter both the foetus and the mother's milk. Nevertheless, some authors stress the teratogenicity of BZDs and suggest that they do not be used at all during pregnancy. (Kohen, 2004) The most important time to avoid such drugs is during the first trimester⁸¹⁷. Breastfeeding may diminish BZD (or antidepressants) withdrawal symptoms in neonates exposed to these drugs during pregnancy and suddenly stopping breastfeeding or a drug by the mother may lead to an abstinence syndrome. The wisdom of stopping BZDs at the time of parturition is questioned by Wang et al (2008, p. 421) who point out that anxiety disorders may be exacerbated and that clonazepam (0.5-3.5 mg/day) has been used in panic disorder patients without ill effects in the perinatal period.

Beta-blockers have been associated with initial growth retardation, the baby catching up after birth.

Antipsychotic drugs: There have been a few reports of neonatal Parkinsonism when the mother had been on oral or depot neuroleptics. The newborn may develop dystonic reactions⁸¹⁸, tremors, be flat and slow to suckle, jaundice, and have a low Apgar score⁸¹⁹. Very little neuroleptic actually enters breast milk: in one report (Gardiner et al, 2003) breast-fed infants were exposed to a calculated olanzapine dose of about only 1%. The neonatal mortality of the offspring of schizophrenic mothers is increased. Generally, high potency typical agents are safe and low potency typicals may be associated with a small excess of congenital malformations, although this is disputed. Howland & Thase (2002) consider typical antipsychotic drugs to be generally safe during pregnancy. Clozapine has not yet been associated with such anomalies, and there is as yet insufficient information on risperidone and olanzapine. A report by Koren et al, (2002) however, raises the possibility of neural tube defects in the offspring of obese patients with low folate levels treated with atypical agents during pregnancy. Newport et al (2007) looked at antipsychotic use close to delivery and found that placental passage ratio was highest for olanzapine, followed by haloperidol, risperidone, and (lowest) quetiapine; there were tendencies toward higher rates of low birth weight and neonatal ICU admission among neonates exposed to olanzapine. McKenna et al (2005) found that babies exposed to the newer antipsychotic in the womb were lighter than controls despite the mothers of the former having higher BMIs! However, Newham et al (2008) found that in utero exposure to atypical antipsychotics was associated with increased infant birth weight and size in relation to gestational age. But, these workers found that exposure to typical antipsychotics was associated with lower birth weight and gestational age-related size compared to a reference group! There has been concern about the anti-emetic agent prochlorperazine (Stemetil) being teratogenic when the foetus is exposed between weeks 6 to 10 of gestation. Kohen (2004)

⁸¹⁶ Foetal alcohol syndrome.

⁸¹⁷ The palate is formed during gestational weeks 5 to 9.

⁸¹⁸ Sometimes misdiagnosed as seizures.

⁸¹⁹ After Virginia Apgar, anaesthesiologist, 1953: items with what scores 2 in brackets: colour (pink overall), heart rate (> 100), respiration (strong cry), reflex irritability (cry), and muscle tone (active baby); record score of 0 to 10 (0, 1, and 2 for each item) at 1 and 5 minutes after birth; healthy baby scores at least 7 at 1 minute and 9/10 at 5 minutes. The predictiveness of the Apgar has been criticised. (Hegarty & Craig, 2007) **APGAR**: Activity, Pulse, Grimace, Appearance, and Respiration.

suggests changing from atypical to typical (conventional) drugs prior to conception. Clozapine could improve the chances of becoming pregnant by not increasing prolactin levels.

Antipsychotic drugs can cause breast engorgement and galactorrhoea⁸²⁰ and may be a factor in amenorrhoea (emotional problems are another contributor). These, together with a false pregnancy test (due to antipsychotics) may simulate pregnancy.

Tricyclic antidepressants (TCAs): According to some workers, in utero exposure to TCAs or fluoxetine (an SSRI) does not affect later global IQ, language development, or behavioural development in preschool and early-school children, or cause congenital anomalies.(Nulman ea, 2002; Simon ea, 2002; *vide infra*) Depression in the mother has a more profound effect on these parameters. A withdrawal reaction consisting of irritability, apparent abdominal cramps, restlessness, insomnia and fever, has been reported in some neonates born to mothers who received TCAs during the last month of pregnancy; constipation, tachycardia and urinary retention represent anticholinergic adverse effects; lethargy and hypotonia has also been reported. TCAs remain the antidepressants of first choice in pregnancy and during breast-feeding. Plasma TCA levels may fall (up to 65%) as pregnancy advances, perhaps as a result of an increased volume of distribution; increased dosages may be required later in pregnancy (Steiner & Yonkers, 1998, p. 40) in order to prevent relapse. Non-sedating TCAs, such as nortriptyline (Weissman ea, 2004) and imipramine, are preferred for nursing mothers: these two drugs are also less likely to cause hypotension and anticholinergic effects. Although follow up of infants whose mothers breast fed whilst on dothiepin found no problems, dothiepin has been associated with tachycardia. Also, nortriptyline may cause urinary retention in the newborn. Doxepin (not available after November, 2006), passed in mother's milk, can cause marked neonatal sedation and respiratory depression. TCAs can be given as a single nocturnal dose after the last feed – and night feeds should be avoided if possible.

Specific (or selective) serotonin reuptake inhibitors (SSRIs) should be considered in a woman prone to overdosing or who cannot tolerate TCAs. SSRIs have been associated with neonatal withdrawal phenomena: convulsions, irritability, jitteriness, tremor, insomnia, abnormal cry, and poor adaptation. Laine ea (2003) describe serotonergic symptoms⁸²¹ in newborns where the baby had been exposed to SSRIs during late pregnancy; symptoms were more pronounced if the umbilical venous 5-HIAA concentration was low. Levinson-Castiel ea (2006) found that of 60 neonates exposed who were exposed to SSRIs *in utero*, 8 had a severe and 10 had a mild abstinence syndrome. Chambers ea (2006) reported an increase in the rate of persistent pulmonary hypertension of the newborn⁸²² from 1 in 500 live births to 1 in 100. While this requires further validation,(Mills, 2006) Suri ea (2007), in a naturalistic and prospective study with pregnant women mostly treated with SSRIs and many of whom continued to have depressive symptoms, found an association between treatment and 'lower gestational age at birth and an increased risk of preterm birth', and that depressive symptoms were not associated with this risk. Oberlander ea (2006) reported an excess of low birth weight and respiratory distress in neonates born to depressed mothers who had been given SSRIs. Oberlander ea (2008), after controlling for maternal factors and dose, used population health data and found that neonatal outcome was no different between infants exposed early or late *in utero* to an SSRI but that longer prenatal exposure was associated with lower birth weight, respiratory distress and reduced gestational age ($p < 0.05$). Stopping SSRIs during the last 14 days of pregnancy seemed initially to reduce the risk of neonatal respiratory distress but this relationship was nullified by controlling for maternal (illness severity) and neonatal confounders.(Warburton ea, 2010) Some authorities avoid SSRIs during breast-feeding because "20-25%" of the maternal serum fluoxetine level is found in her milk. This can lead to neonatal agitation, insomnia, tremor, nausea, diarrhoea, rash and, rarely, convulsions. Similar effects have been reported with sertraline (although mean umbilical cord/maternal serum ratios may be lower for sertraline than for fluoxetine: Hendrick ea, 2003; Weissman ea, 2004). Other authorities say that the infant only gets 10% equivalence of the maternal dose of fluoxetine, that sertraline is undetectable in breast milk, and that SSRIs are safe.(Ericson ea, 1999) If they are really needed and the baby is healthy and carefully monitored, they are probably an option. One review of controlled prospective trials of fluoxetine in pregnancy, which looked at the IQs of offspring, were against a teratogenic effect; also, the small numbers

⁸²⁰ In both sexes – disturbed oestrogen to androgen ratio during chronic antipsychotic treatment may be more important than prolactin in male gynaecomastia.

⁸²¹ Myoclonus, restlessness, tremor, shivering, hyperreflexia, incoordination, rigidity.

⁸²² **Persistent pulmonary hypertension of the newborn** (neonatal circulation fails to adapt completely to extrauterine breathing) has been associated with SSRI exposure after the 20th gestational week.

of babies involved in short-term studies where the breast-feeding mother was on fluoxetine are reassuring. Paroxetine may be relatively safe during breast-feeding because the dose received by the baby is so low. In one overview, paroxetine in animals was not teratogenic.⁸²³ However, the FDA issued a warning in December 2005 that paroxetine use during the first trimester may increase the risk of birth defects relative to other SSRIs or no use of antidepressants, especially cardiac defects. GlaxoSmithKline issued a communiqué in May 2006 to the effect that paroxetine use during the first trimester of pregnancy is associated in some epidemiological studies with a small increase in cardiovascular malformations⁸²⁴. GSK was sued successfully in the US over claims that paroxetine caused birth defects.(Tanne, 2009b,c) The Irish Medicines Board, (2006) whilst acknowledging contradictory findings of congenital malformations, issued a warning that paroxetine only be used in pregnancy if 'strictly indicated' and that women planning a pregnancy or becoming pregnant during therapy be asked to consult their physician. However, Einarson et al (2008) found no evidence to suggest that paroxetine in early pregnancy causes cardiovascular malformations. One database analysis (Sanz et al, 2005) found that of 93 suspected cases of SSRI-induced withdrawal syndrome 64 were associated with paroxetine (fluoxetine 14, sertraline 9, citalopram 7). A prospective American study found no teratogenic effects for fluvoxamine, paroxetine or sertraline. Because of its metabolite norfluoxetine's long half-life, fluoxetine's effects may persist for many weeks despite its being discontinued, during which time the woman may have conceived. According to Nulman et al,(2002) in utero exposure to fluoxetine does not affect later temperament, language development, or behavioural development in preschool and early-school children. Simon et al (2002) reported earlier delivery and (therefore) lower birth weight in babies exposed to SSRIs in utero; third trimester exposure was associated with reduced Apgar scores. According to Austin, (2006) most neonatal adverse effects of SSRI following intrauterine exposure are 'mild and self-limiting'. First trimester exposure to sertraline was significantly associated with omphalocele and septal defects in one study, but any defects found in this study of SSRI use 'are rare and the absolute risks are small'.(Louik et al, 2007) A Danish study (Pedersen et al, 2009) found an increased prevalence of septal cardiac defects in offspring of mothers prescribed an SSRI (especially sertraline, citalopram, or more than one SSRI) in early pregnancy. Whilst stating that absolute risks are small, Alwan et al (2007) found increased risks for anencephaly, craniosynostosis, and omphalocele in cases exposed to SSRIs in early pregnancy, but they failed to find an increase in heart defects. Wisner et al (2009) found that infants exposed to SSRIs throughout pregnancy were at increased risk for preterm birth relative to those who were partially exposed and those not exposed; neither SSRI nor depression exposure increased risk for minor physical anomalies or reduced maternal weight gain; mean infant birth weights were equivalent; and the authors concluded that both continuous SSRI exposure and continuous untreated depression were associated with preterm birth rates exceeding 20%. A meta-analysis ordered by the Pharmacovigilance Working Party of the European Medicines Agency concluded that the risk of bearing an infant with a cardiovascular defect following first trimester fluoxetine exposure is about double the base rate (from 1 up to 2/100), the Agency stating that this 'small' increase must be weighed against the risks associated with not treating depression.(Anonymous, 2010a) Because of inconsistent results and methodological issues (Greene, 2007; Chambers, 2009) these studies raise the question of the ability of statistics to detect true rare associations. Risks, if present are small relative to the risk of no or inadequate treatment.(Chambers, 2009)

Monoamine oxidase inhibitors (MAOIs): Where possible, MAOIs should be avoided in pregnant women. Tranylcypromine may be relatively safe for nursing mothers but more studies need to be done in this area with the MAOIs. In general, it is safer to avoid these drugs in nursing mothers because of the risk of inducing hypertension in the infant. Some authorities view MAOIs as teratogens. An increased rate of congenital anomalies has been noted in animal studies. They can also precipitate hypertensive crises. The long half-life of tranylcypromine has similar implication as with fluoxetine above. Moclobemide appears in very low concentrations in breast milk. Caution is required where labour is concerned since MAOIs may

⁸²³ Owens(2004, p. 282) states that intradermal bruising may occur in animals exposed *in utero*.

⁸²⁴ E.g. VSD and, to a lesser extent, ASD. The risk is increased from about 1/100 to < 2/100. See also Dobson (2006) and Donnelly and Paton.(2007) In 2010 Irish and UK authorities advised that fluoxetine may be ('possible') associated with 'a small increased risk of congenital cardiac defects' when used in early pregnancy. This was accompanied by the usual advice to perform a risk/benefit analysis.

interact adversely with narcotic analgesics. They may also interact with drugs used to delay premature labour.⁸²⁵

Novel antidepressants: Much less is known about these agents, e.g. nefazodone⁸²⁶. However, venlafaxine caused no increase in the risk of major congenital anomalies in one prospective study involving 150 pregnant women.(Einarson ea, 2001)

Lithium is teratogenic during the first trimester, although the risk is small.

Lithium: risk of major congenital anomalies (Marangell ea 2003b p. 1106)

With lithium exposure = 4-12%

Without = 2-4%

Defects of the tricuspid valve⁸²⁷ are well described. Oligo- (fetal nephrotoxicity) or poly-hydramnios (fetal diabetes insipidus) may occur. Cohen ea (1994) suggest offering fetal echocardiography and high-resolution ultrasound examination at 16 to 18 weeks gestation. A fetal goiter may press on the trachea during delivery. Lithium clearance doubles during pregnancy and it may be necessary to raise the dose during the second and third trimesters in order to maintain the same serum concentration. At the time of parturition the clearance falls back to 'normal'. This may happen very quickly and the level of lithium may rise in the serum to toxic concentrations unless the dose is rapidly reduced. The ratio of lithium concentrations in umbilical cord blood to maternal blood was uniform across a wide range of maternal concentrations (0.2-2.6 mEq/L) at delivery in a study by Newport ea (2005); higher levels were associated with lower Apgar scores, longer hospital stays, and higher rates of CNS and neuromuscular complications in the newborn. Certain guidelines can be offered: stop lithium slowly before a planned pregnancy; do not give it during the first trimester; also stop it slowly before parturition or scheduled cesarean section (to avoid a cold, blue, floppy baby) or continue lithium at this time (because of high relapse risk – opinions differ); keep the serum levels just above 0.5 mmol/L during pregnancy. Fluids (IV) should be maintained during labour. Start lithium again after a few weeks if the mother agrees not to breast-feed.⁸²⁸ Some authors restart lithium as soon as mother is stable. There may be an association between lithium and premature delivery. Lithium prophylaxis in non-breastfeeding puerperal women who have a history of bipolar disorder or puerperal psychosis should be considered. Lithium enters breast milk freely (it is free in plasma, not protein bound like phenothiazines or TCAs) and so is best-avoided in nursing mothers; the possibility of lithium accumulation in developing bone is an important consideration.

Anticonvulsants & other 'mood stabilizers' are teratogenic in less than 10% of exposed fetuses. Many studies have not controlled for confounding factors such as smoking.(APA, 2009, p. 43) Stopping mood stabilizers, particularly abruptly, during pregnancy carries a high risk of recurrence of bipolar disorder.⁸²⁹ (Viguera ea, 2007) The safest anti-epileptic in pregnancy is the one that best controls the epilepsy⁸³⁰. Monotherapy is safer than polytherapy, especially if one of the drugs is valproate.(Morrow ea, 2006) If an anticonvulsant is needed then best practice dictates the co-prescription of folic acid (5 mg/day) starting before conception to prevent neural tube defects.(Anonymous, 2005b; Burt & Hendrick, 2005, p. 53; Tomson & Hiilemaa, 2007; Clarke, 2009, p. 1143) The genotype of the exposed conceptus may be relevant in determining susceptibility to malformations due to anticonvulsants since a susceptibility gene for valproate-induced anomalies in the mouse has been located. The metabolism of most anticonvulsant drugs is increased during pregnancy.(Leonard, 2003, p. 318) A fetal hydantoin (phenytoin) syndrome has been described which consists of some degree of intellectual disability, hypertelorism, a flattened nose, epicanthic folds, low set ears, and a wide mouth. Neonatal haemorrhage has been reported in the offspring

⁸²⁵ Tocolytic agents (delay labour), e.g. terbutaline.

⁸²⁶ Withdrawn from market.

⁸²⁷ Ebstein's anomaly [tricuspid valve displaced into right ventricle]: risk = 1:20,000 of general population, and 1:700 among infants of mothers taking lithium in first trimester of pregnancy.

⁸²⁸ However, Viguera ea (2007) studied 10 mother-infant pairs and found no adverse effects of lithium on nursing infants.

⁸²⁹ Predictors of recurrence were bipolar II disorder, earlier onset, more frequent recurrences, recent illness, antidepressant use, and use of anticonvulsants versus lithium.(Viguera ea, 2007)

⁸³⁰ Epilepsy appears to be associated with diminished fertility. Menstrual disorders (due to the disease or the medication) and polycystic ovaries (caused by epilepsy or medication) play a role. Involvement of circuits between the temporal lobe and the hypothalamus may be involved. Obesity, and associated metabolic issues, may be caused by anti-epileptic drugs, particularly valproate. Anti-epileptic drugs, on the other hand, may reduce the efficacy of oral contraceptives.

of phenytoin-treated pregnant women; a similar risk applies to carbamazepine-treated cases and to prevent neonatal haemorrhage the mother should receive vitamin K 10-20 mg/day orally from the 36th week of pregnancy and the neonate should be given 1 mg intramuscularly. In fact, antiepileptic drugs in general may increase the likelihood of fetal bleeding, so vitamin K1 should be given to the mother during the last weeks of pregnancy and to the newborn in all such cases⁸³¹. Carbamazepine (which, like the antipsychotic drugs, can cause a false positive pregnancy test) given during the first trimester is associated with a 0.5-1.0% risk for spina bifida; there is also evidence for developmental delay, cranio-facial anomalies, fingernail hypoplasia, cardiovascular and urinary tract defects, hypoglycaemia, hepatic dysfunction, and, possibly, adverse effects on cognitive function. Carbamazepine may be safer than valproate.(Tomson, 2009) Oxcarbazepine⁸³², the 10-keto analogue of carbamazepine, is of unknown effect in pregnancy, although it may also be associated with facial dystrophism.

Valproic acid/valproate taken during the first trimester carries a 1-6% risk of spina bifida. The risk of major congenital malformations is 2 to 4 times higher with valproate (absolute rates 6-11%) compared to carbamazepine or lamotrigine.(Tomson ea, 2009) There is also possibly developmental delay, cranio-facial anomalies, fingernail hypoplasia, heart defects, hypoglycaemia, hepatic dysfunction, and, probably (subject to methodological issues such as non-randomised samples), cognitive dysfunction (lower IQ in offspring compared to other anticonvulsants: Meador ea, 2009). The risks of continuing valproate or carbamazepine during gestation must be carefully balanced against the chances of relapse.(Marangell ea, 2003b p. 1110 & 1112) Teratogenesis due to valproate occurs between weeks 4 and 5 (the patient may be unaware of gestational status) and this may be important in deciding whether to continue prescribing it or not.(Wang ea, 2008, p. 419) In general, avoid valproate unless it is the only drug that controls seizures in pregnancy. NICE recommends that valproate should not be routinely used in women capable of becoming pregnant.

Verapamil may be safe but its efficacy in bipolar affective disorder is not yet clear. Gabapentin, topiramate, felbamate and vigabatrin are too new to give clear guidance on, so are best avoided. Burt & Hendrick (2005, p. 54) state that lamotrigine may be safer in pregnancy than lithium, carbamazepine, or valproate, although there is evidence for a possible increase in non-syndromic oral clefts⁸³³ in the offspring of lamotrigine-treated women.(Holmes ea, 2006; GlaxoSmithKline memorandum, June 2006)

Anticholinergic agents: Trihexyphenidyl and benztropine have been reported to be associated with minor congenital anomalies and neonatal anticholinergic effects, and amantadine is associated with cardiovascular malformations in animals. These agents should be avoided during pregnancy. Babies being breast-fed may develop dry mouth, urinary retention, constipation, and other predictable side effects. Changing an antipsychotic to a low potency agent might obviate the need for such drugs.

Methadone: It has been suggested that pregnant women should only be detoxified from opioids between weeks 14 and 32; before that there is a risk of abortion; later there is the problem of abstinence-induced fetal distress. According to Mack ea (2003, p. 367) there is no absolute contraindication to methadone during pregnancy because 'treatment of neonates for methadone withdrawal is a common procedure'. Bell and Harvey-Dodds (2008) that methadone should be continued during pregnancy. Buprenorphine may be a safe alternative to methadone in pregnancy (Fischer ea, 2006; Bell & Harvey-Dodds, 2008) and is increasingly used in such circumstances.

Codeine: This usually enters breast milk in very small amounts but mothers who are ultra-rapid metabolisers may convert much of this to morphine, with potential lethal effects for the infant.

Electroconvulsive therapy (ECT): If depression, or mania, fails to respond to drug treatment, ECT may be used without harming the fetus.(Nelson & Holmes, 1989; Miller, 1994) However, it is rarely indicated at this time. Its main indication is for severe, drug-refractory depression. The right hip should be elevated to maintain placental perfusion. Succinylcholine and glycopyrrolate⁸³⁴ appear to be relatively safe during pregnancy.(Burt & Hendrick, 2003, p. 1519) Atropine, which crosses the placenta much more efficiently than glycopyrrolate, should be avoided because it causes fetal tachycardia, variable heart rate, and may mask fetal distress. Sodium citrate may be used to reduce the risk of gastric regurgitation.(Burt & Hendrick, 2005, p. 56)

⁸³¹ These drugs cause a decrease in vitamin K-dependent clotting factors in foetal blood.

⁸³² Compared to carbamazepine oxcarbazepine has an extra oxygen atom.

⁸³³ The risk of oral clefts is about 9/1,000 births.

⁸³⁴ Glycopyrronium bromide.

Cigarette smoking: More women worldwide are smoking than ever before. Smoking during pregnancy, considered here by way of contrast with prescribed drugs, is associated with reduced placental blood flow, decreased fetal activity and breathing movements, premature delivery, increased perinatal mortality (including cot deaths: if the father, mother, or both parents smoke, the risk is increased by 2, 4, and 5 times respectively), spontaneous abortion, placenta praevia and placental abruption, histological changes in the placenta, low Apgar scores, low birth weight⁸³⁵, neonatal acidosis, urinary tract infection in infancy, atopy in childhood, higher blood pressure at 9 years and 18 years of age, and long-term negative effects on stature and educational achievement, including conduct disorder⁸³⁶, attention deficit hyperactivity disorder,⁸³⁷ (Linnet *et al.*, 2003; Gray *et al.*, 2009), substance abuse, violence and criminal arrest.⁸³⁷ Passive maternal smoking may affect birth weight. There is some evidence that exposure to smoking *in utero* may increase the risk of both diabetes mellitus and obesity (Montgomery & Ekbom, 2002) and the offspring may be more likely to smoke themselves as adults.⁸³⁸ (Buka *et al.*, 2003) The risk of sudden infant death syndrome is significantly increased by exposure to tobacco smoke either during gestation or postpartum.⁸³⁸ (McDonnell *et al.*, 2002; Webb *et al.*, 2010) Whilst genes may account for most of the risk in offspring for developing ADHD, smoking in pregnancy may contribute to this risk.⁸³⁸ (Thapar *et al.*, 2003) Mothers who smoke during pregnancy may have adolescent offspring who are at increased risk of experiencing psychotic symptoms.⁸³⁹ (Zammit *et al.*, 2009) Chromosomal instability in cells recovered during amniocentesis has been reported in the case of women smoking at least 10 cigarettes daily.⁸³⁹ (de la Chica *et al.*, 2005) Exposure to maternal smoking *in utero* was found to be associated with detectable changes in DNA methylation patterns of their children (epigenesis) both globally and in the promoter region of genes involved in cancer or development.⁸³⁹ (Breton *et al.*, 2009) Simple interventions, such as self-help booklets, are unlikely to stop pregnant women smoking.⁸⁴⁰ (Moore *et al.*, 2002) Nicotine replacement therapy, whilst best avoided in pregnancy and during breast-feeding, is probably safer than smoking.⁸⁴⁰ (Molyneux, 2004; Coleman *et al.*, 2004) Smokeless tobacco (marketed as a relatively safe form of tobacco) use during pregnancy reduces birth weight and increases the likelihood of preterm delivery.⁸⁴⁰ (Prakash & Streevidya, 2004) Stopping smoking before the 15th week of pregnancy seems to reduce the rates of spontaneous preterm birth and small for gestational age infants to those of non-smoking mothers.⁸⁴⁰ (McCowan *et al.*, 2009)

Caffeine: Caffeine is the most common xenobiotic⁸³⁹ consumed during pregnancy. Maternal caffeine intake is negatively correlated with birth weight if the mother already smokes. Excess caffeine is best avoided because it may be associated with restricted fetal growth (CARE Study Group, 2008) and an increase in the stillbirth rate.⁸⁴⁰ (Wisborg *et al.*, 2003)

*Fetal alcohol syndrome (FAS)*⁸⁴⁰ can include various combinations and degrees of severity of stigmata. Apoptotic neurodegeneration follows alcohol-induced NMDA receptor blockade and GABA receptor activation.⁸⁴⁰ (Hotchkiss *et al.*, 2009)

Stigmata of FAS

Antenatal growth retardation

Microcephaly, porencephaly, agenesis of corpus callosum, spinal dysraphism

Prominent forehead

Maxillary hypoplasia, cleft palate

Microphthalmia/epicanthal folds, short palpebral fissures

Long (or smooth) philtrum with corresponding reduction in vermillion of upper lip

⁸³⁵ The effect of smoking on birth weight may depend to some degree on maternal genotype, e.g. the Aa or aa genotype for CYP1A1 may carry over 3 times the risk associated with the AA genotype.

⁸³⁶ The relationship is heavily confounded by other known risks.⁸³⁶ (Maughan *et al.*, 2004)

⁸³⁷ The last findings may be mediated via substance abuse in the offspring [Brennan *et al.*, 2002], although other factors, such as delivery complications and unwanted pregnancy, may play a part.⁸³⁷ (Ishikawa & Raine, 2003, p. 666) Lotfipour *et al.* (2009) found that prenatal exposure to maternal cigarette smoking was associated with increased likelihood of substance use and that exposed adolescents with thinning of the orbitofrontal cortex (OFC) were more likely to experiment with drugs but that non-exposed adolescents were more likely to have a thicker OFC the more drugs they had tried, the latter effect being modified by a BDNF genotype (Val66Met).

⁸³⁸ Of course, there are other known risk factors for SIDS, such as co-sleeping.⁸³⁸ (Mitchell, 2009) Parental mental illness, including alcoholism, appear to be important contributors to SIDS.⁸³⁸ (Webb *et al.*, 2010)

⁸³⁹ A chemical found in an organism that is not normally produced or expected to be present in it, e.g. antibiotics.

⁸⁴⁰ Described in 1973. In *State vs Deborah Z* a mother who drank during pregnancy was not held responsible for FAS because the Wisconsin Appeals Court stated in 1999 that a fetus is not legally a human being. A similar situation applies in the UK.⁸⁴⁰ (Mukherjee *et al.*, 2007)

Short upturned nose
 'Railroad track' ears
 Cardiac septal defects
 Pectus excavatum
 Fine motor dysfunction, developmental delay or intellectual disability

The alcohol levels of the mothers whose offspring had these signs were, it must be stressed, very high. There is evidence for an increase in spontaneous fetal loss, but whether this excess occurs in the first or second trimester is not yet clear. Alcohol-related late abortions and premature deliveries are much more noticeable among heavy drinkers. Joy ea (2003, p. 566) take a very broad view of fetal alcohol exposure effects, warning clinicians of the need to consider them even when a patient's appearance is unremarkable, and they suggest such exposure 'may be the single most frequent cause of' intellectual disability, 'at least in the developed western world'. They put the incidence of FAS as 1/2,000-3,500 live births, and 'far more frequently' in groups such as Native Americans. One group found no correlation between the mental and physical development of 18-month-old children and their mother's weekly consumption of alcohol at levels in excess of 100g of absolute alcohol. In a 10-year follow up of 60 FAS cases, others noted that cranio-facial malformations diminished over time, but microcephaly, and to a lesser extent short stature, persisted. Boys remained underweight, but body weight normalized in girls during adolescence. Mental handicap persisted and was little influenced by environmental or educational interventions. Follow up of FAS adults over 18 years of age with an IQ in excess of 70 has revealed a high incidence of alcohol (supported by Baer ea, 2003: prenatal exposure to alcohol is a risk factor for problem drinking at 21 years of age) and substance dependence, depression, psychosis⁸⁴¹, and avoidant and antisocial personality disorders. Cigarettes cause less damage to the foetus than does alcohol when either is taken in average amounts. Alcohol causes greater damage when large quantities are taken. Moderate drinking, arbitrarily defined as one alcoholic drink per week to 1.5 drinks per day, and occasional or non-drinking seem to affect the foetus similarly. Binge drinking during pregnancy was associated with an excess of substance dependence/abuse and passive-aggressive/antisocial traits/personality disorders in offspring examined at a mean of 25.7 years.(Barr ea, 2006) Most babies born to heavy drinkers, including alcoholics, are normal. Mothers who take an occasional drink during pregnancy may have little to fear, although Mukherjee ea (2005; 2007) and the BMA (Hitchen, 2007) counsel complete abstinence⁸⁴². Disulfiram use during pregnancy has been associated with fetal limb deformities. Too little is known about acamprosate in pregnancy.

Discussion: 1-2% of pregnancies in developed countries may be associated with some form of foetal abnormality. Before prescribing, a risk-benefit analysis is mandatory, as is full discussion with the patient and her partner. Women on antidepressants should receive counselling before conception⁸⁴³ and, where feasible, tapering and stopping of the drug before trying to get pregnant; they should also have been in receipt of counselling about how to prevent conception in the first place. *In general, older drugs are preferable to new ones.* Most antihistamines are considered safe in the short term, although diphenhydramine has been associated with cardiovascular malformations. The analgesic of choice is paracetamol⁸⁴⁴. Avoid preparations containing alcohol, NSAIDs and iodine, e.g. as found in cold and cough cures. In cases of insomnia, sleep hygiene measures (e.g. regular times for retiring and rising, including weekends and holidays, and exercising during the day but not shortly before sleep), stimulus control (retire only when sleepy, get up for a period if unable to sleep and return to bed when drowsy), sleep restriction (adjust time in bed depending on how much of it is spent in sleep), paradoxical intention (deliberately trying to stay awake reduces performance anxiety and increases likelihood of sleep), cognitive therapy, muscle biofeedback, and relaxation exercises should be tried first.(Sateia & Nowell, 2004) Anything else that can be treated is treated next, e.g. itch or pain. Avoid hypnotics if possible. Late third trimester BZD use is of greatest concern because of floppy infants and neonatal withdrawals. Chloral hydrate is a pro-drug that needs to be metabolised to trichlorethanol to produce an hypnotic effect. It has a

⁸⁴¹ Zammit ea (2009) found that women consuming over 21 units of alcohol/week were at risk of having adolescent offspring who experienced psychotic symptoms.

⁸⁴² This is because behavioural problems in infants have been found after their mothers drank as little 1 drink/week. See also O'Brien ea.(2007)

⁸⁴³ This includes all women of child-bearing age.

⁸⁴⁴ Acetaminophen in USA.

narrow therapeutic window (10 mgs. can cause lethal respiratory depression), potentiates the effects of alcohol, has a high abuse potential, and, on cessation, can be associated with very unpleasant withdrawal effects.(Wood, 1997) It has been used recently to sedate children undergoing MRI scanning, with no respiratory complications, when general anaesthesia was unavailable.(Low ea, 2008) The newest drugs, zopiclone (Zopitan) and zolpidem (Stilnoct), should be avoided because of unclear data, as should buspirone⁸⁴⁵.

Depression in pregnancy may respond to non-drug therapies such as environmental manipulation or cognitive therapy (if available). However, medication is often essential.(Mills, 2006) Do not prescribe unless it is essential to do so and record discussions with patient/relatives in the case notes. **Each case is decided on its own merits, keeping in mind that 10% of pregnant women meet standard diagnostic criteria for depression and that relapse rates following discontinuation of medication are high.** TCAs should be slowly tapered and stopped before delivery to avoid neonatal neuromuscular irritability, restlessness, fever and fits.

Ramos ea (2008) found no support for a connection between duration of antidepressant use in general during the first trimester of pregnancy and major congenital malformations diagnosed during the first year of life. It is probably safest to avoid breast-feeding premature babies if the mother is on psychotropics because of hepatic and renal immaturity.

Lithium, TCA and SSRI use in pregnancy is justified *if clinically essential*. Untreated maternal illness may adversely affect obstetric outcome. The nursing infant's daily dose of drug is less than the mother's daily dose. Some authorities are more inclined to stop breast-feeding if the mother is on high doses or combinations of antidepressants⁸⁴⁶. Oestrogens, which may help some cases of postpartum depression, should not be combined with breast-feeding. Interpersonal psychotherapy,(O'Hara ea, 2000) various brief therapies, and counselling (again, depending on availability) are effective alternatives to medication for postpartum depression.

Regarding OCD, it has been suggested that clomipramine is generally safe, despite anecdotal reports of neonatal seizures at time of labour/delivery. SSRIs are *probably* also (relatively) safe. Expert use of exposure and response prevention are alternatives to drugs.

It should be recalled that schizophrenia itself appears to be associated with minor physical anomalies.

Some tentative conclusions derived from a review of the salient literature are shown in the box.

Nevertheless, manufacturer's guidelines should be consulted before prescribing.

Some conclusions

Interpreting statistics: Clinicians and their patients are bombarded with novel drug-risk information.(Avorn & Schneeweiss, 2009) When data on numerous patients taking many compounds are analysed it is inevitable that statistical significance will emerge, sometimes by chance alone. P-value-based thresholds may not tell us anything about severity of the alleged adverse event and fail to provide guidance on safer treatments or factor in benefit from the indicted compound. Hasty reactions may lead to discontinuation of efficacious interventions whereas non-reaction might lead to 'another thalidomide'!

Pregnancy: Polypharmacy is best avoided and doses should be as low as is compatible with maintenance of health. TCAs and fluoxetine do not seem to cause congenital malformations (CMs) and are probably relatively safe. Nevertheless, data on neonatal withdrawal syndrome suggests caution. Reports of a small risk for cardiac defects (paroxetine, fluoxetine) and persistent pulmonary hypertension of the newborn (SSRIs) require further research. Paroxetine is probably best avoided during pregnancy until matters are clarified. Authorities, including the FDA, often suggest discontinuing antidepressants prior to delivery; however, this puts the patient at risk during the high-risk postpartum period. There have been a few reports of MAOIs and associated CMs in humans, more so in animal studies, and they are usually avoided. ECT is as safe as at other times of life. Bupropion use during pregnancy does not appear to be associated with an excess of malformations.(Wang ea, 2008, p. 416) The following drugs are associated with no clear data; only small samples have been reported; and they should not be seen as first-line therapies: psychostimulants, trazodone, venlafaxine, and nefazodone (withdrawn, 2003). Lithium is safer than anticonvulsants (for mood disorders). If used, it should be avoided during the first trimester, and levels

⁸⁴⁵ Buspar was withdrawn, December 2009.

⁸⁴⁶ E.g. Fava and Papakostas (2008, p. 609) discourage mothers from breast-feeding if they are on TCAs.

should be monitored frequently with changes in dosages as necessary. For people planning a pregnancy who are receiving anticonvulsants and who have never been on lithium it may be worth considering a trial of lithium during the non-gravid period. Serum anticonvulsant levels may drop during pregnancy and so should be monitored carefully. Alcohol and nicotine intake can damage the foetus (vide supra). Multiple dosing of neuroleptics (instead of a larger once a day dose) is advised during pregnancy to avoid peak serum concentrations. General advice regarding antipsychotics is to have a drug-free interval around delivery, which necessitated changing to oral medication. The last depot injection can be given at week 28 of the pregnancy and a high potency agent is started on the date when the depot would have next been due. The dose is increased to rough equivalence with the depot and it is again reduced, starting 2 weeks before the expected date of delivery, the aim being to have the mother drug-free 2 to 3 days before onset of labour. Neuroleptics are rapidly reinstated (oral plus depot) shortly after the baby is born. Strong consideration should be given to giving folate supplementation to pregnant patients on atypical neuroleptics. First trimester exposure to folic acid antagonists⁸⁴⁷ should be avoided as far as possible since they double the risk for congenital malformations and increase the risk for neural tube defects six times. (Matok et al, 2009b) Excess coffee intake during pregnancy may be associated with an increased risk of stillbirth. (Wisborg et al, 2003) The decision to employ SSRIs is made on a case-by-case basis in consultation with mother and her significant other. (Austin, 2006)

Breast-feeding: Exposure is reduced by taking medication just after breast-feeding⁸⁴⁸ and by discarding hind milk (contains a higher concentration of milk). Premature infants (immature P450 enzymes) or those with poor liver function are least likely to be able to handle drugs transmitted via mother's milk and it is often decided to defer breast-feeding in such cases. TCAs are usually well tolerated (doxepin may be an exception). SSRIs are mostly safe. High levels of bupropion in breast milk were devoid of adverse effects but data is very limited. BZDs are well tolerated (use lowest possible dose; avoid if infant premature; observe for sedation/CNS effects). Antipsychotics have limited data but probably safe (do not breast feed if on clozapine; [Howard et al, 2004; Kohen, 2005] one case of excessive sleepiness and one case of reversible agranulocytosis in infants breast fed by clozapine treated mothers: Dev & Krupp, 1995) – the older ones have more data than the newer 'atypicals'; however, there is some data attesting to the safety of olanzapine in small numbers of offspring of breastfeeding mothers. (Cohen et al, 2004, p. 602) Malt and Lloyd (2007, p. 785) suggest that sulpiride is the antipsychotic of choice during breast-feeding because of the very low milk levels achieved. Milk lithium levels are up to half maternal plasma levels - if used observe closely, especially infant's fluid status. Valproic acid and carbamazepine (very cautious: breast milk levels are low) use require close monitoring because of the risk to the infant of liver problems and white cell toxicity, although only low levels appear in maternal milk. Adele C. Viguera of Boston (2004) recommended breast feeding to bipolar patients on mood stabilisers. Bromocriptine should be avoided as it suppresses lactation.

In cases of doubt, many clinicians advocate bottle feeding rather than leaving the mother's (serious) mental disorder untreated. It should be noted that stress in later pregnancy has been correlated with preterm delivery. Progestogens inhibit the metabolism of many psychotropic drugs: therefore, stopping a contraceptive preparation may necessitate increasing the dose of a psychotropic, and pregnant women, who have elevated progesterone levels, may need lower doses of psychotropics during gestation, their dosage requirements increasing after delivery. Interestingly, although progesterone is widely used for postnatal depression there is no evidence that it works, and postnatal norethisterone may increase the risk of depression. Oestrogens on the other hand may relieve some severe cases of postnatal depression. The latter may be tried alone or with a standard antidepressant drug.

Where available, psychotherapy may obviate the need for medication in selected cases. A morning walk or light therapy may help patients with seasonal affective disorder; and those with regular summer depressions may benefit from cooling and dark glasses.

Finally, some pregnant women use illegal drugs, e.g. urine testing of pregnant women and post-delivery mothers in Dublin (Bosio et al, 1997) found a prevalence of 2.8%, the most commonly detected drug being cannabis.

⁸⁴⁷ **Folic acid antagonists** include dihydrofolate reductase inhibitors (e.g. trimethoprim and sulfasalazine) that prevent conversion of folate to active metabolites and drugs that reduce serum/tissue folate levels (e.g. carbamazepine, phenytoin, lamotrigine, primidone, valproic acid, phenobarbital, and cholestyramine).

⁸⁴⁸ The problem here is that newborn babies usually feed every 2-3 hours.

Evidence-based medicine (EBM)

'A truth which is clearly understood can no longer be written with sincerity'. (Marcel Proust, 1871-1922)

'Thus, even if not entirely evidence based, psychiatry should always be evidence informed'. (Puri & Treasden, 2010, p. xi)

Levels of evidence in clinical research are shown in the box.

Levels of evidence

Level I DBRCT* - Ia, PC**; Ib, non-PC, meta-analysis/systematic review

Level II Open randomised trial

Level III Observational study – IIIa, non-randomised, controlled study; IIIb, large (> 100 cases) non-randomised, uncontrolled study; IIIc, medium-sized (50 to 100 cases) non-randomised, uncontrolled study

Level IV Small (10-50 cases) non-randomised, uncontrolled study

Level V Expert review/opinion***, single cases (case report) or less than 10 cases (case series)

* Double-blind randomised controlled trial. ** Placebo-controlled. *** 'Eminence-based medicine'.

Steps in evaluation of evidence (Carney, 2010, p. 17)

What am I not sure about and how can I put this in question form?

Where can I find answers, how do I go about it, and how do I measure level of evidence?

How does the available evidence apply to my patient?

Provide information to my patient in a sensitive and balanced fashion in order to elicit informed consent

Monitor performance to enhance learning

No one published research paper should be interpreted in isolation. (Glasziou et al, 2004) EBM consists of a set of strategies designed to help clinicians keep abreast of developments and to base decisions on best available external evidence. A precise definition of the clinical problem is mandatory, as are an efficient search for the best available evidence, and a critical appraisal of the evidence. Evidence must be integrated with clinical experience: EBM v PBM (practice-based medicine: Travis & Azorin, 2002; Battaglia & Ogliari, 2004; Coomarasamy & Khan, 2004) EBM users should assess the outcome of the process and continue to improve their skills in using this approach. Absence of research evidence forces one back on clinical experience. According to Geddes (1997), clinical practice lags behind research, although one can legitimately argue that much research lags behind clinical need and may not be applicable to clinical work. Also, sources of evidence vary greatly in quality (Kelly, 2002) and the message given out. (Straus & Jones, 2004) In the real world of clinical medicine, evidence from randomised controlled trials, which often disagree with one another, is insufficient on its own to inform practice, and all possible sources of information should be tapped, not least the patients themselves. (Baldwin, 1999) Depending on the published evidence one reads, for example, exercise relieves minor depression⁸⁴⁹, reduces the number of depressive symptoms but does not affect the incidence of depression, or increases the risk of becoming depressed! (Baldwin et al, 2002, p. 86) In summary, while a degree of consensus is necessary among colleagues, the ideology of EBM should not become so entrenched as to ignore clinical complexity. (Williams & Garner, 2002; Berrios & Marková, 2002; Cooper 2003; Wu, 2005) Clinicians need to acquire the skills necessary to interpret published research. (Straus, 2004) Even if the evidence exists for a particular strategy it is not always certain that it will receive funding. Every patient is unique and blind application of EBM is inappropriate and doctors should not be pilloried by the legal profession for practising their ancient art. (Hurwitz, 2004) Of course, practitioners who deviate from guidelines based on research should document their reasons for doing so. (Tallis, 2004, p. 35) Randomised control trials have uses (valid) and weaknesses (not generalisable), as has 'lower order' evidence (generalisable, if not 'valid'). (Ghaemi, 2003, p. 55) It should be recalled that Cade's original post-rodent human study of lithium therapy in mania was tiny (n = 10) and many years passed before the efficacy of lithium was 'proven'. Finally, studies can be classified into 'positive' (e.g. efficacy of a treatment is confirmed), 'negative' (e.g.

⁸⁴⁹ In animal studies, running mice show increased neurogenesis in the dentate gyrus of the hippocampal formation. (Stahl & Niculescu, 2002, p.41) Playing with dolphins may be a better antidepressant than simply playing in water (Coryell, 2008, p. 519), the so-called 'biophilia' hypothesis.

finding that a particular treatment does not work) and ‘failed’ (e.g. failing to discover what was not sought, such as an adverse effect).

Psychiatry of Intellectual Disabilities

Dr. Philip Dodd, Clinical Senior Lecturer, Consultant Psychiatrist, St. Michael's House, Dublin & **Dr. Angela Carballedo**, Senior Registrar Psychiatry, St. Michael's House, Dublin

DEFINITIONS

Many terms have been used to describe people with intellectual disability (ID) in the past, including mental handicap, mental retardation, subnormal, feeble minded, moron, idiot and imbecile. These terms have tended to attract the stigma attached to the group they describe.

The term Intellectual Disability has increasingly being used by the International Scientific Community. In Ireland, Learning Disability or ID usually means people who meet World Health Organisation (ICD-10) definition of 'Mental Retardation'. ID is a 'condition of arrested or incomplete development of the mind', characterised by a:

- Significant global impairment of intelligence.
- Significant impairment of social or adaptive functioning (which is ability of a person to effectively interact with society on all levels and care for one's self).
- That arose during the developmental period.

The *Mental Health Act (2001)* specifies three categories of 'mental disorder', one of which is 'severe intellectual disability'. This definition incorporates (approximately) the ICD-10 definition, but in addition the intellectual disability is associated with 'abnormally aggressive or seriously irresponsible conduct on the part of the person concerned'. In completing Orders under the Act (**Section 3**), doctors recommending admission need to specify the category of mental disorder requiring compulsory treatment in hospital.

The World Health Organisation in their *International Classification of Functioning Disability and Health (2001)* recognises the following components to disability:

- *Impairments* are problems of body function or structure such as significant deviation or loss.
- *Activity limitations*⁸⁵⁰ are difficulties an individual may have in executing tasks or actions.
- *Participation restrictions*⁸⁵¹ are problems an individual may experience in involvement in life situations. It is important to consider the part that society plays in restricting an individual's participation.

Intelligence can be considered the sum of those cognitive abilities that underline adaptation to the environment. Intelligence is assessed using intelligence tests, the results of which are often reported as Intelligence Quotient (IQ). In children, IQ is the ratio of mental age (MA) to chronological age (CA).

$$\left(IQ = \frac{MA}{CA} \times 100 \right)$$

Intelligence tests are standardised to have a mean IQ in the population of 100, with a standard deviation (SD) of 15. These tests attempt to be independent of culture, but cultural biases remain. Their reliability can

⁸⁵⁰ Activity limitations were known as 'disabilities' in the 1980 WHO Classification of Impairments Disabilities and Handicaps

⁸⁵¹ Participation restrictions were known as 'handicaps'

be affected by degree of co-operation, performance anxiety, and mental and physical illness. They correlate only moderately well with measures of adaptive function. For example, *WISC-III* is one of those tests. (Wechsler D, 1991)

ICD-10 subdivides people with ID into four subtypes based on severity of intellectual impairment:

Severity Intellectual Disability	Prevalence	IQ range	Clinical Picture (ICD-10)
Mild	3%* (males predominate)	50-69	Language acquisition delayed but can use speech for everyday purposes - frequent reading and writing problems Mostly independent in self care Capable of practical jobs Social and emotional immaturity may occur
Moderate	0.3%	35-49	Language acquisition slow and eventual achievement limited Support required in self care Simple practical work possible under supervision Often develop significant social skills
Severe		20-34	
Profound	0.05%	<20	Language limited to understanding simple commands/making simple requests. Often non-verbal. Multiple physical disabilities common. Poor motor skills. Often incontinent. Very little ability to care for basic needs - require constant help and supervision Can learn some new skills - but very slowly

*not all of this 3% have significant impairment of adaptive behaviour

Prevalence of more severe ID may be influenced by increased survival of premature babies, prenatal screening and selective termination, trend to later childbearing, and survival into older age of people with severe ID.

AETIOLOGY

An ID is not an illness entity in itself but the developmental consequence of some pathogenic process. Aetiology of ID may be grouped into prenatal, perinatal and postnatal, depending on the timing of the brain insult or development of pathology. The effect of the process upon the brain may have physical, cognitive and social consequences. In many of those with mild ID, and some with more severe disability, no specific syndrome can be identified to account for the disability. It is believed that in approximately 30% of people with severe ID and in 50% of those with mild ID, a cause cannot be identified.

Mild ID is known to be associated strong environmental factors such as social class (V) and other family characteristics like overcrowding, poverty, irregular unskilled employment, and intellectually "uninterested" parents. In many people with an ID, the disability accounts for by the lower end of the (near) normal distribution of intelligence. This appears to be familial, and dependent on both environmental and genetic influences.

Some specific causes of intellectual disability are:

<i>Pre-Natal (before birth)</i>	<i>Perinatal (birth-1 month of life)</i>	<i>Post-Natal</i>
<ul style="list-style-type: none"> • Chromosomal • Genetic • Metabolic • Nutritional • Infections • Drugs & alcohol • Antenatal complications • Maternal infections 	<ul style="list-style-type: none"> • Abnormalities foetal growth • Prematurity • Obstetric complications • Labour complications 	<ul style="list-style-type: none"> • Infections • Brain injury • Allergic/vaccine reactions • Accidents • Deprivation & abuse • Epilepsy

Some specific pre-natal causes of ID are summarized as follows.

Autosomal dominant conditions

- *Tuberous sclerosis* (variable disability, cafe-au-lait spots, epilepsy, brain nodules, renal and retinal lesions, genetic heterogeneity with 9 & 16 chromosomes implicated)
- *Velocardiofacial syndrome* (microdeletion at 22q11.2; congenital abnormalities of palate and heart, and a characteristic long face; associated with learning disability and a schizophreniform psychosis)

Autosomal recessive conditions (mostly inborn errors of metabolism)

- *Phenylketonuria* (ID, epilepsy, microcephaly, autistic features, eczema). 1:10,000 live births, newborn screening at 6-14 days (Guthrie test). Lack/inactivity of phenylalanine hydroxylase. Treatable if dietary phenylalanine restriction commences early.
- *Fragile X syndrome*, second most common specific cause of ID, after Down's Syndrome. 0.5-1:1000 males and 1:2000 females. Accounts for about 7% of moderate and 4% of hitherto unexplained mild ID. The fragile site is located at the long arm of the X chromosome (Xq27.3) and consists of excess CGG triplet repeats. The condition can be transmitted through non-disabled males or those who show no fragile site. Women are less severely affected than men and are usually unaffected carriers. May show *anticipation* (increased severity of disorder and earlier age of onset in progressive generations). Symptoms and signs include macro-orchidism, large ears, LD, microcephaly, marked social fears, autism, speech & language problems.

Chromosomal Abnormalities: cause 40% of severe ID; includes aneuploidy, deletions, translocations

- *Down's syndrome* is the commonest specific cause of ID, causing 30% of severe ID. 1:650-1000 live births. 94% of individuals have trisomy 21, 2% show mosaicism and 3% translocation. Increased risk of recurrence if extra chromosome due to translocation (this type is independent of maternal age). Increased risk factors include older mothers, but most infants are born to younger mothers. The syndrome is characterized by craniofacial abnormalities, cardiac defects, gastrointestinal abnormalities, hypothyroidism, acute leukaemia, depression and dementia in about 45% of those >40 yrs.

Sex Chromosome Abnormalities

- Turner's Syndrome (usually normal intelligence) - 46X0 karyotype
- Klinefelter's Syndrome (associated with mild LD) - 47XXY
- 47XYY Syndrome
- 47XXX Syndrome

Neural Tube Defects

- Incidence varies even within restricted geographical areas. Nutritional factors (folic acid) are important environmental components. May occur as part of other syndromes with severe malformations

HISTORICAL PERSPECTIVE

Caring for people with ID requires an understanding of the history of ID services. A wide number of philosophical and legislative shifts in ideology have impacted on the lives of people with ID and their carers. Changes in ideology over the years have seen perceptions move from people with ID being feared and dehumanized, to being seen as in need of care and protection, to a welcome and significant emphasis on people being seen as capable citizens with their own rights. People with ID were viewed as incapable and incompetent in their capacity for decision-making and development. Fortunately, within the last 40 years we have moved from institutional models of care, with the closure of long-stay institutions to models of care which promote social inclusion and ordinary living.

Modern Western health care provision is now primarily community-based. Modern mental health services for people with ID have either developed as part of general ID services or into specialist mental health teams. Support services are based on community inclusion, using concepts such as [social role valorization](#) and increased self-determination. But this has definitely not been the case throughout history. Here there is a brief explanatory summary of the changes that have occurred in the history of the health care and social care for people with ID.

Date (Society)	Health Care	Social Care	Education	Legal

*Normalisation is making available to people with ID patterns of life and conditions of everyday living as close as possible to the regular circumstances and ways of society.

EFFECTIVE COMMUNICATION

Good communication is essential in all health care settings where people are often feeling unwell, are in unfamiliar environment and are trying to understand and retain medical information. All this limits communication, comprehension and social skills. Therefore, understanding and improving communication can greatly enhance clinical care and the experience of people with ID and those working with them. Research indicates that 50% to 90% of people with ID have communication difficulties. The higher incidence of sensory, physical, visual and hearing impairments in people with ID can also impact on their communication skills. People with ID are also more likely to depend on others so therefore the importance of establishing good communication to meet their needs and wishes and to have those acted upon. Good communication will include spoken language, non-verbal communication such as facial expression, body language and gestures and any written forms of communication. Considerations should also be made to ensure that communication is culturally appropriate with increased use of interpreters versus reliance on family members.

Communication skills of people with intellectual disabilities can be divided as following:

-pre-verbal: this means that people do not have the cognitive abilities to understand words: they have profound and multiple learning difficulties; they can be helped to understand through routines, tone of voice, repetition, the context of the situation, objects and their own experience.

-non-verbal: this means that people have the ability to understand words but do not have the ability to express themselves using words and will use alternative means, such as signing or pictures.

-verbal: this means that people have a variety of skills in understanding language and expressing themselves, predominantly using speech.

As mentioned, people with an ID often find it possible to understand what is being said, even though some words are not understood as they use a variety of different strategies. These include the familiarity with the context or the person speaking, guessing or understanding of speaker's non-verbal cues such as body language, facial expression and gestures or signing. As we know non-verbal communication is very powerful and people gain around 55% of the information through body language and 38% through the tone, pitch and intonation, leaving only 7% to the actual verbal language information.

Although literacy skills are often reduced in people with ID many can understand written information when they have support such as pictures, symbols and photos. Another relevant factor that influences communication is the context. The physical environment can easily be manipulated in most circumstances and ideally this would be a quiet and comfortable environment as many people with ID have sensory hypersensitivities and this can be the cause of distress and the origin of some challenging behaviours. It is important to consider also the emotional context for the individual with ID, for whom emotional self-regulation might be largely dependent on his/her cognitive abilities, social skills and previous experiences. Some tips for good communication between health professionals and people with an ID include:

- Speak slowly; using everyday words, simple grammar and short sentences, that is plain English with no jargon.
- Use pictures/photographs to help explain or draw pictures.
- Link your explanation with everyday things especially if you need to talk about more abstract things such as time concepts.
- Write the key information down and then people can go through it with a friend/carer/support worker afterwards.
- Be aware of your facial expression and body language. Are they giving the same message as your speech? Use lots of non-verbal feedback, especially head nods and facial expression to show that you are listening.
- People with ID may have difficulties ignoring distractions. Make sure that you are talking to them in a quiet place.
- Think about how to ask questions. Remember that open questions can be more difficult. Closed questions, that are yes/no questions, are often not helpful as people may answer "yes" because they think you want them to say yes. Either/or questions may be easier, but keep them short, so that they do not just repeat the last thing you say, for example, "do you like tea or orange juice?"
- Give the person plenty of time to respond; you might have to wait longer than you expect.
- Check the person has understood you. You may need to ask them to repeat back what you said. Some people will find this hard to do.
- Be aware of other things that may affect communication, for example hearing difficulties, vision problems, physical and mental health problems, epilepsy, medication related issues, time of the day, general mood, interest in the topic.
- Be sensitive to any cultural "rules" the person may have, particularly with regard to eye contact, personal space and gestures that may have different meanings. Check what language the person is most comfortable with and whether you would need an interpreter.
- Some people with ID have more difficulties with using language in a particular manner, particularly those with autism. They might use learnt phrases or echo what is being said or what they have heard from past experiences.

HISTORY TAKING AND MENTAL STATE EXAMINATION

The format of history taking and assessing adults with intellectual disabilities is broadly similar to that used in the general population but as there are some differences these will be considered in the following section.

1. History taking

People with ID constitute a heterogeneous population ranging from non-verbal individuals with profound disabilities to those with borderline/mild disabilities and good linguistic skills. Most of the observations in this section refer to those with moderate, severe or profound ID.

The recognition of mental disorders in people with an ID is particularly difficult, due partly to linguistic limitations that often make it difficult for the individual to describe psychiatric symptoms, and partly to diagnostic overshadowing (ascribing the symptoms and signs of mental illness as being normal or due to the person's lifelong ID). In addition, people with ID who present to psychiatrists, often have baseline behaviour that would be considered abnormal in people without ID. Therefore, diagnosis depends on the interaction of a number of factors such as what the person says they are experiencing, what others say about them, how they are seen to behave and the history of their complaint.

While much of the psychiatric interview for people with ID is similar to that of other people, there are certain differences that require to be highlighted:

- Limited communication skills

As we mentioned in the previous section, many people with ID have limited communication skills, and may have difficulties in describing their symptoms. They have also difficulties understanding questions so questions should be asked in simple language, using short sentences, appropriate to the adult's developmental level. The assessment may need to be repeated, and longer periods of time may be needed for answers to be given and understood.

- Acquiescence

People with ID are more likely to acquiesce to what they believe the interviewer wants to hear. While minimizing the tendency to acquiescence is a skill that has general applicability to any psychiatric interview, it is particularly important in this population. The attitude of anyone being interviewed is likely to be influenced by expectations of the interaction. People with ID may have had negative experiences of interviews with professionals that colour their expectations. It is therefore important for the interviewer to maximise the patient's confidence and sense of security by extensive explanation of the purpose of the interview as well as constant reassurance.

- Short attention span

Persons with ID often have a short attention span. Therefore it is important to recapitulate and summarize previously stated material. This has the benefit of re-engaging and focusing the patient's attention as well as giving an opportunity to collect more detail, in addition to allowing the patient to agree or disagree with the interviewer's interpretation of what has been said.

- Linguistic and phonological problems

A wide range of linguistic and phonological problems, including poor grammar and abnormal intonation, can make patient's responses difficult to understand. If doubt exists about the meaning of responses, it is very important to clarify with the help of a carer or family member who knows the patient well.

- Carers and relatives

It is essential to complete the psychiatric history and assessment with the help of someone who knows the person well, a carer or relative. It is often necessary to collate details from several informants.

2. The Mental State Examination (MSE)

The MSE for adults with an ID is essentially similar to that taken for adults without an ID. However, in general, because of the communication problems described before that people with ID frequently have, it is often difficult to elicit accurately certain psychopathological presentations. It is important to note the following:

- Abnormal thought content

Anxiety and phobias: while the cognitive features of anxiety disorders are infrequently elicited in adults with ID, behavioural features are often seen. Irritability and restlessness are more commonly observed as symptoms of anxiety.

Obsessional symptoms: it is very difficult to obtain a clear description of obsessions being the product of a person's own mind, for example. Resistance is often found to be minimal, especially if the obsessions are long-standing.

Depersonalisation and derealisation: people with ID are frequently unable to describe these complex cognitive phenomena.

Psychotic thoughts: people with ID are prone to giving complaint answers as mentioned previously. Therefore it is quite possible to "convince" a person with ID that their beliefs are untrue. A better indicator of delusions is when the false belief is repeatedly stated. The use of open-ended, non leading questions is very important in this instance. It is also significant to remember that the content of the delusional beliefs is usually developmentally appropriate for the person's overall ability. Sometimes, beliefs that, on the surface, appear to be delusional, may simply be a reflection of overall cognitive development of the patient. This discernment requires careful evaluation during the interview. In general, complex psychotic symptoms such as delusional perceptions are infrequently found, due to the difficulty in eliciting such phenomena in people with limited verbal and intellectual skills.

- Abnormal thought form

People with ID may be more at risk of presenting with fragmentation of thought processes, sometimes precipitated by anxiety or depression. This may present in a similar fashion to formal thought disorder. A careful assessment, with collateral information, will help distinguish these presentations.

- Cognitive assessment

The diagnosis of ID is based on the person having an intelligence quotient below 70, together with continued impairment in adaptive behavioural/social functioning, and with onset during the developmental phase (before the age of 18 years). Specific assessment procedures and tools need to be utilised to accurately diagnose levels of ID, the description of which is beyond the scope of this text. The cognitive assessment already described in the Older Adult section is largely appropriate for the use in people with ID, but may need to be simplified depending on the level of ability of the person with ID.

- Functional analysis

Changes in behaviour may not signify mental illness, but may be due to learned manipulation of the environment, or the behaviour may be acting as a form of communication. A functional analysis of behaviour is frequently needed to ensure accurate diagnosis.

3. Diagnosis and Diagnostic Classification

Assessment aims not only to detect the presence of psychiatric illness and make a diagnosis, but also to identify the features that make a person vulnerable to them. Any therapeutic interventions must take into account a number of factors, including the patient's wishes, the diagnosis and vulnerability factors including psychological (for instance characteristic ways of thinking), biological (such as genetic predisposition or medication) and social (including environmental factors). Some of these vulnerability factors (such as brain damage) cannot be changed, but others (such as an optimal control of Epilepsy) can and should form part of the care plan. The introduction of operational criteria in ICD-10 (World Health Organization, 1992) and DSM-IV (American Psychiatric Association, 1994) and the use of structured and semi-structured interviews, such as the *Psychiatric Assessment Schedule for Adults with Developmental Disability* (PAS-ADD), have significantly increased the reliability of the diagnostic process in psychiatry.

The National Association for the Dually Diagnosed (NADD) in the USA, in association with the APA, developed the *Diagnostic Manual -- Intellectual Disability (DM-ID): A Textbook of Diagnosis of Mental Disorders in Persons with Intellectual Disability*. This offers a summary of diagnostic criteria, a review of the literature and research and an evaluation of the strength of evidence supporting the literature conclusions, a discussion of the aetiology and pathogenesis of the disorders, and adaptations of the diagnostic criteria for the ID population.

Again for those with moderate to severe ID, the *Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning Disabilities/Mental Retardation* (DC-LD; Royal College of Psychiatrists, 2001) describes criteria for the diagnostic classification of mental health problems based on a consensus of current practice and opinion among psychiatrists working with people with ID. It is a multi-axial system that is being used alongside ICD-10. When appropriate, ICD-10 criteria should be used, as in most individuals with mild ID. A hierarchical approach to diagnosis is adopted:

HIERACHICAL DIAGNOSTIC DC-LD CLASSIFICATION:

Axis I: Severity of the Intellectual Disability

Axis II: Cause of the Intellectual Disability

Axis III: Psychiatric Disorders

DC-LD Level A: Developmental Disorders (such as autism)

DC-LD Level B: Psychiatric illness

DC-LD Level C: Personality Disorders

DC-LD Level D: Problem Behaviours

DC-LD Level E: Other Disorders

MENTAL ILLNESS

Mental illness and ID have been distinguished since at least medieval times but the fact that both could coexist in the same individual has only been appreciated more recently. This phenomenon is sometimes called dual diagnosis. Mental illness can be difficult to diagnose in people with an ID for the following reasons:

- Psychiatric illness may present non-specifically as behavioural disorder (e.g. aggression, self-injury, withdrawal and stereotypies).
- Physical illness may also present with emotional or behavioural symptoms.
- All symptoms may be attributed to the intellectual disability per se, rather than any additional disorder (this is known as diagnostic overshadowing).
- Although all people have communication skills, a communication barrier may exist between doctor and the patient with ID.
- Therefore a change in behaviour or a change in level of functioning in someone with ID should always be taken seriously and merits further investigation

1. Aetiology and risk factors of mental illness

There are many biological, psychological and social factors that contribute to the aetiology of mental illness in people with ID. Many of the factors are the same as in the general population and it is their interaction that is important in creating the particular vulnerability to developing mental illness. Those with ID tend to have more factors present and fewer resources to deal with them. Some of the factors, which can contribute to the development of mental illness in people with ID, are:

Biological factors:

- Brain damage (epilepsy, congenital disorders)
- Specific abnormalities (Prader-Willi syndrome, Lesch Nyhan syndrome, Fragile X)
- Family history of mental illness or learning disability/other brain disorders
- Iatrogenic (anti-epileptics, other compounds)
- Communication and sensory impairments

Psychological factors:

- Childhood experiences (separation, rejection, overprotection, abuse)
- Poor personality development (lack of self esteem, dependency, low expectations)
- Life Events (difficulty in making and maintaining relationships, labelling, bereavement, institutionalisation)
- Societal reactions (stigma, isolation, poor support, abuse)

Social factors:

- Limited choice of occupation
- Social isolation and limited peer relationships
- Lack of role models in developing adaptive skills

2. Epidemiology and characteristics of mental illness in people with ID

Mental illness is in general significantly more common in people with ID than it is in the general population, both in children and in adults. The co-occurrence of psychiatric illness with ID has been well established, and people with intellectual disabilities are more likely to suffer from mental ill health

(including behavioural disorders, personality disorders, autistic-spectrum disorders and attention-deficit hyperactivity disorder). (Debeaux, 2001)

The arrival of effective medical and psychosocial treatments for psychiatric disorders makes their diagnosis in those with ID all the more pressing. It is also essential that the development and delivery of clinical services hold what is known as prevention and minimization of those disturbances.

Mental Disorder	Epidemiology	Characteristics
Schizophrenia	Prevalence of 3% (3x general population) Associated with velocardiofacial syndrome	Difficult to diagnose in people with IQ<45. Psychotic phenomena tend to be simpler, and thought alienation less common. Bizarre behaviours and adaptive regression can occur
Bipolar Affective Disorder	More common than general population	It can be diagnosed whatever the degree of disability. In manic states, irritability is common. Recording behavioural correlates of mood can help to establish the cyclical nature of the disorder, and be used to monitor treatment.
Depression	Depression and anxiety up to four times more common in people with ID compared to the general population Associated with Down's syndrome	Often missed in people with ID because they are less likely to complain of low mood. 'Biological' symptoms are important in making the diagnosis
Prolonged grief/ Adjustment disorder	Common	Carers often unaware, problems often attributed to other causes
Acute confusional states (delirium)	More common, especially people with more severe disability or coexistent dementia.	Due to physical illness which will need diagnosis and treatment
Dementia	More prevalent than in general population (14% v. 5% in those over 65)	Psychotic symptoms and epilepsy may be a feature. Strong association with Down's syndrome, where it presents earlier.
Autism	Prevalence 4.9:10.000, female: male = 1: 4 ¾ of people with autism have ID Associated with Fragile X, Tuberous Sclerosis and phenylketonuria.	Developmental disorder that is apparent by the age of three. Features include triad of abnormal social interaction, including a particular lack of empathy, abnormal communication (e.g. echolalia, pronoun reversal), stereotyped patterns of behaviour and adherence to routines

3. Psychotic illness

The prevalence of psychotic symptoms in adults with ID is higher than in the general population. The prevalence of schizophrenia in the general population is around 1% while in the ID population is about 3%. Point prevalence rates of psychotic disorder (including schizoaffective disorder) have been found to be 5.8% in adults with mild ID and 3.5% in those with moderate/severe ID.

Assessment, diagnosis and management of psychosis in ID would follow a similar format to that in adults without an ID but adults with moderate/severe ID are more likely to have communication problems and cognitive deficits, which may pose some difficulties for thorough assessment. In those patients it could be more difficult to elicit all the symptoms required for a diagnosis using ICD-10 or DSM-IV. Psychosis is therefore more likely to be defined in a broader term in the ID population than in the general population.

Definitions within non-affective psychotic disorders in DC-LD include:

- Schizophrenic/Delusional episode or disorder
- Schizoaffective episode or disorder
- Other non-affective psychotic disorders

As opposed to the following types of psychotic disorders included in ICD-10 code and that can be specified in those with mild/borderline ID:

- Schizophrenia
- Delusional Disorder
- Acute or transient psychotic disorders
- Induced delusional disorder
- Schizoaffective disorder

A DC-LD guideline gives a summary of the symptom criteria required for a diagnosis of Schizophrenic/delusional episode:

- A. *The symptoms/signs are not a direct consequence of any other psychiatric or physical disorder or a result of prescribed or illegal drugs or alcohol.*
- B. The criteria for schizoaffective episode are not met. (In DC-LD, unlike ICD-10, a diagnosis of schizoaffective disorder trumps a diagnosis of schizophrenic/delusional disorder).
- C. One of item groups 1, 2 or 3 are met:
 1. One of the following symptoms present on most days for at least two weeks:
 - a. Third-person auditory hallucinations.
 - b. Hallucinatory voices coming from some part of the body.
 - c. Impossible/fantastic delusions (delusions that are culturally inappropriate and completely impossible).
 - d. Thought insertion or withdrawal or broadcasting, or thought echo or delusions of control, influence or passivity, or delusional perception or hallucinatory voices giving a running commentary.
 2. One of following present for most of the time during one month, or some time every day for at least a month:
 - a. Delusions that are not mood congruent.
 - b. Hallucinations (in any sensory modality) that are not mood congruent.
 3. Two of the following present on most days for at least two weeks:
 - a. Delusions which are not mood congruent.
 - b. Hallucinations which are not mood congruent.
 - c. Catatonic symptoms.
 - d. Negative symptoms, where there is definite evidence that this is a change from the individual's premorbid state.
 - e. Disordered form of thought, where is definite evidence that this is a change from the individual's premorbid state.

It is important to be aware of some other diagnosis that might present with similar symptoms to psychosis and that constitute the differential diagnosis:

- Physical illness: epilepsy, infections, endocrines causes, hearing or visual impairments, pain or discomfort.
- Drug or alcohol-related causes.
- Other psychiatric conditions including: affective illness, anxiety disorders, and post-traumatic stress disorder.
- Dementia.
- Autistic Spectrum Disorder.
- Other differential diagnosis such as challenging behaviours, or ID itself, can sometimes be misdiagnosed as psychosis.

An adequate mental health assessment should always take into account the individual's developmental level and it should include a history from the patient and a mental state examination, a detailed collateral history and a risk assessment. Physical examination and investigations are relevant, including blood test, septic screen if indicated and CT/MRI and EEG if indicated and no contraindications for the patient.

There are also useful checklists that can be used along with the above to identify psychiatric disorders in people with ID such as the *Reiss screen*, the Mini PAS-ADDs (*Mini Psychiatric Assessment Schedules for Adults with Developmental Disorders*), the DASH-II (*Diagnostic Assessment for the Severely Handicapped-II*) and the ADD (*Assessment of Dual Diagnosis*). These are useful tools as general indicators but less useful at determining the nature of the illness (http://www.ets.org/disabilities/documentation/documenting_learning_disabilities).

4. Affective disorders

Depression

Point prevalence of depression in those with ID is higher than in the general population. (Debeaux, 2008) People with Down's syndrome are more likely to be diagnosed as having a depressive disorder than those with ID due to other causes. The clinical features of depression in adults with ID vary with the level of disability. Those with mild ID show the same symptoms as their non-disabled peers. In those with more-severe forms of ID, somatic symptoms and their behavioural correlates, such as changes in activity levels, diurnal mood variation, sleep and appetite changes, and social withdrawal are suggestive of affective disorders. Regression to increased dependency, psychomotor agitation, increased irritability, worsening of existing behavioural and self-injurious behaviours, reduced communication and social isolation, catatonic features and visual hallucinations are more common in this group. Suicidal thoughts and behaviours are thought seldom occur in people with depression and ID, as they might not be able to form such an intention. Negative automatic thoughts and feelings of hopelessness can be ascertained in people with mild ID. As with psychosis, depression may be a component part of the psychiatric phenotype of genetic syndromes associated with ID e.g. fragile X syndrome.

Bipolar affective disorder

The lifetime prevalence rate of bipolar disorder is 1% in those without an ID. Higher prevalence is encountered in the ID population. Changes in affect and activity levels can be observed and reported by people with mania and mild to even very severe intellectual disabilities and their carers. The mania rating scale items of the DASH-II screening instrument for those with ID ('restless or agitated', 'decreased need for sleep', 'irritable', 'easily distracted', 'extremely happy or cheerful for no obvious reason', 'talks loudly and quickly') demonstrate good internal correlation and specificity with the mania DSM-IV diagnosis. Pressure of speech rather than flight of ideas, increased and decreased appetite, echolalia, crying and over-activity might be more common in the ID population with bipolar illness. Mixed affective states and rapid cycling forms (more than four episodes a year) of bipolar affective disorder might be more common in

those with ID. In Down's syndrome, mania is very uncommon among women, whereas in the general population the male: female ratio is equal. Interestingly, those with Down's syndrome less frequently have a positive family history. In the general population, rapid cycling forms are seen more commonly in women, but in those with ID, the gender ratio is equal.

Persistent mood disorders

There are few studies of dysthymia, which is probably underdiagnosed, in those with ID. Similarly, cyclothymia (persistent mood swings not meeting severity criteria for affective disorders) has as yet received little attention in this population.

5. Anxiety disorder

Panic Disorder and Generalized Anxiety Disorder

Over-activity, panic attacks, agoraphobia, sexual dysfunction, mood changes, depersonalisation and derealisation, disruptive behaviours (including aggression and self-mutilation), somatic complaints, and sleep and appetite disturbance are all common symptoms of anxiety in the ID population. In mild ID, symptoms of generalised anxiety disorder are similar to those in the general population, with increased 'brooding', somatic complaints and sleep disorder. In more severe ID, only the behavioural symptoms associated with anxiety can be reliably assessed, ruling out many core psychological symptoms of the disorder. Comorbidity with other psychiatric illnesses such as depression is common. High levels of anxiety are thought to be part of the behavioural psychiatric phenotype in William's syndrome.

Obsessive Compulsive Disorder

Compulsive behaviours have reported frequencies of 3.5% in adults with mild ID and 40% in adults with severe ID. Ordering compulsions are the most prevalent in the ID group. Complex cognitive experiences such as the recognition that the thoughts or acts are under self-control may be impossible to identify in a person with ID. Compulsions are significantly associated with stereotypies and self-injurious behaviour. Obsessions and compulsions can arise in a number of disorders other than obsessive-compulsive disorder, such as depression and pervasive developmental disorder. They are also associated with specific syndromes such as Prader-Willi syndrome. Some specific stereotyped movements have been associated with disorders such as Rett syndrome (hand-wringing movements in front of the body) and Smith-Magenis syndrome (body self-hugging, self-biting). Although obsessions and compulsions may need pharmacological treatment in individuals with Prader-Willi syndrome, the effectiveness of serotonin reuptake inhibitors in the treatment of stereotyped movements in Rett syndrome and Smith-Magenis syndrome is less established.

Adjustment disorder and post-traumatic stress disorder

Children and adults with ID are vulnerable to emotional, physical and sexual abuse. The risk of posttraumatic stress disorder and adjustment disorder is therefore likely to be significantly increased.

Eating disorders

1–19% of adults with ID living in the community and 3–42% of those living in institutions have an eating disorder, with higher rates in those with more-severe ID. Eating disorder research in those with ID has covered pica, regurgitation, psychogenic vomiting, food faddiness or refusal, psychogenic loss of appetite, binge eating disorders and anorexia nervosa. In individuals with ID living in the community, deviant eating behaviour is more likely to occur in those with a comorbid psychiatric disorder and to be associated with physical and social comorbidity. However, the impact of eating disorders on weight, physical and mental health and social functioning in the ID population has not yet been adequately addressed.

MANAGEMENT OF MENTAL HEALTH (Pharmacological, Psychological and community care interventions)

Management of Psychosis in ID

Management of psychosis in ID is similar to that of those without ID, and can be considered using a biopsychosocial approach. In the acute phase, management usually focuses in accessing services, ensuring safety of the patient and others and initiation of medication. After resolution of the acute phase, management is more likely to focus on maintaining good mental health, insight-related work and relapse prevention planning.

Evidence for the effectiveness of antipsychotic medication in people with these disorders and ID rests mainly on extrapolation of findings from general adult psychiatry. Treatments should be tailored to the individual, and so take into account any co-existing medical conditions such as epilepsy, other drugs being taken and any other particular requirements. The National Institute for Clinical Excellence (NICE) guidelines for schizophrenia (update 2009) suggests that people with schizophrenia have a physical health review by their GP at least once a year and an ECG prior to starting on antipsychotics and at regular intervals thereafter to monitor any abnormalities, in particular any QT interval prolongation. Monitoring for prevention of metabolic syndrome is also recommended. Small studies in the literature show that clozapine appears to be efficacious and safe in people with ID. However, careful monitoring of side effects is recommended. A Cochrane review in 2004 did not find any significant randomized controlled trials that examined antipsychotic medication versus placebo in people with psychosis and ID. There is still a need for further research in the field.

With regards to psychological treatment in psychosis we should mention that for a long time the role of psychology in ID was to provide therapy in the form of behavioural therapy to manage behaviours deemed undesirable in the large long-stay institutions. Historically the emotional lives of those with an ID were largely neglected. With the gradual closure of the long stay units and the focus in community care, the role of psychology has expanded enormously. Interventions such as cognitive-behavioural therapy, psychodynamic and systemic therapy do deserve attention in those with mild or borderline IQ, but have seldom been formally researched in the moderate and severe ID population. Assessment and management of expressed emotion in families and professional carers can also be beneficial. Psychological risk factors common to many people with ID include a history of unstable attachments, learned helplessness, low self-esteem, limited social skills and poor problem solving strategies. Social and environmental risk factors relate to social barriers and dependence support from carers, and may include stigma and segregation, over-protection, lack of opportunities, neglect and abuse, limited social networks and poorly managed changes and losses.

Respite care and rehabilitation for those with more chronic illnesses, including the use of day services, should be part of a comprehensive long-term person-centred management plan. Practical social interventions, tailored to the individual's needs, are important in order to support both the patient and the support network.

Management of Mood and Anxiety disorders in ID

The National Institute of Clinical Excellence (NICE) in the UK has provided clinical guidelines for the identification, management and treatment of anxiety and mood disorders (panic disorder, with and without agoraphobia, generalized anxiety disorder, PTSD, obsessive-compulsive disorder, depression and bipolar disorder). These guidelines, with adaptations for those individuals with greater communication difficulties, are also applicable to those with an ID. Treatment as for the general population is appropriate with the following cautions:

- Treatment with medication: start low, go slow and change one medication at a time, as there is higher frequency of idiosyncratic responses to psychotropic drugs.

- Psychological therapies: adapted according to the individual's cognitive, communication and concentration capacities.
- Multi-modal interventions, for example psychotherapy, sensory therapy, behavioural therapy, stress management, attention to communication and medication may be necessary.
- Client, family and carers need to agree the treatment plan and where more than one intervention is being offered; they need to understand the focus of each intervention. Where different medications are being used simultaneously, the reason for each needs to be explained.
- Clinical relapse may be due to different cause from the aetiology for which the medications or other interventions are being targeted. It is wise therefore to have a crisis plan mapped ahead of time in order to address safety and other issues at these times.

The full range of bio-psychosocial treatments should be available for people with ID. For those with the most severe forms of depression and those with suicidal intent, hospital admission needs to be considered. Antidepressants can be effective in those with an ID and depressive disorder, but may have considerable side effects, including increased irritability. Electroconvulsive therapy might be effective as an adjunct to treatment in the acute phase of the most severe acute and otherwise nonresponsive episodes of depression in those with ID. Antipsychotics might need to be used for the acute phase of bipolar illness. A mood stabilizer then should be used as maintenance therapy to prevent relapse. There is some evidence that anxiolytic drugs such as buspirone are effective in treating those with ID and anxiety. Treatment with selective serotonin reuptake inhibitors may be beneficial in obsessive-compulsive disorder, as may various behavioural techniques. Social treatments can include interventions in the social network and helping people to find meaningful occupation and develop their skills. It can mean ensuring that people are treated with appropriate dignity and respect and are able to make choices in their lives.

ESSENTIAL HEALTHCARE IN ID

ID is by definition related to some form of cerebral trauma in the developmental period. This is not only confined to just those areas of the brain responsible for cognitive and social functioning but also associated to a variety of physical impairments that can lead to additional health needs over and above those experienced by the general population. There is generally a graduation with the prevalence and severity of physical problems usually increasing from people with mild to more severe ID. Common health deficits in people with ID are highlighted in the box below.

- Sight problems
- Hearing difficulties
- Dental diseases
- Epilepsy
- Psychiatric illness
- Eating Disorders
- Sleeping Disorders

- Challenging behaviours
- Obesity
- Poor diet
- Communication Problems
- Respiratory Function Problems
- Skin conditions
- Foot Care Problems

Structured health checks in primary care can identify clinically significant previously unrecognized morbidity among adults with intellectual disabilities and an annual health check is recommendable in people with ID. Psychiatric disorders can also have a significant impact on the physical health of a person with ID. For example, depression and psychosis may predispose to poor compliance with medication, and chronic psychiatric illness is associated with poor physical health and morbidity.

EPILEPSY

Rates of epilepsy are much higher in the ID population than in the general population and an underlying brain abnormality is often the common pathway in both. The prevalence in the general population is 0.5%, in mild ID it is 4%, in moderate/severe ID 30%, and in profound ID it is 50%. A third of adolescents with autism develop epilepsy, and it is associated with other syndromes such as Tuberose Sclerosis, Sturge-Weber syndrome and Rett's syndrome. Severe epilepsy and ID may lead to progressive deterioration or sudden death. Diagnostic overshadowing may occur when assessing epilepsy. "Strange behaviour" has a wide differential e.g. epilepsy, mental illness, a harmless or harmful habit that the individual has developed over time, an attempt at communication, a response to a stressful situation, a side effect of a drug. That is why a thorough full psychiatric and medical history and mental state is required. An informant is essential especially as witness to the seizures and a full description of seizure is required, i.e. frequency, duration, severity (e.g. led to injury, impact on life in general).

Epilepsy is associated with increased prevalence of nearly all forms of psychiatric disorder. Possible mechanisms include greater social disadvantage, chronic potentially life threatening illness, accidents, head injuries, self-esteem issues, dependency on others. Temporal lobe epilepsy presents often with psychiatric symptoms. Some studies report that rates of psychosis are higher in those with milder disability and epilepsy, whereas depression rates are higher in those with severe disability. A complex relationship exists between poor impulse control, epilepsy and socio-cultural factors. Interestingly, 'Forced Normalisation' is an uncertain phenomenon but relatives/carers frequently report that patient is improved in mental health terms when fit control not so optimal.

Epilepsy seems to present as more complex in the ID group than in the general population and is often treatment resistant. Studies report generalized tonic-clonic seizures as the most common type in this group and complex partial seizures as the most common in people with ID and autism. It is important to mention that non-epileptic seizures (pseudo seizures) are more common in people with ID. Possible mechanisms may be the limited communication skills that people with ID have, their crude expression of emotional conflicts and increased suggestibility. However, people with genuine epilepsy may also have pseudo seizures.

Epilepsy and its treatment can have a profound effect on individuals with ID. This can impact on physical health, psychological health and mortality, and in turn also could have an impact on the families and carers of these individuals. Anti-epileptic drugs of proven efficacy in the general population are also effective in people with ID. However, adverse reactions to anti-epileptic drugs are seen more frequently than in the general population, being somnolence and ataxia the most common in people with ID. Most antiepileptic drugs have agitation or mental illness as an associated side effect, although carbamazepine, lamotrigine and

sodium valproate are also used as mood stabilisers. Finally, the treatment of epilepsy may also reduce cognitive ability (both drugs and surgery).

MENTAL HEALTH ISSUES OF AUTISM

Autism spectrum disorder (ASD) is the term currently used for people with ICD-10 defined childhood autism, Asperger's syndrome or atypical autism. The cause of ASD is unknown but best considered as a multifactorial illness. The distribution of ASD within families indicates that it cannot be caused by a single gene but must involve the interaction of several. Some people with ASD without a family history of same would have a personal history of perinatal or childhood neurological complication.

The ICD-10 criteria for diagnosing ASD can be summarized as follows: if the person meets the following criteria and onset before age 3, we can talk of childhood autism; if only meet two of the criteria or onset after age 3, it is called atypical autism; and if no delay in development of communication or cognitive development, a diagnosis of Asperger's syndrome can be made. The main characteristic features for diagnosis of ASD are:

-Qualitative impairments in reciprocal social interaction:

- Lack of responses to other's emotions.
- Lack of modulation of behaviour according to social context.
- Poor use of social signals.
- Poor use of non-verbal signals to regulate social interactions.
- Weak integration of social, emotional and communicative behaviours.
- Lack of socio-emotional reciprocity.
- Failure to develop peer relationships involving sharing.

-Qualitative impairment in communication:

- Delay in development of language (without attempts to use other methods of communication).
- Lack of social usage of language skills.
- Repetitive speech.
- Poor synchrony and reciprocity in conversational interchange.
- Lack of emotional response to other people's verbal and non-verbal overtures.
- Poor flexibility in language expression.
- Impaired use of cadence or emphasis to modulate communication.
- Impaired use of gesture to augment spoken communication.
- Impairment in make-believe and social imitative play.
- Relative lack of creativity and fantasy in thought processes.

-Restricted, repetitive and stereotyped patterns of behaviour:

- Tendency to impose rigidity and routine on day-to-day living.
- Resistance to change in environment or routines
- Attachment to unusual objects, or interests.
- Non-functional routines.
- Interest in non-functional elements of objects.
- Motor stereotypies.

The main problem in diagnosing mental health illness in ASD is for those with more limited communication skills and for those who cannot describe how they are feeling or what they want. However, people with ASD do have the same emotional needs that people with no ASD. They often report feeling isolated and wanting to have friends, though they may not have the skills necessary to form relationships. People with ASD also find particularly unsettling the normal changes in life such as leaving school, a different job or an argument with a friend. The impact of those life changes in people with ASD can be

quite dramatic, even precipitating the development of mental health illness, which requires proper assessment and management.

Anxiety is often more common in people with ASD than in the general population, causing all type of uncomfortable emotional feelings and physical reactions. Frequently, due to the “one shot learning” style of memory, one unpleasant experience may lead to avoidance and a phobic reaction. Most able people with ASD are also aware that they are different to other people and can develop a severe social performance anxiety and phobia. They classically have repetitive behaviours and routines that they do usually for pleasure or to calm down their anxiety. In some cases, however, they might develop obsessive-compulsive disorder.

Attention Deficit Hyperactivity Disorder (ADHD) can also coexist with a diagnosis of ASD. The difficulty is deciding whether the level of distractibility or restlessness of the person is in keeping with their general level of functioning, or more severe than should be expected. In the later, stimulant medication could be considered in combination with behavioural programmes and bearing in mind the possibility of exacerbation of epilepsy and tics.

People with ASD can suffer from unstable mood that is rapidly changing and usually dependent on a recent stressor. That type of mood instability is linked to lack of self-awareness and emotional regulation and managed most successfully with psychological support. Despite of this, the most common psychiatric disorders associated with ASD are severe depression and mania, which are usually managed with the conventional pharmacological and psychological strategies. Hypomania and agitated depression are particularly difficult to distinguish in a person with ASD. The most common prominent feature is the degree of sexual activity, which is associate with hypomania but very unusual in agitated depression.

With regards to psychosis in ASD it is important to say that there might be an over-diagnosis of schizophrenia in people with ASD due to the rate’s misinterpretation of odd beliefs and strange habits as psychotic or delusional thinking. It is common that with anxiety and stress at times of crises develops into an acute and transient psychotic episode. People with ASD can also present as quite paranoid towards other people, mostly due to not being able to understand what is going on around them.

No conclusion has been finalised on whether to include personality disorder diagnosis in people with ASD. People with ASD appear to have much greater problems controlling impulses, mostly due to not learning many of the self-controls gained during social skill development.

CHALLENGING BEHAVIOUR

People with ID are sometimes described as having ‘Challenging Behaviour’. This is defined as ‘culturally abnormal behaviour of such an intensity, frequency or duration that the physical safety of the person or others is likely to be placed in serious jeopardy, or behaviour which is likely to limit use of, or result in the person being denied access to, ordinary community facilities’.(Emerson, 2001) Challenging behaviour can have a number of different causes, including psychiatric and physical illness, but it is not a medical diagnosis in itself. For example, self-injurious behaviour is a common type of ‘challenging behaviour’ occurring in 8-15% of those with ID in institutions and 2-4% in the community; 50% of those with self-injurious behaviour have additional behavioural disorders. It can be caused by mental illness such as depression or psychotic disorders, or by environmental factors such as lack of sensory stimulation. It is also associated with specific syndromes, i.e. Lesch-Nyhan syndrome and several neurotransmitters have also been implicated in its aetiology, e.g. serotonin deficiency.

Generally challenging behaviour presents as a communication of the individual’s needs, whether intentionally or unintentionally. That behaviour that has been labeled as challenging may reflect the lack of resources and the label may reflect the needs of the network rather than the individual. However, challenging behaviour is the most common reason for referral to a psychiatrist in those with ID. The presentation may have physical, psychological or social underpinnings or a combination of the three and these may have an impact on the treatment and management strategies. At least four types of relationship of clinical significance between challenging behaviour and psychiatric disorder have been identified:

- (1) Family factors associated with the development of challenging behaviour appear to be similar to those associated with the development of conduct disorder;

- (2) Challenging behaviours may represent the atypical presentation of an underlying psychiatric disorder; some forms of self-injurious behaviour may represent an obsessive–compulsive disorder;
- (3) Challenging behaviours may occur as secondary features of psychiatric disorders among those with severe ID;
- (4) Psychiatric disorders may establish a motivational basis for the expression of challenging behaviours, maintained by operant behavioural processes.

A thorough process of assessment is necessary to then be able to manage a case successfully. The assessment usually would include several interviews with professionals, carers and relatives. Physical examination and investigations are required and for more complex cases a deep understanding of the social and systemic context the individual lives in can be quite revealing. Some of the common physical and mental disorders associated with challenging behaviours are:

Diagnosed physical complaints: -Dental pain

- Urinary tract infection
- Respiratory infections
- Gastritis/gastric ulcer
- Constipation

Presumptive physical complaints: -Pyrexia with evidence of local infection

- Gastro-esophageal reflux
- Gastritis
- Headache

Diagnosed mental disorders: -Anxiety disorders

- Depressive disorder
- Psychotic disorders
- Insomnia
- Hyperkinetic disorders
- Autistic disorders

Presumptive mental disorders and sub-syndromal: -Anxiety and distress

Functional assessment is an interactive process that allows a better understanding of the environment and the routines of an individual as well as what the triggers or reinforcing factors of a particular behaviour. It essentially looks at the antecedents (what is happening before the behaviour occurs) and the consequences (what happens after the behaviour) of the behaviour in an attempt to determine what its function might be. The Positive Behaviour Support (PBS: Lavigna & Donnellan, 1986) is a combined behavioural analysis and person centred approach to working with challenging behaviour. Its aim is to replace the difficult behaviour with functionally equivalent ones while looking at and changing environmental and social factors that influence the behaviour or maintain it. A proper PBS should include the following:

- Descriptions of replacement behaviours and how these should be implemented.
- Teaching functionally equivalent behaviours and communication and when and how these will be taught.
- The manipulation of setting events that leads to the person displaying challenging behaviour.
- The manipulation of antecedents and consequences to behaviour.
- How and when appropriate behaviour should be rewarded or reinforced.

With regards to treatment of challenging behaviour with pharmacological interventions it should be mentioned that a Cochrane review of antipsychotic medication for treatment of challenging behaviour confirmed that there is not clear support for drug treatment. In clinical practice though, some of the most complex cases of challenging behaviour might benefit to some extent from this type of medication.

CONSENT ISSUES

Capacity is the ability of a person to make a decision at the time it is needed. Capacity to consent is a concept that means decision specific – a person might have capacity for one sort of decision but not another. People who can't consent deserve to be treated in their best interests and relevant parties should be consulted when assessing capacity to consent e.g. relatives, carers, but they cannot consent for an adult who can't consent for him/herself. In controversial cases or where there is disagreement between parties, a Court can be asked to make a ruling. For treatment of mental disorder, the *Mental Health Act (2001)* could be used for treatment against a patient's wishes.

Despite of the general public belief, most people with ID can make decisions for themselves and do have capacity to consent in most cases. However, some people with severe or profound ID are not able to make decisions if they are complex ones, lacking therefore capacity in such cases. Capacity may also fluctuate over time, for example in the case of delirium or during the course of a relapse of a mental illness. A person can have capacity to make some more straightforward decisions and lack capacity for more complex decisions for example. For someone to have capacity the following criteria should be met. A person is considered to be lacking capacity to make a decision if they are unable to meet at least one of the following:

- Ability to understand the information relevant to the decision.
- Ability to understand the choices and weigh up the pros and cons.
- Ability to retain the information
- Ability to communicate the decision (by any means).

If a person lacks capacity, then it may be necessary to make decisions on their behalf, in their best interests. Health professionals are often driven by their aspirations to be successful with treatment or avoid complications that they have a very narrow view of the person's best interests. However, other factors should be taken into account such as:

- a. All the issues that are identified as relevant for the person who lacks capacity
- b. Likelihood of the person regaining capacity
- c. Involvement of the person in the decision process as much as possible
- d. Consulting other people close to the person lacking capacity in order to find out about past wishes, interests, views and beliefs.

In Ireland, the *Mental Capacity Bill of 2008* reformed the laws that protect adults who, due to illness, accident or intellectual disability, are unable to make decisions for themselves or exercise their legal capacity. The Bill replaced the Wards of Court system, which was the existing mechanism for managing the affairs of persons who lack decision-making capacity.

CLINICAL SYNDROMES ASSOCIATED WITH ID

The most common syndromes associated with ID are summarized below. We highlight their main clinical and phenotypic characteristics and provide information regarding website links for further reading.

Down's Syndrome

• Inheritance	Trisomy Chr 21: 94% non-disjunction, 3-5% translocation, 1-3% mosaicism
• Cognitive phenotype	Mostly moderate ID (IQ 20-75, mean 50)
• Psychiatric phenotype	Alzheimer's dementia (45% over 45 years), Depression and OCD.
• Behavioural phenotype	Sociable, good-natured, stubborn.
• CNS	Epilepsy (mostly linked to Alzheimer's).
• Cardio-vascular	Congenital heart disease (40-60%), AV canal defect, tetralogy of Fallot.
• Endocrine	Thyroid disorder in 25% (mostly hypothyroidism)
• Audiovisual	Multifactorial visual and hearing impairments.
• Muscular/skeletal	Atlanto-occipital and atlanto-axial instability, hypotonia.
• Other	Blood dyscrasias, skin disorders, gastrointestinal disorders, genitor-urinary disorders, obesity, sleep apnoea, recurrent infections, leukaemia.
• Weblink	www.downs-syndrome.org.uk

Prader Willi Syndrome

• Inheritance	70% sporadic (deletion on Chr 15 of paternal origin), 25% uniparental disomy (2 maternal Chr 15)-IMPRINTING
• Cognitive phenotype	Normal IQ or Mild-moderate ID
• Psychiatric phenotype	Psychosis, OCD, Anxiety.
• Behavioural phenotype	Hyperphagia, self-injury (skin picking), stubborn, poor impulse control, sleep problems, emotional lability.
• CNS	Microcephaly
• Cardio-vascular	Heart failure secondary to obesity may arise
• Endocrine	Diabetes secondary to obesity
• Audiovisual	
• Muscular/skeletal	Short stature, scoliosis, hypotonia, small extremities.

• Other	Severe obesity, undescended testes, hypogonadism, sleep apnoea.
• Weblink	www.pwsa.co.uk

Fragile X Syndrome

• Inheritance	X-linked (FMR-1 gene has expansion of trinucleotide repeats at fragile site on X Chr)-ANTICIPATION.
• Cognitive phenotype	Borderline, mild or moderate ID (females tend to have higher IQ than males).
• Psychiatric phenotype	Depression
• Behavioural phenotype	Hyperactivity, social avoidance, gaze aversion, shyness, autistic features, hand flapping and biting.
• CNS	Epilepsy
• Cardio-vascular	Aortic dilation, mitral valve prolapse.
• Endocrine	
• Audiovisual	Multifactorial visual and hearing impairment.
• Muscular/skeletal	Connective tissue disorder, scoliosis, high-arched palate, macrocephaly.
• Other	Hernia, large ears, macro-orchidism, speech and language abnormalities.
• Weblink	www.fragilex.org

Velocardio Facial Syndrome 22q 11

• Inheritance	Sporadic microdeletion in Chr 22, maybe autosomal dominant.
• Cognitive phenotype	ID in 30% of cases, usually mild ID.
• Psychiatric phenotype	Schizophreniform psychosis (less than 25%), Bipolar affective disorder, Anxiety, Depression.
• Behavioural phenotype	Hyperactivity, autistic features.
• CNS	
• Cardio-vascular	Congenital heart disease (more than 70%), especially conotruncal malformations.
• Endocrine	Hypocalcaemia
• Audiovisual	Multifactorial hearing impairment.
• Muscular/skeletal	Polydactyly
• Other	Cleft lip/palate, thymic dysplasia, hypernasal speech, immune problems, characteristic facies, dysphagia, renal abnormalities, and gastric reflux.
• Weblink	www.geneclinics.org/profiles/22q11deletion

Phenylketonuria

• Inheritance	Autosomal recessive (inborn error of metabolism Chr 12).
• Cognitive phenotype	Variable IQ and social disability: progressive brain damage in untreated PKU with a 50 point drop in IQ by one year.

• Psychiatric phenotype	Anxiety
• Behavioural phenotype	Autism, poor concentration, hyperactivity, irritability.
• CNS	Microcephaly, epilepsy, spasticity.
• Cardio-vascular	Poor peripheral circulation.
• Endocrine	
• Audiovisual	
• Muscular/skeletal	Hypotonia
• Other	Variable clinical picture depending on deficiency of phenylalanine hydroxylase enzyme, eczema, light skin pigmentation.
• Weblink	www.ncbi.nlm.nih.gov

Neurofibromatosis

• Inheritance	Usually Autosomal dominant but can be also sporadic (Chr 17 and 22).
• Cognitive phenotype	Variable IQ (ID in less than 10%).
• Psychiatric phenotype	
• Behavioural phenotype	Hyperactivity
• CNS	10% have epilepsy depending on the sites of tumours.
• Cardio-vascular	Cardiac problems depending on the site of tumours.
• Endocrine	Depending on the site of glioma.
• Audiovisual	Glioma affecting visual and hearing, iris hamartomas.
• Muscular/skeletal	Skeletal abnormalities (kyphoscoliosis).
• Other	Variable picture depending on tumour sites, tumours are susceptible to malignant change.
• Weblink	www.ninds.nih.gov

Tuberous Sclerosis

• Inheritance	Usually sporadic, can be autosomal dominant (Chr 9, 11, 16).
• Cognitive phenotype	Variable IQ, 50% have ID (mostly severe-profound).
• Psychiatric phenotype	Depression, Anxiety, Specific phobias, Psychosis (epilepsy related).
• Behavioural phenotype	Autistic features, hyperactivity, self-injury, sleep problems, aggression.
• CNS	Epilepsy in 70% of cases, cerebral astrocytomas.
• Cardio-vascular	Cardiac rhabdomyomas.
• Endocrine	
• Audiovisual	Retinal tumours.

• Muscular/skeletal	
• Other	Renal and lung hamartomas, polycystic kidneys, skin lesions (fibromas, fibrous plaques, hypomelanotic macules, adenoma sebaceum, café au lait spots).
• Weblink	www.nlm.nih.gov/medlineplus/tuberousclerosis.html www.ninds.nih.gov

Books Beyond Words Series

These are picture books for adults and adolescents who cannot read or who have difficulty reading. They are about difficult events people may experience, especially the emotional aspects of such events. The books actively address the problems of understanding that people with learning and communication difficulties experience. The stories are told through colour pictures, helping readers to cope with events such as going to the doctor, bereavement, sexual abuse and depression. The stylised drawings include mime and body language to communicate simple, explicit messages to the reader.

Aspects of Genetics

Brian O'Shea

'Most researchers cannot possibly know what it is like to grow up in a family haunted by a genetic disease – nor should we expect them to'. (Hayes, 1992)

'It has become fashionable to ascribe much psychopathology to the evils of modern society... Often imbued with political overtones... it does not take into account the obvious fact that the biological heritage of mankind extends back many millions of years'. (Trimble, 1996)

'But for every gene that codes for a protein, there are others that regulate its actions and yet others that regulate the regulators'. (LeFanu, 1999)

A gene is a part of DNA containing the message for a polypeptide sequence. Genetics⁸⁵² (Gk *gennō*, to give birth) have come to psychiatry to stay, (Emery, 1991; Murray & McGuffin, 1993; Iles, 2009) and with them have arrived a plethora of ethical and social issues, not least of which is the involvement of the commercial sector. (Tanne, 1992) Society should not become so habituated to genetic data that it ceases to try to better the environment. (Faraone *et al.*, 1999; Foley *et al.*, 2004) Molecular genetic techniques⁸⁵³ have been very successful in single gene disorders, which are usually rare, whereas common familial disorders provide greater difficulties because of their complex and non-mendelian patterns of transmission. (Owen & McGuffin, 1992) An abnormal gene may not function at all, as in phenylketonuria, or may malfunction, as in Huntington's disease. Nearly all genetically-influenced behaviours, be they normal or abnormal, are likely to reflect the additive effects of more than one gene (at different loci). (Plomin, 1990; Watson, 2004, p. 26) The multifactorial nature of mental illness makes simple genetic deductions about cause problematic. (Baron *et al.*, 1990) Disorders may show variable penetrance (not all gene carriers develop the disorder), genetic heterogeneity (a number of different genetic routes leading to the same condition or syndrome), pleiotropy (the same gene is expressed differently in different people), and people who are not genetically predisposed may manifest the disorder (phenocopy). Also, psychiatric disorders have developed improved reliability as distinct from proven validity over the years, i.e. it is unclear where one clinical disorder ends and another begins. The reasons why a disorder is familial⁸⁵⁴ include genetic, early and current shared environments (e.g. the language used), learned behaviour, role modelling, etc. Geneticists divide environmental factors into *unique* (to siblings in the same family) and *common/shared* (by siblings in the same family).

Male foetuses are spontaneously aborted more often than female foetuses.

The fundamental property of single-stranded DNA is its tendency to bind to another strand consisting of a complementary base sequence⁸⁵⁵.

There are 46 chromosomes⁸⁵⁶ in 23 pairs in the human somatic cell compared to four pairs in the fruit fly *Drosophila* and over 300 pairs in some fern cells. (Gribbin, 2002, p. 542) Each chromosome contains one

⁸⁵² Term coined by the British biologist William Bateson (1861-1926) in 1909.

⁸⁵³ **Molecular genetics** investigates the chemical and physical nature of genes and how genes exert control over development, growth and physiology. Various technologies are employed. Recombinant technology (molecular cloning – foreign gene put into a host cell so that it can be replicated and studied), PCR (oligonucleotide primers, tiny bits of DNA, are made to complement the DNA on either side of the sequence on wishes to amplify), rapid genotyping using chip (containing up to a million DNA variants) technology, genomics (how the functions and interactions of genes occur), and bioinformatics (ways of using large amounts of data in the search for similar sequences and predicting gene structure and function).

⁸⁵⁴ Runs in a family.

⁸⁵⁵ Francis Crick, James Watson, and Maurice Wilkins received the 1962 Nobel Prize for discoveries concerning molecular structure of nucleic acids and their role in information transfer. There are about 3 bn bases in the human genome.

⁸⁵⁶ Walter Flemming (1843-1915) of Germany identified structures in the cell nucleus in 1879 that are known as chromosomes. Albert Levan (1905-1998, Swedish botanist) and Joe Hin Tijo (1919-2001, Javanese cytogeneticist) reported the human complement of 23

very long (in relative terms) continuous molecule of DNA (deoxyribonucleic acid). DNA consists of deoxyribose, phosphate, the purine bases adenine (A) and guanine (G), and the pyrimidine bases cytosine (C) and thymine (T). Mammalian DNA is supercoiled around proteins called histones⁸⁵⁷.

Bacteriophages are viruses that stick to bacteria and inject their DNA or RNA into the bacterial cell wherein new viruses are manufactured. The bacterial cell then dies⁸⁵⁸.

*Gene mutations*⁸⁵⁹ involve the substitution of one base for another. Commonly this changes a *missense* mutation (a triplet coding for an amino acid is changed to that for another amino acid, which can have different effects on protein activity depending on the position of that amino acid within the protein molecule); about a third are *nonsense* mutations (the substitution changes the codon to a stop signal, which often reduces or stops mRNA formation or, in the cases where the stop codon is skipped over, aberrant mRNA is formed); *splice-junction* mutations (changes the way mRNA is spliced, which can have pathological consequences); and, *silent* mutations (these are not expressed phenotypically). *Point mutations* are created by changes in a single base pair (the simplest mutation) or by the deletion or insertion of one gene; if the coding region is affected then a codon may be made that leads to a missense or nonsense mutation with the production of the wrong amino acid or (because of changed sequence to a stop codon) or an incomplete protein.

Pseudogene

Mutated gene duplication incapable of translation into functional proteins

May misalign with neighbouring normal gene during meiosis

Any crossover may mutate the normal gene

E.g. mutation of gene for 21-hydroxylase causing congenital adrenal hyperplasia

A genetic disorder is one that is coded in one or more DNA segments. A genetic aberration may be hereditary or non-hereditary. RNA (ribonucleic acid) differs from DNA in that it is single-stranded instead of double-stranded, has ribose (R) instead of deoxyribose, and uracil (U) instead of thymine. RNA can hybridize with a complementary sequence of single-stranded DNA (ssDNA). RNA exists in several forms: messenger (mRNA) and transfer (tRNA) RNA. The product of the mRNA for the gene for Huntington's disease has been called 'huntingtin'. (Huntington's Disease Collaborative Research Group, 1993) This protein contains more than the normal amount of glutamine (the CAG triplet⁸⁶⁰ codes for the amino acid glutamine): uninterrupted glutamine residues known as a polyglutamine tract. Apparently, those proteins containing more than 50⁸⁶¹ glutamine molecules form tight intranuclear balls that are lethal to the cell. cDNA or complementary DNA, libraries of which are used in research into genetic defects, is DNA produced by reverse transcription from mRNA. In other words, reverse transcriptase catalyses the synthesis of DNA from RNA and can make a complementary copy of DNA (cDNA) from mRNA, which can then be used to synthesise a gene probe⁸⁶². A molecule of complementary DNA (cDNA) contains the information required to make a functional protein. However, cDNA contains no introns. Genes showing high DNA sequence similarity between different species (e.g. human and fly) and that perform similar functions in such creatures are known as *orthologs*⁸⁶³.

chromosomes (46 chromosomes instead of the 48 believed to be present until then) in 1956 in *Hereditas* ('The chromosome number of man', vol. 42, pp. 1-6), three years after Watson and Crick proposed the structure of DNA.

⁸⁵⁷ I.e. histones are proteins that package DNA in chromatin (complexes of DNA and protein) inside the cell nucleus.

⁸⁵⁸ Usually it dies by lysis.

⁸⁵⁹ Errors in DNA replication or somatic mutations are nearly always repaired by DNA repair enzymes. Progeria is due to a mutation in such an enzyme.

⁸⁶⁰ Examples of disorders associated with **triplet repeats** are Huntington's disease, fragile-X syndrome, dentate-rubro-pallido-luysian atrophy, the spinocerebellar atrophies, and myotonic dystrophy.

⁸⁶¹ Authors give different figures for the number of repeats that are associated with disease. One source gives a range of 36-120 CAG repeats for affected individuals, unaffected individuals having 2-25 repeats. Another source states that under 34 repeats carries no risk, 30-40 carries 'intermediate' risk, and 41 or more repeats suggests that disease will follow if the patient lives long enough.

⁸⁶² A **gene probe** = radioactively labelled molecule that binds to target gene and can then be detected by an assay such as autoradiography.

⁸⁶³ A *homolog* is a gene that is related to another gene by descent from a common ancestral DNA sequence. It includes the *ortholog* (keeps same function) and the *paralog* (genes related by duplication within a genome; this evolves a novel function, even if it is only a slightly different one).

Genes contain exons (coding sequences) and introns (non-coding sequences⁸⁶⁴). The initial mRNA formed from a gene is precursor RNA. The part of mRNA formed from introns is excised and those parts from the exons are joined or spliced together to form the final mRNA (post-transcriptional processing). Despite being from the one gene, exons may be spliced together in different ways so that different proteins may be manufactured in different tissues. This means that organisms did not need to add many new genes over evolutionary time in order to become more complex. Abnormalities in splicing may lead to disease. The process of producing mRNA from DNA occurs inside the nucleus and is termed transcription⁸⁶⁵. RNA polymerase (RNAPol) can exist in one of three forms in eukaryotes: RNAPol I (creates ribosomal RNA, i.e. rRNA), II (creates messenger RNA, i.e. mRNA), and III (creates transport RNA, i.e. tRNA). Activator and co-activator (*transcription factors*⁸⁶⁶) proteins provide a link to distant enhancer elements in the DNA sequence and are involved in regulating both transcription and correct positioning of RNAPol at the commencement of an open reading frame, the latter being a set of codons lying between start and stop codons. In the cytoplasm (neuroplasm) each amino acid becomes attached to a particular tRNA, the latter then combining with a complimentary mRNA. Ribosomes (large complexes of ribosomal RNA [rRNA] and protein) move along the mRNA, linking up amino acids to form a polypeptide chain, a process termed translation.

The c-fos and zif 268 genes are members of a class designated as *immediate early genes* (IEGs). IEGs encode transcription factors that are rapidly and transiently induced in the CNS by a variety of extracellular stimuli. They translate extracellular signals into alterations in intracellular neuronal function by regulating the expression of other genes, the latter being referred to as *late-response* or *target genes*. The IEG fos B may have a role in maternal care of offspring, at least in mice. (Brown et al., 1986)

There are 46 chromosomes (as 23 pairs) in human somatic cells. These are named from 1-22 in terms of decreasing length; there is also a pair of sex chromosomes, X and Y, or X and X. No known disorders are carried on the Y chromosome. A dominant trait is one that manifests in the heterozygote. A father cannot transmit an X-linked trait, be it dominant or recessive, to his son. A monoploid cell has one member of each homologous pair of chromosomes. A euploid cell contains an exact multiplication of the monoploid number of chromosomes, the normal euploid number in humans being 46, i.e. diploid (twice monoploid number). Aneuploid cells are non-euploid, such as exists in Turner's (XO) and Down's syndromes (trisomy 21⁸⁶⁷, described in 1959: 95% of Down's is trisomy 21, 4% is translocation, and 1% is mosaic where some cells are normal and others are trisomy 21). Non-disjunction occurs at or after the first zygotic division in mosaic Down's syndrome.

Down's syndrome

Copy number variation (CNV) refers to a segment⁸⁶⁸ of DNA for which copy-number differences have been found by comparing two or more genomes. Humans, being diploid, normally have 2 copies of each

⁸⁶⁴ Introns were once seen as merely evolutionary vestiges. However, they can influence the pattern of gene slicing and an intron variant may point toward a functionally important variation in another part of the gene.

⁸⁶⁵ Cells need to be able to start or stop transcription when the body is developing or when responses to external events dictate. Transcriptional factors stick to DNA in order to activate or repress this process. Additionally, hormone levels and other extracellular factors exert influences on transcription.

⁸⁶⁶ These proteins, either *activators* (increase transcriptions) or *repressors* (decrease transcriptions), recognise specific DNA sequences inside *promotor sequences* (regulatory sequences that may up- or down-stream of, or within, a gene). These factors often bind to DNA as pairs – members of the pair may be identical (*homodimers*) or non-identical (*heterodimers*). Transcription factors are required for the normal differentiation of cortical nerve cells.

⁸⁶⁷ 8 out of 10 children with **trisomy 21** will now reach at least their 60th birthday. The features/complications of this trisomy include a classic facies, mild/moderate low IQ, deafness, hypothyroidism, cardiac defects, leukaemia, duodenal atresia, and seizures.

⁸⁶⁸ Segment length may range from one kilobase to several megabases in size.

chromosomal region (1/chromosome). This may vary because of deletion or duplication.⁸⁶⁹ CNVs may have a role in autism, intellectual disability, and schizophrenia. (Guilmatre et al, 2009)

Mitosis⁸⁷⁰, the usual type of cell division, leads to an increase in the number of cells⁸⁷¹ for body growth and cell replacement; all chromosomes are duplicated and distributed equally to two daughter nuclei, each containing the same set of chromosomes as the parent nucleus. Mitosis is artificially divided into interphase⁸⁷², prophase, metaphase, anaphase and telophase. Cell division is completed by cleavage of the cytoplasm.

Meiosis involves gamete production (gametogenesis), both sperm and egg. It is also called reduction division, because the number of chromosomes in the cells produced by meiosis is halved. Put another way, each gamete receives either of a pair of homologous (matching) chromosomes. Four haploid gametes are present at the end of meiosis: in the case of the male germline these are retained as sperm, whereas in the female germline only one is retained as an ovum, the other three forming polar bodies. The process of meiosis consists of 2 steps, each with a prophase, metaphase, anaphase and telophase. *Crossing over*, the exchange of genetic material between chromatids of maternal and paternal homologous chromosomes, may occur when these chromosomes are paired during prophase of the first meiotic division.

Most fetuses with chromosomal abnormalities do not survive. Half of all spontaneously aborted fetuses in the first trimester have major chromosomal abnormalities. Ten percent of couples who habitually abort have minor chromosomal abnormalities. 0.6% of babies have detectable chromosomal abnormalities, two-thirds of these being autosomal and one-third sex-chromosomal.

A biological marker is a biological characteristic or abnormality that may be associated with an abnormal gene or a gene close to (linked) to that gene. Use of biological markers allows a more direct search for a 'candidate' (for the disorder) gene. The researcher can focus on the genomic region, if known.

Unfortunately, some markers are state rather than trait markers, the latter being more informative.

Gregor Mendel⁸⁷³ worked out his Laws of Heredity by studying the results of crossing pea plant seeds, which can be smooth or wrinkled. He described the phenomenon of *independent assortment*: the pattern of inheritance for one trait was unaffected by the transmission of another trait. However, it has since been shown that when genes for two traits lie close to one another on a chromosome they do not obey Mendel's independent assortment, i.e. they demonstrate linkage.

*Recombination*⁸⁷⁴ (crossover) is a rearrangement of alleles due to crossovers, i.e. an exchange of genetic material between pairs of homologous chromosomes during meiosis. For example, Mr A got a copy of chromosome 12 from his mother (another the other copy from his father) which is a mix of her 2 copies of that chromosome, one of which came from her mother (the other from her father), and so on back through the generations. If the recombination fragment, a measure of the recombination event, is close to zero, *linkage* (inheritance of 2 or more markers as a single unit because of their close proximity on the chromosome and not because of chance) is likely. The ratio is expressed as its logarithm (ratio, i.e. between probability of there being linkage at a given recombination fragment and that of there being no measurable linkage), also known as the *lod score*. In other words, the lod score is the log of the odds on linkage in genetic research: the logarithm of the odds ratio. The *odds ratio* equals the odds of the observed pattern of co-segregation between marker and disorder occurring if the marker and disorder are linked divided by the odds of the same co-segregation occurring if the marker and disorder are not linked. Morton (1955) devised the lod score. A lod score of +3 or more carries a high chance of linkage (1,000 to 1 chance that co-segregation of DNA marker and disease did not occur simply by chance). Scores below -2 exclude linkage.

⁸⁶⁹ Duplication refers to the presence of 2 copies of part of a chromosome on the chromosome, e.g. involving part of chromosome 17 in the myopathy Charcot-Marie-Tooth disease.

⁸⁷⁰ Quiescent cells (G0 phase) are stimulated by growth factors like insulin-like growth factor via second messenger molecules. Transcription factors in the nucleus activate transcription factors and thence DNA synthesis. In G1 phase chromosomes are prepared for replication. In the S phase chromosomes are duplicated into chromatids. In the following G2 phase diploid cells divide into daughter phase. The cell then enters mitosis.

⁸⁷¹ Megakaryocytes are derived from megakaryoblasts by endomitotic reduplication, i.e. nucleus but not the cell divides (megakaryocytes therefore have many nuclei). Of course the cell then fragments into numerous platelets.

⁸⁷² The microtubule-organising centre (MTOC – tubulin-containing centrosomes) rearranges microtubules during interphase. This gives a structure on which daughter chromosomes separate. Paclitaxel, used to treat cancer, bind to microtubules and prevents movement of organelles. This action prevents formation of mitotic spindles and leads to death of the cell.

⁸⁷³ Augustinian monk.

⁸⁷⁴ Discovered by T H Morgan of Columbia University in fruit flies (*Drosophila melanogaster*).

Pardes ea,(1989) state that the risks for first-degree relatives developing a condition more often than controls are: bipolar affective disorder: 24 times higher; schizophrenia: 18; alcoholism: 10; and, panic disorder: 9.

The *pseudoautosomal region* of the sex chromosomes is a segment of sequence homology between the X and Y chromosomes in which meiotic cross-over (recombination) can occur. Depending on its exact location, a gene situated within this region could be inherited either in an autosomal or in a sex-linked manner. The process of inactivation of the X chromosome is complex. Normally, one X chromosome exists in an inactive, packaged state, formed during the late blastocyst stage: heterochromatic *Barr body*. The X inactivation centre is found at Xq13.3. There, an X inactive-specific-transcript produces an RNA called Xist that coats its own chromosome. This is followed by other chemical events that maintains the inactivated state. Some parts of the 'inactivated' X chromosome remain active, the so-called pseudoautosomal regions.

Epigenetics investigates heritable modifications of gene function, such as the expression of a gene via DNA methylation or changes in chromatin structure. Such changes are heritable but reversible. They can be caused by the environment during life and then be passed on to progeny. Such processes can change phenotypes and might explain why major psychiatric disorders do not follow the Laws on Mendel and they may explain how environmental factors translate into biology. Chromatin configuration can allow it to be activated (open; euchromatin - can be accessed by transcription factors) or inactivated (condensed; heterochromatin - cannot be accessed by transcription factors). Histone acetylation or methylation and DNA methylation influence transcriptional activity in various ways⁸⁷⁵. Some neuropsychiatric conditions seem to be caused by epigenetic changes, e.g. Rett syndrome and even some of the major 'function disorders' such as schizophrenia. Modern ideas of inheritance have been called '*hard inheritance*' (you transmit to offspring only those characteristics with which you were born - based on ideas of Sir Francis Galton [1822-1911] an English eugenicist and polymath and relative of Charles Darwin, and those of Friedrich Leopold August Weismann [1834-1914] a German biologist and evolutionary theorist). Jean-Baptiste Lamarck (1744-1829), a French biologist, believed that the genetic basis of characters could be changed by factors such as the environment or disuse. The modified genotype could then be transmitted to the next generation. A German-born biologist who died in the US, Ernst Mayr (1904-2005) coined the term '*soft inheritance*' to encompass Lamarckism and related ideas. Epigenetics, a modern concept, suggests that Lamarck may have not have been far wrong.

Modern psychiatric classifications involve tighter criteria than heretofore. They do not address the question of external validity or the likely clinical heterogeneity within a given diagnosis (e.g. PSE). Psychiatric disorders are probably heterogeneous, with different genetic and non-genetic mechanisms underlying different major genes, polygenetic forms, and environmental causes. The problem is made more complex by reduced penetrance and variable expressivity of the genotype. It may be that certain genes cause non-specific genetic predisposition to psychopathology, and that other genetic and non-genetic components are required to bring about a specific psychiatric disorder. Price, ea,(1987) suggested that many psychiatric 'illnesses', e.g. bipolar affective disorder and schizophrenia, may constitute a spectrum of disorders, rather than single entities; possible reasons include *nonallelic genetic heterogeneity* (genes interfere in developmental pathways at different points but ultimately lead to similar clinical manifestations) and *phenocopies* (non-genetic cases of an illness that present a clinical picture similar to that of a hereditary form, such as the possible roles for viruses or perinatal brain damage in schizophrenia). Assortive mating refers to the tendency of people with a mental disorder to mate with a person with a similar disorder. It is not uncommon in psychiatric hospitals. Assortive mating may confound linkage analysis (Q.V.) by increasing the extent of genetic heterogeneity within pedigrees: the person marrying into a family may introduce a genetic type of the disorder different from the one already segregating in the pedigree.(Baron ea, 1990)

⁸⁷⁵ Gene expression can also be controlled by RNAi (RNA interference) due to non-coding RNAs (e.g. siRNA [short interfering], shRNA [small hairpin], and mi RNA [micro])

Twin studies carry certain inherent difficulties. Monozygotic twins (MZ) derive from the division of one fertilised ovum and share an identical set of genes; monozygosity appears randomly⁸⁷⁶ in approximately 4/1,000 pregnancies. On average, dizygotic twins (DZ) have 50% of their genes in common, just like full siblings. MZ twins are always of the same sex, whereas DZ may or may not be. MZ twins, more than DZ twins or singletons, are more likely to have defects such as congenital heart disease, and obstetric problems are more common in twins, which might predispose to psychiatric disorder. Also, twins, especially if MZ (or DZ of the same sex), share intrauterine and rearing environments more than even other siblings. We will come across this issue again in other chapters, especially when discussing schizophrenia. The recurrence in families of DZ twins is common, but it is rare for MZ twins to recur in a family. One quarter of MZ twins have separate placentas. (Watson, 2004, p. 401) Also, the incidence of dizygosity varies in different populations, from about 3 to 40/1,000 pregnancies. According to some (Tsuang & Faraone, 1997; Riley ea, 2003, p. 254) but not all authorities (Löffler ea, 1994), twins *per se* are not at increased risk for schizophrenia. In fact, the 'typical schizophrenic is more likely than not to have no schizophrenic or schizotypal relatives'. (Tsuang & Faraone, 1997) Also, MZ are discordant for schizophrenia 50% of the time.

The Amish people, a small and isolated population with a small number of founders, are said to be prone to manic-depression: this group is likely to be genetically homogeneous, and the generality of the genetic findings to other populations remains to be determined (Egeland, ea, 1987). Baron, ea, (1987) reported tight linkage of affective illness to the classical X-chromosome markers, colour-blindness and G6PD deficiency, findings that strongly supported earlier suggestions that a gene on the X-chromosome is a causative factor in some cases of manic-depression. Many reports of linkage of psychiatric disorders to various chromosomes fail to be replicated, a fact that should temper enthusiasm for reported breakthroughs. (O'Donovan & McGuffin, 1991; Mendlewicz ea, 1991) The failure to replicate chromosomal findings in depression may not invalidate the original discoveries in 'isolated populations' like the Amish. (Weller, 1992) Price, ea (1987) wondered if major depressions with an age of onset greater than 30 years might be non-genetic, whereas cases of earlier onset may be familial and genetic. When genetic predisposition is worked out, prospective studies of at-risk individuals to identify specific non-genetic factors that contribute to the development of illness can be designed.

Terms

Aetiological heterogeneity: this may result from having both genetic and environmental causes.

Alleles: alternative forms, or versions, of the same gene, be they normal or abnormal.

Alternative splicing: the manner in which different protein isoforms can be produced. Different RNA species are produced by transcribing different exons (regions of coding). For example, if a gene contained 4 exons and if all 4 exons were transcribed one would be left with a large isoform. A smaller isoform are derived from a lesser number of transcribed exons. In other words, a given gene may yield a number of different proteins.

Aneuploidy: having an abnormal number of chromosomes. Aneuploidy may affect all cells or, as in mosaicism, some cells only, i.e. a mixture of normal and aneuploid cells as in some cases of Down's and Klinefelter's syndromes. Work is underway to non-invasively diagnose fetal aneuploidies before birth by analysis of free fetal DNA in maternal plasma. (Benachi & Costa, 2007; Dhallan ea, 2007; Driscoll & Gross, 2009)

Antisense oligonucleotide: piece of synthetic DNA with nucleotide sequence that is reverse of and complements part of messenger RNA.

Barr body: inactivated X-chromosome material produced by *lyonisation*⁸⁷⁷; the number of Barr bodies = the number of X-chromosomes minus one. They are usually detected on buccal smear. The gene for glucose-6-phosphate dehydrogenase (G6PD) is found at Xq28. G6PD deficiency occurs more often in males than females but, because of lyonisation, female heterozygotes may experience problems: because of random inactivation of X chromosomes there are two red cell populations, normal and G6PD deficient.

Candidate genes: genes encoding for neuroreceptors, enzymes involved in neurotransmission, or other proteins that might play a part in the pathogenesis of a disorder. Previous evidence suggests that such genes

⁸⁷⁶ Geneticists use the term *stochastic* which simply means a random event.

⁸⁷⁷ This is called after the English geneticist Dr Mary Frances Lyon who was born in 1925. Barr bodies get there name from the Canadian physician Murray Llewellyn Barr (1908-95).

may influence a phenotype. *Biological candidates* (e.g. a neurotransmitter) might be involved in biological or therapeutic aspects of the disorder of interest whereas *positional candidates* (e.g. disrupted in schizophrenia 1 on 1q) are chosen because of linkage or cytogenetic results suggesting a particular part (position) of the genome might harbour a susceptibility gene.

Anlage: primordium, inborn disposition.

Anticipation: a condition deteriorates clinically or manifests at an earlier age through successive generations, e.g. as happens in myotonic dystrophy and Huntington's disease (and debatably schizophrenia) due to triplet (trinucleotide) repeat expansion.

Anticodon: 3-base sequence in t (transfer) RNA molecule.

Autosomal dominant disorders: examples include achondroplasia, Huntington's disease (gene at 4p16.3), Marfan's syndrome, osteogenesis imperfecta, neurofibromatosis type 2⁸⁷⁸, and tuberous sclerosis⁸⁷⁹. In a normal gene, that repeats a sequence, CAG, the sequence repeat is 9-39, but in people with the Huntington's disease gene, the CAG repeat is 40 or more. Myotonic dystrophy is another example of a triplet (trinucleotide) expansion disorder. Trinucleotide repeat and age of onset are inversely correlated in Huntington's disease: the more repeats the earlier the onset. (Gusella & MacDonald, 1994)

Balanced translocation: a translocation without the presence of extra chromosomal material; persons with this type of translocation are called translocation carriers.

Bands: certain stains, such as Giemsa, reveal that chromosomes have a specific banding pattern that allows their identification. Chromosomes can also be identified by, for example, length and position of centromere.

Behavioural phenotype: The observed specific relationship between genotype of a syndrome and its behavioural or cognitive developmental profile and/or any specific association with comorbid psychiatric disorder. Examples include bipolar and schizophrenia-like states in the velocardiofacial syndrome, social anxiety in fragile X patients, and self-injury in Lesch-Nyhan syndrome.

Caenorhabditis elegans: A nematode worm with circa one hundred neurones. Presenilins code for a protein resembling G protein-coupled receptors and similar proteins are found in *C. elegans*. The latter proteins are involved in intracellular trafficking of proteins and may therefore be involved in apoptosis and β -amyloid protein processing.

Candidate loci or genes: association studies of disorders and genes (or loci) are more useful if there is reason to believe from prior evidence that the gene or locus is involved in a phenotype, i.e. is a candidate for, in the disorder. Positional candidate genes (e.g. dysbindin at 6p) are derived from linkage studies or cytogenetic research whereas biological candidate genes (receptors, transporters, or enzymes involved with a neurotransmitter) are chosen because they are thought to have a role in influencing the biological aspects of a condition or its treatment.

⁸⁷⁸ **Neurofibromatosis** consists of a number of related conditions. Skin pigmentation and tumour formation involving Schwann cells are found in these disorders. The two relatively common types are autosomal dominant conditions, often with fresh mutations. *Von Recklinghausen's disease* or *neurofibromatosis type 1* (**NF1**) is the commonest type (NF1 mutation on chromosome 17 coding for neurofibromin). Most patients have low average IQs with some cases scoring above or below this. Performance IQ is particularly affected. Learning difficulties and ADHD may occur. Here one finds peripheral neurofibromas, café-au-lait spots, and pigmented hamartomata of the iris (Lish nodules). Large subcutaneous plexiform neurofibromata may deform parts of the body such as face or limb. Malignant transformation is possible. Blindness may occur in children with astrocytomas involving the visual pathways. Hydrocephalus may be due to stenosis of the aqueduct. A few patients develop seizures. A variant involving non-germline mutation (i.e. a somatic mutation) is called Turcot's syndrome (brain tumour-polypoidosis syndrome 1).

Deletion of the region containing NF1 gene gives rise to a particularly severe form of the disease with intellectual disability. In **NF2** there may be no skin lesions and bilateral acoustic schwannomas is the usual presentation. It is a multiple neoplasia syndrome due to mutations in NF2 tumour suppressor gene (22q). (Asthagiri et al, 2009)

⁸⁷⁹ **Tuberous sclerosis** (epiloia), affecting 1/6-10,000 of the population, is a multi-system, highly penetrant autosomal dominant disorder with hamartomata in many organs. The CNS shows abnormal neuronal and glial proliferation. It results from mutation of (at least) one of two genes on chromosomes 9 (TSC1 at 9q23, coding for hamartin) and 16 (TSC2 at 16p13.3, coding for tuberin). Tuberin and hamartin are associated with dysfunction neuronal and glial proliferation/differentiation. Affected people may have pitting of the teeth, seizures, skin problems (angiofibromata, ash leaf spots, shagreen patches, etc), tumours of the CNS (cortical tubers and subependymal nodules [+/- calcification] and giant cell astrocytoma), hamartomas of the retina, angiomyolipomata of the kidney, and rhabdomyomas of the heart. Neuropsychiatric problems include low IQ (65%), behaviour problems, autistic spectrum disorder, psychosis, and seizures (80% - most types of seizure are represented).

*Centimorgan (cM)*⁸⁸⁰: genetic distance in which the probability of a recombination between two loci occurring is 1%.

Centriole: one of the 2 poles of the spindle during metaphase.

Centromere: constricted chromosomal region including site of attachment to spindle; divides chromosome into 2, usually unequal, lengths or 'arms'.

Chromatid: at the end of interphase each chromosome has divided along its length into 2 daughter chromosomes, or chromatids; these remain attached to each other at the centromere.

Chromatin: basic unit of structure of chromosomes; irregular network of long coiled threads composed of DNA, histones and non-histone proteins.

Chromosome: one of a number of small bodies, found in pairs, into which the chromatin of a cell nucleus resolves itself before cell division; visible only during cell division, i.e. at prophase they become visible as discrete structures.

Codon: 3-base sequence in DNA molecule, each being decoded into one amino acid. An 'open reading frame' is a full set of codons lying between start and stop codons.

Coefficient of kinship: measure of expected proportion of genes in common between individuals: ½ for first-degree relatives, ¼ for second-degree relatives.

Deep resequencing: a method for sequencing a gene in thousands of subjects, usually employing high-throughput sequencing in order to increase speed and reduce cost.

Deletions: loss of whole or part of a chromosome; major deletions (partial monosomy) include Wolf-Hirschhorn (4p-) cri du chat (5p-); terminal deletions involve loss of the telomere; and interstitial deletion occurs within an arm of a chromosome.

Dichotomous trait: traits that can only be present or absent, with no 'shades of grey'.

Drumstick: lobular projection from nucleus of polymorphonuclear leucocytes in females. No relationship exists between number of X-chromosomes and number of drumsticks.

*Endophenotype*⁸⁸¹ (*intermediate phenotype*): a biological abnormality that seems to represent a more immediate result of the hypothesised genetic defect than does the clinical syndrome, e.g. panic following sodium lactate infusion in panic disorder, dysfunctional smooth-pursuit eye movement (Greenwood ea, 2007) or olfactory abnormality in schizophrenia (Turetsky ea, 2008), gating of the theta-alpha-frequency oscillatory signal in the paired-click paradigm in schizophrenia (Hong ea, 2008), deficient inhibitory control in ADHD (Goos ea, 2009), cognitive inflexibility in obsessive-compulsive disorder, or a small P300 amplitude in alcoholism. The usefulness of endophenotypes as a simpler path to the genetics of psychiatric disorders has been questioned. (Flint & Munafò, 2007) Also, biomarkers of incipient psychosis and schizophrenia may be unstable due to brain maturation (Pantelis ea, 2009) and longitudinal assessment may be needed to distinguish a normal from an abnormal trajectory of neurodevelopment.

Epistasis: 2 or more loci show a multiplicative interaction where the final result is greater than the sum of the effects of individual loci. This phenomenon may be important in interpreting genetic studies of families containing members with schizophrenia.

Exome: all expressed mRNA sequences in a given tissue.

Expressivity: variability in clinical manifestation of a genetic trait (see penetrance), e.g. neurofibromatosis may be expressed as anything from a visceral nodule to the Joseph Merrick syndrome ('elephant man').

Family studies: These can be of the family history variety where a history is taken from the proband, who may not be very knowledgeable, or the family study variety where all available relatives are directly interviewed.

F body: fluorescent body exhibited by males during interphase; consists of the Y-chromosome. Number of F bodies = the number of Y-chromosomes.

Fine mapping: precise mapping of a locus it has been identified by linkage (within megabases of DNA) or association (within tens of kilobases).

First-degree relatives: parents, siblings, children, all having 50% of the index person's genes; second-degree relatives are grandparents, grandchildren, aunts and uncles, all sharing an average of one-quarter of the index person's genes. (see coefficient of kinship)

⁸⁸⁰ This is a measure of 'genetic distance' between loci whereas 'physical distance' is measured in base pairs. 1 cM = 1 million base pairs.

⁸⁸¹ See complete issue of *Dialogues in Clinical Neuroscience* 2005; 7(2).

Flanking markers: 2 markers, one located on the telomeric side and the other on the centromeric side of a gene.

Genetic heterogeneity: this may be allelic when there are different alleles at the same locus, or nonallelic when there are defects at different loci.

Genetic marker: a 'tag' in close proximity to the chromosomal locus that actually expresses or causes disease.

Genetic probes: usually purified lengths of DNA or RNA specific for the particular gene or DNA segment suspected to be variant under study. In some conditions, such as sickle-cell anaemia, it is possible to detect the defective gene directly, without using a specific probe, by using one of the specific restriction enzymes⁸⁸² that reveal a pattern of DNA fragments unique to the mutation of interest. Some people affected by a disease or syndrome will have inherited the disease gene but will not have inherited the marker that is linked to it in the other family members. DNA markers can be used to detect carriers of abnormal alleles as early as the first trimester of pregnancy, using foetal DNA analysis.

Genome: the total DNA of a cell or organism; *genomics* is the study of genomes; the Human Genome Project refers to the co-ordinated international mapping of the genome. The mouse genome was thoroughly mapped before that of humans.

Germinal mutation: mutation in pre-gamete stage cell; can be inherited. (Cf. somatic m.) More than one-third of the human genome is expressed (turned on) primarily in the brain. (Sutcliffe ea, 1984) The genome is not simply the sum of individual genes; it is more like a recipe, variously influenced by individual ingredients. The notion of one gene for one protein is an oversimplification, many of them being capable of producing multiple proteins. The human genome contains about 25,000-30,000 (double that of the fruit fly) that are able to make at least a quarter of a million proteins! (Gribbin, 2002, p. 570)

*Heritability*⁸⁸³: a calculation of the contribution to causation made by genes in a population⁸⁸⁴; it is calculated from the known incidence of the condition in the general population and in relative, e.g. it has been calculated as being higher in schizophrenia (63-85%) than in congenital club foot (68%), anencephaly and spina bifida (60%), or congenital heart disease (35%). (Emery & Rimoin, 1990; McGuffin ea, 1995; Szumukler, 1998) Owen ea (2000) estimated heritability for schizophrenia (80%), bipolar disorder (80%), alcohol abuse/dependence (60%), major depression (40%), panic disorder (40%), phobia (35%), and generalised anxiety disorder (30%). Smoller ea (2008, p. 857) give the following approximate heritabilities: autism (90%), schizophrenia (70-80%), bipolar disorder (60-85%), ADHD (75%), late-onset Alzheimer's disease (60%), OCD (30-45%), major depression (40%), panic disorder (45%), alcohol dependence (35-60%), and phobic disorders (10-39%). One long-term follow-up of schizophrenic patients failed to find a history of the disorder in first- or second-degree relatives in 60% of cases. (Bleuler, 1978)

Hybridisation: single-stranded DNA immobilised on a membrane is probed with a DNA fragment complementary to that sought, so allowing its presence and size to be confirmed.

Homotypia: a tendency for a disorder to breed true within families. Early studies of schizophrenia supported this phenomenon, but more recent reports have been more equivocal. Also, the subtype of schizophrenia in an individual patient may change over time.

Hox (homeotic) genes: first discovered in flies but known to exist in humans, mutation in these genes cause conversion of one part of the body into another.

Hypervariable probes: those probes recognising several different alleles; therefore more likely to be highly informative since variation between individuals is high.

Imprinting: the foetus is able to tell the difference between maternally- and paternally-derived chromosomes; deletion of part of paternal 15q gives rise to the Prader Willi syndrome, whereas deletion of a similar region of the same chromosome from the mother causes Angelman syndrome. 'Imprinting' is also used to describe how newborn animals follow the first thing they see.

Informative family: one containing many affected members, the disorder running through one side (father or mother of proband) of the family only.

⁸⁸² Wener A D Nathans and Hamilton Smith received Nobel Prize in 1978 for discovery of restriction enzymes.

⁸⁸³ This statistic applies to populations and to not to individuals.

⁸⁸⁴ Heritability may vary with the population being studies. Also, as the population becomes more genetically homogeneous the apparent heritability of a trait decreases.

In-situ hybridization: technique using labelled DNA or RNA probes to hybridize to complementary RNA coding for a particular protein. Using autoradiographic methods, it is possible to quantitatively study gene expression in individual neurones.

Isochromosomes: rarely, the centromere (often of the X chromosome) divides horizontally instead of longitudinally leaving a chromosome consisting of either 2 long arms or 2 short arms.

Junk DNA: stretches of DNA separating genes; accounts for more than one-third of genome; of unknown function, but may be important, e.g. for evolution.

Karyotyping: chromosomes can only be viewed with clarity during cell division; phytohaemagglutinin is used to stimulate cell division in vitro, then colchicine is used to arrest cell division in metaphase; hypotonic saline is then used to swell the cell so as to separate the chromosomes from one another; stains, such as Giemsa, demonstrate the banding properties (light and dark bands that are characteristic of each chromosome⁸⁸⁵); a photograph is taken, from which the chromosomes are cut and arranged in homologous pairs. The term *karyotype analysis* simply refers to the visualisation of chromosome number and gross structure. *Fluorescent in-situ hybridization (FISH)* involves using fluorescent probes to investigate chromosomal or submicroscopic chromosomal changes, e.g. foetal cells may 2 or 3 intranuclear fluorescent patches indicating a disomy or trisomy chromosome 21, the latter indicating Down's syndrome.

Kilobase (Kb): 1,000 base pairs.

Ligase: an enzyme that allows separate DNA sequences to be joined together.

Linkage analysis: tests if observed co-occurrence of a disorder and a marker for a genetic locus within a given pedigree are compatible with that locus contributing to disease susceptibility. One can attempt to trace a gene from a protein or a protein from a gene, or look at candidate genes.(Q.V.)

Linkage disequilibrium: in meiosis, alleles in one generation tend to diminish in subsequent generations because of recombinations aimed at reshuffling of genes. However, for loci closely situated to one another, recombination is rare, and associations tend to persist for many generations.

Locus (loci): a specific site(s) on a chromosome.

Major histocompatibility complex (MHC): the HLA system consists of a series of closely linked genetic loci situated in the MHC on chromosome 6p. T cells use HLA antigens as recognition molecules. Various psychiatric 'HLA-associated diseases' have been described, e.g. schizophrenia (A28) and narcolepsy (DQB1-0602 and DQA1-0101). Multiple sclerosis may share certain HLA associations with narcolepsy (DR7, DR2).

Monogenic disorders: single gene disorders. These disorders have low population prevalences, which suggests that common diseases (>1% of the population) are likely to be polygenic, as are many traits that have been genetically studies, such as IQ, height, or skin colour.

Monosomy: loss of a whole autosome; probably incompatible with human survival.

Mosaicism (in Down's syndrome): occurs when non-disjunction takes place during any cell division after fertilisation; there are normal and trisomic cells in the same person; the effects on cognitive development are very variable.(Thapar ea, 1994)

Multifactorial characteristics: this should be contrasted with unifactorial disorders (Q.V.). Various contributions come from one or more genes and the environment. Liability must pass a certain threshold: population incidence represents the threshold for the general population. Familial incidence is the threshold for relatives of patients with multifactorial disorder. Familial incidence will be greater than population incidence. The curve of liability is shifted to the right. Examples include IQ, weight, height, blood pressure, skin colour, and possibly schizophrenia, cleft palate, and congenital heart disease. These often have a normal frequency distribution curve.

Mutagen: any agent increasing mutation (change) rate in DNA, such as radiation⁸⁸⁶, high parental age, or chemicals.

Northern blotting: RNA fragments are not cut by restriction enzymes in this technique; instead they are blotted as full-length mRNAs onto membranes.

Notation for gene locations: this is a shorthand way of describing the position of a gene in the genome. E.g. Xq27-28 means that the gene is on the X chromosome, on the long arm (p, short arm, from French for

⁸⁸⁵ Each band is assigned a number. The gene underlying cystic fibrosis (CFTR at 17q.21) is in band 21 of long arm of chromosome 17.

⁸⁸⁶ Hermann Müller received the Nobel Prize in 1946 for discoveries regarding mutations caused by X-rays.

small; q comes after p), and, numbered from the centromere, in segments 27 and 28. The astute observer will have noticed that the example given is that of the fragile site in the fragile X syndrome. A + or – sign before a symbol refer to the addition or absence of whole chromosomes (e.g. 47, XY, +21 = male with Down's syndrome), whereas the same signs after a symbol refers to only part of a chromosome (e.g. 46, XY, 5p- = male missing part of chromosome 5, i.e. cri du chat syndrome).

Nucleotide: e.g. the organic bases thymine and uracil + phosphate + 5-carbon sugar, repeated. Bases are the only source of variability within nucleic acids.

Oncogenes: DNA sequences homologous to oncogenic nucleic acid sequences of mammalian retroviruses. A retrovirus is one that is able to induce its host cell to use viral RNA as a model from which to construct DNA. This reverses the dogma 'DNA makes RNA'.

Pairwise concordance: the proportion of pairs of twins concordant for a particular trait. To be more exact: number of twin pairs in which both twins are affected by a condition divided by the total number of twins.(see probandwise c.)

Paracentric inversion: stretches of chromosomal material are inverted within the same chromosomal arm (e.g. in haemophilia).

Partial trisomy: a translocation occurs where a part of a chromosome becomes attached to a different one. If parents are phenotypically normal carriers of translocations are at risk for having a partial trisomy for the first mentioned chromosome, i.e. they carry 1 pair of a chromosome plus a piece of another similar chromosome; about 5% of cases of Down's syndrome are partial trisomy 21.

Penetrance: probability of a disease genotype resulting in abnormal phenotype. In other words, the proportion of heterozygotes who express (see expressivity) the gene in any degree (some authors see penetrance as an all or none phenomenon, and expressivity as a more variable phenomenon); penetrance is a product of the modifying influence of other genes and the environment; some cases of tuberous sclerosis, for example, have only sparse facial papules because of low penetrance.

Pericentric inversion: swapping of chromosomal material from one arm of a single chromosome with the other arm of the same chromosome.

Phenocopy: environment-induced disorder that resembles an inherited one, e.g. congenital deafness could be caused by rubella, radiation, drugs, or a rare recessive gene.

Phenotype: The outwardly observable trait (e.g. height) or laboratory finding (e.g. protein) that results from (is coded for by) the genotype. When people have 1 copy of a certain allele and share the same phenotype as do people with 2 copies of the same allele the allele is dominant for that trait. A recessive allele would need to occur twice in the same person (2 copies) to be expressed in the phenotype. Co-dominance refers to the situation where the person has 1 copy of the allele and a phenotype that is somewhere between (intermediate) those with 0 and 2 copies of the allele.

Philadelphia chromosome: acquired chromosomal abnormality involving a deleted chromosome 22, its long arm being translocated to another autosome, usually chromosome 9; associated with chronic myeloid leukaemia.

Pleiotropism (pleiotropic genes): a gene with more than one effect on the phenotype; several genes may contribute to one disorder, and a single gene may contribute to several disorders; many psychiatric disorders may be polygenic, the summation of a number of genes, each of small effect.

Polygenes (polygenic): a character that is determined by more than one gene; many genes of small effect acting in concert to produce a phenotype, e.g. schizophrenia.(Gill, 1988) McClellan et al (2007) suggest that schizophrenia is not due to multiple common polymorphisms acting together but rather that genetically highly heterogeneous with many rare, highly penetrant, often individual- or family-specific predisposing mutations (common disease-rare alleles hypothesis).

*Polymerase chain reaction*⁸⁸⁷ (PCR): method for amplifying a specific DNA region to allow its analysis; in principle, the reaction can be performed starting from a single DNA molecule. There are a number of types of PCR (differential display, quantitative, real-time). These have demonstrated downregulation of key oligodendrocyte and myelination genes (incl. transcription factors that regulate these genes) in bipolar and schizophrenic patients,(Thachev et al, 2003) pointing to an overlap between both conditions.

⁸⁸⁷ The American biochemist Arthur Kornberg (1918-2007) discovered DNA polymerase (Nobel Prize in Physiology or Medicine 1959 – shared with the American biochemist Severo Ochoa [b. 1944] who worked on RNA synthesis). PCR discovered by Kary Mullis in 1984 (Nobel Prize in Chemistry, 1993).

Polymorphic: the information coded by base pairs is not a continuous series of base sequences that give the code for proteins. 'Spacers' that are edited out when RNA is manufactured interrupt them. Hence RFLPs (Q.V.), or the variation in fragment length (polymorphism) produced by the spacers.

Polymorphic markers: markers recognising fragments of variable size; at least 2 alleles should be present in the population to be useful.

Polymorphism: more than one in a hundred of the general population over a number of generations contains a particular DNA variation resulting from a mutation.

Polymorphism information constant (PIC): figure indicating usefulness of a polymorphic DNA marker, e.g. a PIC of 0.45 means that the probe would be informative in 45% of families.

Polyploidy: a whole set of chromosomes gained; incompatible with human life.

Positional cloning: a set of techniques by means of which disease genes are identified through their position in the genome rather than through their function.

Presumed obligate carriers: non-affected relatives the gene or genes for a disorder, such as the mother of a patient with schizophrenia who, although not psychotic herself, has a parent or sibling with schizophrenia.

Proband: a sampled individual with a condition or trait; propositus if male, propoita if female.

Probandwise concordance: the proportion of co-twins concordant for a trait when ascertained through affected probands; or, number of affected co-twins of an affected proband divided by the total number of twins.

Promoter and enhancer regions: stretches of DNA around genes that prompt the gene to express or shut down; they can act as binding sites for transcription factors that have a role in determining in what tissue or at what time in life a gene is turned on or off.

Protein kinase: enzyme that transfers a phosphate radical to a protein.

Proteomics: the study of proteins at a functional level (McGuffin, 2002, p. 20) or the study of how abnormal genes lead to the production of dysfunctional proteins and the latter's abnormal interactions with other molecules. (Pennington ea, 2005) An example is the finding of excess clusterin, an extracellular chaperone that regulates formation and clearance of amyloid, in Alzheimer's disease. (Thambisetty ea, 2010)

Recessive trait: recessive traits manifest only in the homozygous state, where there is a double dose of mutant gene. Offspring are usually normal, as would have been most of their parents. The most likely relatives to be affected are siblings. It is very difficult to trace affected individuals in the family history. If 2 heterozygous parents produce children, there is a 1 in 4 chance of a child being affected: ¼ will be normal, ½ will be carriers or healthy heterozygotes, and ¼ will be affected. Consanguineous mating is more likely when dealing with rare recessive diseases. The chances of first cousins carrying the same recessive gene are 1:8. In practice, consanguineous matings lead to a slight increase in perinatal mortality rate, congenital abnormalities and learning disorder. The risk is greatly increased if there is a history of recessive disorder in the family. Examples of autosomal recessive disorders include oculocutaneous albinism (ocular albinism is X-linked), congenital goitrous cretinism, Crigler-Najjar syndrome, cystic fibrosis, Friedrich's ataxia, galactosaemia, Gaucher's disease, glycogen storage disease, Hurler's syndrome, Niemann-Pick disease, phenylketonuria, Tay-Sachs disease, and Wilson's disease.

Reciprocal translocation: mutual swapping of part of chromosome between autosomes or between autosomes and sex chromosomes – when this occurs in germ cells the result may be partial trisomies and monosomies; however, the balanced genetic rearrangement may continue on and not be manifest phenotypically unless a gene is disrupted.

Recombinant DNA: chemically synthesised DNA, DNA produced in a different species from the original one (usually a bacterium) or DNA formed by joining DNA from 2 or more different sources.

Recombinant DNA technology: genetic engineering.

Recurrence risk: the risk of a relative developing the same condition as an affected probands.

Recurrence risk ratio (λ_1): ratio of risk of a disorder in a first-degree relative of an affected person/prevalence in general population. When the base rate of a disorder is low a high relative risk is still compatible with a low absolute risk.

Restriction enzymes: derived from certain strains of bacteria, these are able to recognise specific DNA sequences as targets for cleavage. Each particular enzyme has a particular target or site of action. The enzyme cuts the DNA at every point where the specific site or DNA sequence appears.

Restriction-fragment-length polymorphisms (RFLPs): inherited differences in the length of DNA fragments (due to loss of an existing restriction site or the acquisition of a new site) generated with restriction enzymes (restriction endonuclease digestion due to variation in DNA sequence at enzyme recognition site); they can be millions of nucleotides away from the disease gene. Two types of bacterial enzymes are used. Firstly, restriction endonucleases recognise specific DNA sequences of restriction sites at which they bring about cleavage of the molecule and are able to cut out a fragment containing a particular gene. There are also reverse transcriptases that allow synthesis of DNA from mRNA (the reverse of usual), the DNA then being labelled with radioactive marker and the resultant probe being employed to find a section of DNA with the complementary base sequence, to which it will hybridise, i.e. stick. (Weatherall, 1991) Fragments can be recognised by their different mobilities on a Southern blot. (Cf. VNTRs) New technology have superseded the study of RFLPs, e.g. single nucleotide polymorphisms (SNPs or 'SNIPS': variations [polymorphisms] in single bases [nucleotides: A, C, T, or G] in the DNA sequence: Nangle et al., 2004)⁸⁸⁸ and 'CHIPS' (allowing scanning of all chromosomes for allelic variations – false positives may be a problem with this technique). The DNA sequence variation underlying the majority of RFLPs is the SNP.

Reverse transcriptase: an enzyme that copies viral RNA into DNA, the latter inserting itself into host cell nuclear DNA. Zidovudine (azidothymidine, AZT) inhibits reverse transcriptase.

Ring chromosomes: rare deletion of the 2 ends of a chromosome, the broken ends (telomeres) fusing to form a ring; usually loses some chromosomal material; commonly associated with intellectual disability.

Segregation analysis: compares observed frequency of a disorder in a pedigree (i.e. ancestors of individuals over at least 2 generations) with the pattern that would occur if a hypothesised mode of inheritance were true. This is mainly used for conditions where one gene accounts for much of the variance, which does not include most of the major psychiatric disorders.

Sequence motif: sequences of DNA whose function can be inferred because of their resemblance to sequences whose function has been determined biologically.

Sex-linked conditions: There are no proven examples of Y-linked single gene disorders in man. All known sex-linked conditions are due to genes on the X-chromosome, and these traits may be dominant or recessive. The affected male cannot transmit an X-linked trait to his sons, but all his daughters are affected. Affected females transmit the trait to 50% of offspring of either sex. X-linked recessive traits manifest only in homozygous females, but they always manifest in males, there being nothing on the Y-chromosome to modify the trait. Carriers are usually healthy. The family tree will be modified by the ability or inability of affected males to reproduce. X-linked traits are never transmitted from father to son. It is very rare for a female to exhibit an X-linked recessive trait if she has an abnormal chromosomal constitution (such as XO, Turner's syndrome), or if she is homozygous for the mutant gene (from both parents). If, in females, in most cells, the normal X-chromosome is inactivated, the result is a 'manifesting heterozygote'. X-linked recessive traits include Christmas disease, haemophilia, Hunter's syndrome, Lesch-Nyhan syndrome, and nephrogenic diabetes insipidus.

Short interfering RNA (siRNA): This is a class of double-stranded RNA, 20-25 nucleotides in length, that interferes with the expression of a specific gene.⁸⁸⁹

Single nucleotide polymorphisms: These SNPs or 'SNIPS' comprise variations [polymorphisms] in single bases [nucleotides] in the DNA sequence. The DNA sequence variation in most RFLPs (Q.V.) is an SNP.

Somatic mutation: mutation in post-gamete stage cell; cannot be inherited. (Cf. germinal m.)

Southern blotting: Named for E M Southern. DNA fragments provided by cloning or using restriction enzymes are separated using electrophoresis in a suitable gel (such as agarose) and then visualised by dyes or radiolabelling. The fragments are transferred and attached to a membrane for further examination.

Telomere: natural end of a chromosome. It contains no genes. A repeated sequence (TTAGGG) halts replication at this site. Telomeres become shortened with age⁸⁹⁰, and cigarette smoking and obesity (via

⁸⁸⁸ SNPs for corticotrophin releasing hormone receptor 1 may have a protective role in reducing severity of symptoms of depression in adulthood in people who were severely abused as children. (Bradley et al., 2008)

⁸⁸⁹ Other functions include viral antagonism and genomic chromatin shaping. Other names include 'silencing' or 'small interfering' RNA. siRNA was discovered in Norwich in England during work on post-transcriptional gene silencing in plants.

⁸⁹⁰ The DNA repeat sequences plus associated proteins cap the ends of chromosomes. Women generally have longer **telomeres**. A common research approach is to measure telomere length in leucocytes. Each cell division shortens the telomere (because DNA polymerase is unable to completely replicate the 3' end of linear DNA) and such shortening accelerates with disease (insulin resistance, diabetes, obesity, atherosclerosis, hypertension, cancers, cardiovascular disease, vascular dementia, and chronic and severe stress). Telomeric defects are known to be involved in some inherited disorders, including certain congenital aplastic anaemias.

oxidative stress) shorten telomeres. (Valdes et al, 2005) Stem cells have longer telomeres than do differentiated offspring and progeria have very short telomeres. Because of the protective presence of telomerase, a germ cell replicates with no telomeric shortening. Most somatic cells do not express telomerase. Reactivation of telomerase protects malignant cells.

Transcriptome: description of all DNA that is transcribed into (all types of) RNA.

Transgenic: transfer of genes from one organism to another. The transferred genes or transgenes may work normally in the recipient. The latter organism is said to be transgenic or transformed, e.g. transgenic mouse.

Translocation: part of one chromosome becomes attached to a different chromosome (or a different part of the original chromosome, or assumes a different orientation such as inversion), e.g. material from chromosome 21 being attached to chromosome 14 in Down's syndrome.

Transposons: genome regions that commonly change location.

Triplet (trinucleotide) repeats: these consist of 3 nucleotides consecutive repeated within a region of DNA, e.g. CCG, CCG, CCG. They are not uncommon in the genomes of humans and other species. In 1991, a new type of genetic mutation was discovered, a dynamic or expansion mutation, in which the number of triplets in a repeat increases and the length becomes unstable. Nearly 20 diseases, including Huntington's disease, 2 forms of fragile X syndrome, and myotonic dystrophy, have been linked to trinucleotide repeat expansions. Such repeats are unstable and lead to inheritance patterns at odds with traditional Mendelian genetics. Prediction of Huntington's disease may never be 100% accurate due to some cases having a borderline number of repeats, i.e. there is no absolute cut-off. (Hayden, 2000) Suggestions have been made that psychiatric disorders like schizophrenia (But see Fortune et al, 2003), bipolar disorder, and autism might be caused in this way. (Margolis et al, 1999)

Trisomy: addition of an extra chromosome – less severe defects than with monosomy. Trisomy 8 usually results in (usually male) foetal loss, but survival, when it happens, is associated with moderate intellectual disability. Patau's syndrome⁸⁹¹ is due to trisomy 13. Trisomy 16 correlates with age of the mother. Trisomy 18 (Edward's syndrome⁸⁹²) is nearly always lethal in infancy with less than 10% surviving for the first year. Trisomy 21 is associated with Down's syndrome.

Unifactorial (unigenetic) disorders: these are single gene disorders, (the autosomal dominant and recessive disorders and X-linked recessive disorders) the opposite of multifactorial characteristics (Q.V.).

Vector: a DNA sequence capable of self-replication independently of the DNA of the host cell (e.g. a bacterium or yeast) into which it has been inserted.

VNTRs (minisatellites): a different form of polymorphism to RFLPs. Variable number of tandem repeats (VNTRs) of a relatively short oligonucleotide sequence. Tend to cluster at ends of chromosomes. The differences in the number of short oligonucleotide sequences found between 2 adjacent restriction fragment sites cause the variation in length of the DNA restriction fragments in VNTRs. *Simple sequence repeat markers (microsatellites)* are similar to VNTRs except that they are abundant and evenly distributed across the human genome, consisting usually of 2-5 nucleotides (di-, tri-, tetra-, and pentanucleotides). Because of high inter-individual variability microsatellites are commonly used as markers for linkage analysis.

Western blotting: a mechanism for blotting proteins.

Xenotransplant: organ or tissue transplanted from one species of animal into another.

Mitochondrial chromosomes

Mitochondria, highly motile subcellular organelles that fuse and divide (Chan, 2007), contain their own chromosomes. (Behan & Farrell, 2005) Mitochondrial DNA is abbreviated as mtDNA. The mitochondrion and its genome are thought to be remnants of a free-living bacterium, probably a proteobacterium.

Telomerase repairs and extends telomeres. Statins and omega-3 fatty acids (Farzaneh-Far et al, 2010) hold promise in blunting the effects of telomere shortening, as may physical activity. The 2009 Nobel Prize for Physiology or Medicine went to Elizabeth Blackburn, Carol Greider and Jack Szostak in the US who identified yeast cells with mutations that shortened telomeres leading eventually to cessation of cell division. They created telomeric RNA mutations in *Tetrahymena*, a ciliate protozoan, which led to cellular senescence. Aging of human cells is delayed by functional telomerase, the DNA in telomerase attracting proteins that form a protective cap at the end of the telomere.

⁸⁹¹ **Patau's syndrome** is usually fatal in the first days/weeks of life, although a small minority of cases survive the first year. Features include severe mental retardation, microcephaly, holoprosencephaly, deafness, seizures, heart and kidney anomalies, cleft lip/palate, and omphalocele.

⁸⁹² **Edward's syndrome** is characterised by severe mental retardation, intrauterine growth retardation, CNS/heart/kidney anomalies, breathing/feeding problems, omphalocele, micrognathia, low-set ears, and 'rocker-bottom' feet.

Mitochondrial chromosomes are circular, densely packed with no introns, and contain genes that encode for proteins or RNA molecules involved in mitochondrial metabolism. However, most of the proteins involved in regulating transcription, translation, and replication mtDNA are encoded in the nuclear genome, the latter also encoding seventy subunits of the mitochondrial respiratory chain.⁸⁹³ Unlike nuclear chromosomes that present normally in 2 copies per cell at the most, thousands of copies of mitochondrial chromosomes are present in each cell. *Heteroplasmy* refers to the uncommon coexistence of more than one type of mtDNA in a single individual.⁸⁹⁴ Since sperm contain no or very few mitochondria, these mitochondria **derive from the mother**. Leber's optic atrophy, leading to blindness in young men, is inherited via mitochondrial genes. The latter condition will affect all the offspring of an affected woman but none of the children of an affected male. Other examples of mitochondrial chromosomal disorders are MELAS, myoclonic epilepsy with ragged-red fibres (MERRF), Pearson's syndrome (various blood, exocrine, GIT, endocrine, and renal problems), Leigh's syndrome (subacute necrotising encephalomyelopathy), Kearns-Sayre syndrome (ophthalmoplegia, deafness, intellectual disability, cerebellar ataxia and heart block), and familial bilateral striatal necrosis.

Ageing

One theory of ageing is that spontaneous or free radical-induced base pairs deletions from or mutations in mitochondrial DNA diminish respiratory ability. This is unlikely given the huge mitochondrial DNA capacity compared to the low observed frequency of such mutations, although it might be a factor if the repair and catabolic needs of the body reached a critical enough level.(Bittles, 1997)

The telomere helps chromosomes not to fray when they divide. Younger cells have longer telomeres than older ones: they become shorter with each cell division. In progeria telomeres are short from the beginning. The enzyme telomerase is present in sperm, ova and foetus, but not in adults. It can increase telomere length, e.g. in skin cells. One potential danger of using telomerase would be excessive cell division (cancer).

Counselling

Genetic counselling is the process by which patients or relatives at risk of a disorder that may be hereditary are advised of the consequences of the disorder, the probability of developing and transmitting it, and of the ways in which this may be prevented or ameliorated. The process is made difficult by a lack of a sufficient number of available generations, lack of post-mortem studies, early death of a parent, illegitimacy, mutations, and a relative lack of experience in assessing people for psychopathology before genetic testing.(Berrios ea, 1995; Dermaut & Van Broeckhoven, 2002) Age-related estimation of risks can be provided with the help of a life-table (Newcombe, 1981). Counselling for dementing disorders should probably be given in a medical genetics facility by a multidisciplinary team.(Dermaut & Van Broeckhoven, 2002)

Prediction

Although not as straightforward in practice as in theory, consent for testing should be freely given, informed, continuing and given by a person to be tested who is competent to do so, i.e. has capacity. The growth of un-regulated direct to consumer testing⁸⁹⁵ is worrying.(Lenzer & Brownlee, 2008; Anonymous, 2008) Presymptomatic or predictive testing (PT) must include adequate provision for pre- and post-test counselling as well as long term psychological support.(Farrer, 1987) Resources for counselling are not always adequate.(Green, 1994) Farmer and Owen (1996) found that most people who request PT for Huntington's disease did not proceed with testing after initial counselling. They also warn against pressuring a couple into terminating a pregnancy simply because they would have to look after a disabled individual. It is important to be sure that the patient understands the nature and implications of the test.(Green, 1994) Although it would be wrong to overestimate the negative consequences of such tests,(Bundey, 1997) the reader should note the following problems encountered during PT for Huntington's disease (Morris ea, 1989; Harper, 1993a,b; Scourfield ea, 1997; Hayden, 2000): referral without the permission of the individual or of at-risk relatives; referral of minors; requests from adoption societies; lack

⁸⁹³ It is thought that nuclear and mitochondrial genomic expression is highly coordinated.

⁸⁹⁴ **Heteroplasmy** helped to identify the last tsar of Russia's remains. Age of onset and clinical severity of *myoclonic epilepsy with ragged-red fibres* vary widely, even in the same nuclear family, mainly due to heteroplasmy: each sufferer inherits a different mixture of normal and mutated mitochondria from the mother.

⁸⁹⁵ The commercial field of 'molecular diagnostics'. The Human Genetics Commission in the UK published guidelines for direct-to-consumer genetic testing in August 2010 but these may lack teeth when dealing with an international industry.

of a clear family history of the disease; the patient being already clinically affected, or only equivocally affected, or the patient is in denial about the possibility of an untoward test result; affected relatives unknown to applicant; refusal by subject or relatives to donate blood sample; use of false names; refusal to allow GP access to result; and, result requested by insurance company.(see Greely, 2005) A young German teacher was refused a permanent job in 2003 on the grounds that relatives had Huntington's disease.(Burgermeister, 2003; see also Tuffs, 2005) A Canadian study (Bombard ea, 2009) found that a family history of Huntington's disease, rather than genetic test results, resulted in distressing discrimination for about 40% of respondents. The Minister for Health (Republic of Ireland) told the Dáil (Lower House of parliament) that the *Health Insurance (Amendment) Bill*, 2000 retains prohibition on taking genetic testing into account when determining health insurance premiums.(Anonymous, 2000a) Britain applied a moratorium on such usage. The United Nations Educational, Scientific and Cultural Organization (UNESCO) released a set of rules governing the handling of human genetic data in July 2003 in the hope that governments would prevent third parties from misusing genes predisposing individuals to a given disease, although it appears to have left open the possibility of disclosure 'in the public interest'.(Bosch, 2003)

Apart from any religious consideration,(Crauford ea, 1989; Bloch ea, 1989) the fact that Huntington's disease is usually deferred until mature adulthood may make prenatal testing a problem for some.(Smurl & Weaver, 1987) According to Connor (1993), writing about Down's syndrome, about one in 12 people in Britain strongly oppose all forms of prenatal testing. The attitudes of those who may share ones genes must be considered,(Shaw, 1987) as must the possible adverse psychological reactions to testees to the results (Kessler, 1987) or the procedure.(Marteau, 1993; Statham & Green, 1993) Depression in applicants for PT should be treated if found.(Bundey, 1997) According to Marteau and Croyle (1998) the psychological impact of PT depends more on pretest expectations, mood, and social support than the results of the test itself. People may be less likely to take up offers of predictive testing if no treatment is available.(Hayden, 2000; Neumann ea, 2001) Americans say that they would be more likely to take a foolproof test for Alzheimer's disease than one with a 10% false result; those who would not have a test would, naturally, not like the idea of having to live with the result; and confidentiality is only a concern for about a third of people.(Neumann ea, 2001) Disclosure of APOE genotyping results to adult children of patients with Alzheimer's disease in the US did not result in 'significant short-term psychological risks' but pre-test distress predicted post-test distress (Green ea, 2009), and test-related distress was reduced by a finding of APOE $\epsilon 4$ negativity. Advance directives, time spent with the family, and settling of financial affairs would be important considerations should a test prove positive.

Genetic research may ways in which environmental manipulation might mitigate pathogenic endowment from our genes.(Kirley & Gill, 2003)

Human gene therapy

Gene therapy is a highly contentious undertaking,(Anonymous, 1991; Anonymous, 2000b) still in its infancy. Pyeritz (1990) pointed out that this would need to be attempted soon after conception. Somatic gene therapy involves the introduction and expression of recombinant genes in somatic cells for the purpose of treating a disease.(Leiden, 1995) Back in 1993, (Davies & Williamson, 1993) at Great Ormond Street in London, bone marrow⁸⁹⁶ was taken from a child with severe combined immunodeficiency due to absence of adenosine deaminase. The normal gene was put into the child's cells using disabled retrovirus. The cells were then put back into the circulating blood. American scientists used ooplasmic transfer to produce live offspring, i.e. they took some mitochondria from a donor's egg cell and injected them into the egg of an infertile woman with presumed mitochondrial defects, the egg then being fertilised in vitro. The main source of human embryonic stem cells (ESCs) are embryos not needed for in vitro fertilisation⁸⁹⁷. However ESCs were created in 2007 by reprogramming⁸⁹⁸ human skin cells⁸⁹⁹ to behave like ESCs, a

⁸⁹⁶ Some children who received their own marrow after it had been genetically engineered developed leukaemia-like conditions.

⁸⁹⁷ President George W Bush banned use of federal funds to support ESC research, but the ban was overturned by President Obama in 2009. This order does not allow funding to create new ESC lines because of the Dickey-Wicker amendment which prevents use of federal funds to create human embryos for research in which they are later destroyed, as occurs when ESCs are extracted.(Tanne, 2009)

⁸⁹⁸ Genes are inserted into cells using a virus.

⁸⁹⁹ Mouse skin cells had been reprogrammed in Kyoto in 2006.

process not without hazards⁹⁰⁰. Modified fibroblasts that produce nerve growth factor have been transplanted in human forebrain to ameliorate the cognitive effects of Alzheimer's disease.(Tuszynski ea, 2005) However, a more practical approach may be to develop NGF mimetic drugs. McGuffin (2003) does not believe that gene therapy is a viable treatment for schizophrenia because of delivery (to CNS) problems, multiple gene involvement, and so on, but there remains the possibility of better drug targeting.

Cloning

A clone is a colony of cells that originated from a single cell. The cloning of the sheep 'Dolly' in Scotland was announced in March 1997. A nucleus taken from a sheep's mammary gland and implanted into an unfertilised oocyte which has had its genome destroyed.⁹⁰¹ Cloning of rhesus monkeys followed in America, leading to presidential concerns about the cloning of human beings. Cloning of human embryos in order to produce tissues for transplant purposes was reported from America in November 2001.

President Obama stated in 2009 that human cloning would never be allowed.

Cloning in humans was thought to be prohibited in Britain under the *Human Fertilisation and Embryology Act 1990* but a November 2001 High Court ruling pointed out that such was not the case and led to a governmental reaction to ensure prohibitive legislation. However, in May 2005, the Law Lords ruled that such cloning was not prohibited, i.e. it allowed a family to create a 'saviour sibling' so that it could donate various tissues to save the life of a brother or sister.(see also Wilmut, 2004)

The British *Human Fertilisation and Embryology Act 2008* became active in 2009. It regulates assisted reproduction (*vide infra*) allows scientific investigation into treatments for conditions such as Parkinson's disease. Extracorporeal embryos are regulated as are human-admixed embryos (a mixture of human and animal genetic material that is used in stem cell research). Selection of offspring on the basis of sex is banned. Same-sexed parents are recognised as legal parents of children conceived via donated sperm, eggs or embryos. Embryos can be stored for up to 55 years in cases of premature infertility.

As Clare (2000, p. 118-9) points out, the cloned offspring has only one genetic parent.

In 2009 the Irish Medical Council (medicalcouncil.ie) stated that doctors should not create new forms of life solely for experimental purposes. Neither should they involve themselves in human reproductive cloning.

Assisted reproduction

Advances in this technology are beyond the way people normally think and feel about having a baby.

Sperm from an anonymous donor or an ovum from the mother's sibling may create problems of identification with the baby for the woman's spouse. Confusion and distress can be minimised by appropriate counselling.(Apfel & Handel, 1999)

Schizophrenia and other non-affective, non-organic psychoses

Brian O'Shea

Schizophrenias

'In real life we don't treat diagnoses, rather we treat symptoms'. (Murray, 2003a)

'Schizophrenia is a misconnection syndrome. "Cognitive dysmetria", or poor mental coordination, leads to perceptions and actions becoming disorganised and confused, which creates difficulty in distinguishing between the internal and external world'. (Andreasen, 2003)

*'Like a sandcastle with the sides falling away'.*⁹⁰² (Prof Elyn R Saks, 2009)

Definition

'In the 100 years that we have known the diagnosis of schizophrenia, its definition has swung between a biological illness, a psychological dysfunction, and a social construct'. (van Os & Kapur, 2009)

Schizophrenia⁹⁰³ refers to an incongruity of mental functions as when, for example, the expressed mood is not in keeping with the accompanying words or thoughts⁹⁰⁴. Areas affected areas include mood⁹⁰⁵, thinking or talking⁹⁰⁶, behaviour⁹⁰⁷, and social functioning⁹⁰⁸.

Schizophrenia (Andreasen, 1999):

A brain disease

Manifested as diseased mind

Symptoms and signs too diverse to localise the disorder to a single brain region

A disorder of neural connectivity⁹⁰⁹ (Symond ea, 2005) caused by multiple factors affecting brain development

Final common pathway is a misregulation of information processing in the brain⁹¹⁰

⁹⁰² Prof Saks is a law professor in Southern California who has schizophrenia controlled by clozapine. Here she is describing what it felt like when she was becoming psychotic.

⁹⁰³ According to Jablensky (2003, p. 203), the attributes that define schizophrenia are inferential and are highly dependent on the patient relating private mental activity, there being no 'test' for schizophrenia. The word *schizophrenia* comes from two Greek words meaning a disconnection or splitting of the psychic functions and has no connection, except in popular fiction, with the Jekyll and Hyde character, the latter being more likely a psychopath. Bleuler's 'schizophrenia' is reminiscent of Kraepelin's 'intrapyschic ataxia' (splitting/fragmentation of functions of the mind). According to ICD-10, *psychosis* 'simply indicates the presence of hallucinations, delusions, or a limited number of several abnormalities of behaviour, such as gross excitement and overactivity, marked psychomotor retardation, and catatonic behaviour'.

⁹⁰⁴ The person smiles or grins when relating to a personal disaster.

⁹⁰⁵ Incongruous or blunted (reduced intensity of emotional expression). Impaired facial expressiveness also occurs in depression. (Trémeau ea, 2005)

⁹⁰⁶ Thought disorder, including delusions and 'loosening of associations', i.e. the connections between phrases or thoughts are tenuous or lost.

⁹⁰⁷ Mannerisms, stereotypies, excitement, stupor, posturing, etc.

⁹⁰⁸ Including a tendency to drift down the social scale. Hindrance to social achievement starts long before the first admission. (Agerbo ea, 2004) **Empathy** includes emotional recognition, emotional perspective-taking, and affective responsiveness. People with schizophrenia have difficulties identifying emotions correctly, spontaneously simulating the emotional world of another person, and responding adequately in terms of their personal emotional experience. (Derntl ea, 2009)

⁹⁰⁹ 'A wiring problem'. Semaphorins are one of a family molecular cues (receptors) implicated in nervous system development, including guidance of axonal projections and neuronal migration. Plexins are semaphorins that act with neuropilins. A variant of the gene encoding plexin A2 (PLXNA2) may be associated with schizophrenia (Mah ea, 2006) and with anxiety. (Wray ea, 2007)

The degree of impairment is relatively stable after a long fulminant course, following which cognition may even improve⁹¹¹

Andreasen and colleagues (Fuller ea, 2003, p. 27-8):

(a) Synchrony: ‘the normal fluid processing of information required during thought and speech’

(b) Cognitive dysmetria: disturbed synchrony (disturbed fluid co-ordination of mental activity resulting from anatomical or functional misconnections arising during early development and manifested as the symptoms of schizophrenia)

Handicaps associated with schizophrenia (Wing and Brown, 1970)

Premorbid - predating illness, e.g. deficient in skills, poor motor coordination in childhood (Schiffman ea, 2009)

Primary - positive or negative symptoms due to the illness

Secondary - from having an illness e.g. institutionalisation, demoralisation, and medication

Problems with the diagnosis

Diagnosis is not the strict equivalent of disorder and is subject to change over time in both directions

Longitudinal observation across episodes is required for validation

Major problem in defining limits of the disorder/s - where does schizophrenia end and something else start?

Inconstancy - patients’ symptoms change over time

Number of patients diagnosed with schizophrenia depends on classification system employed (Murray, 2002)

Bias – simply changing the ethnicity of vignette cases may change the given diagnosis (Kay & Tasman, 2006, p. 937)

Various attempts at average economic cost⁹¹²/year to society (see O’Shea, 1997; Carr ea, 2004)

1987 British estimate: £1,1670 (\$2,5000)/patient

Broadly defined conservative costing (direct and indirect) for schizophrenia in England of £2.6 billion in 1997

UK’s National Institute for Clinical Excellence (NICE, a NHS body – Hargreaves, 2003) estimated schizophrenia accounted for > 5% of NHS budget

Another estimate from early 1990s was \$20-30 billion in direct and indirect costs/year for all US schizophrenic patients

Tsuang (2003) - direct costs (amounting to 41% of total cost) were \$19 billion⁹¹³; indirect costs made up 59% of total cost

Knapp ea (2004 - systematic review of cost of schizophrenia): schizophrenia accounted for 1.5-3% of total national healthcare expenditures; one-third to two-thirds of these costs derived from hospitalisation, irrespective of communitisation level of national inpatient provision

Non-adherence to antipsychotic medication significantly increases the cost of treating schizophrenia (Knapp ea, 2004)

Clinical trial-based cost-effectiveness analyses of antipsychotic tend to be favourable to newer antipsychotics, but face a number of threats to validity (Polsky ea, 2006)

⁹¹⁰ She would later propose a ‘misconnection syndrome’ involving connections between cortex and cerebellum with mediation via the thalamus. (Mitelman ea, 2005)

⁹¹¹ Various extensions of this theory, such as abnormalities of corollary discharge and feed-forward (preparation of sensory cortex for sensations arising from intended thoughts and actions) mechanisms, have been put forward in an attempt to explain hallucinations, (Heinks-Maldonado ea, 2007) a disrupted sense of self and will, and delusions. Andreasen agrees with Bleuler that thought disorder is the primary defining feature of schizophrenia, rather than some positive symptoms (additions to behaviour and emotion) as delusions and hallucinations. However, it is probably unlikely that one unitary model (e.g. insensitivity to linguistic violations) is universally valid.

⁹¹² James Joyce spent a large proportion of his earnings on a forlorn attempt at finding a cure for his daughter Lucia (1907-1982), including having her treated by Carl Jung. He refused to accept the severity of her illness. She was eventually diagnosed with schizophrenia at the Burgholzi psychiatric clinic in Zurich and died at St Andrews Hospital, Northampton. She may have been the muse for her father’s *Finnegans Wake*.

⁹¹³ \$10 bn for inpatients, \$1 bn for outpatients, \$6 bn for nursing home/domiciliary care, and \$2 bn for the criminal justice system.

Conventional antipsychotics save on costs and are associated with a gain in QALYs⁹¹⁴ compared with atypical drugs; (Davies ea, 2007) RCT in 'routine clinical practice' where treating clinician chose drug treatment in advance.

Reduction in tardive dyskinesia with atypical antipsychotics may *not* be cost-effective.(Rosenheck, 2007)

The author admits that this is not the whole story.

Using Standard Cost of Illness procedures Behan ea (2008) estimate total cost (in millions) of schizophrenia in Ireland, subject to limitations posed by unavailable data, was €460.6 in 2006: direct cost of care €117.5; indirect costs €343 (of which €43.8 was borne by families); and lost productivity €277.

Early intervention in those at high risk of psychosis may reduce costs.(Valmaggia ea, 2009)

Early intervention for psychosis in London 'highly likely' to be cost-effective.(McCrone ea, 2010)

Epidemiology

Prevalence: Male prevalence arguably equals female prevalence (see below). The British Office of Population Censuses and Survey (OPCS) reported a prevalence of 'functional psychoses' of 0.4% in 1993. The one-year prevalence rate for schizophrenia is of the order of 2-5 cases/1,000 of the population/year.⁹¹⁵

Incidence: The incidence of schizophrenia is much higher in the unmarried of both sexes than in the married and is probably no higher in Ireland than elsewhere. The figures for schizophrenia vary widely depending on admission policies⁹¹⁶, diagnostic practices⁹¹⁷, and differing methods of case finding. Taking admission diagnoses made by inexperienced staff and lumping together anything half-resembling schizophrenia all too often represents official statistics⁹¹⁸. Studies showing a higher incidence among males may suffer from missing late-onset⁹¹⁹ female cases. In fact, US criteria held that schizophrenia could not start after 45 years of age. Females may outnumber males in the 20% of cases starting after 45. There is some indication that the risk to siblings for developing schizophrenia in the case of late-onset disorder may be less than for younger onset but higher than for the general population.

Average incidence of schizophrenia = 21.8/100,000/year (0.03% or 22 new cases/100,000/year) (Tsuang and Faraone (1997)

⁹¹⁴ Quality-adjusted life-years.

⁹¹⁵ The lifetime prevalence of DSM-III-R schizophrenia in one rural part of Ireland was estimated at 0.54% for men and 0.28% for women. The study in which these interesting if unexplained figures were reported (Kendler & Walsh, 1995) found no sex difference in age of onset. The same group later found no connection between age of onset and the risk for schizophrenia in relatives. Aleman ea (2003) conducted a meta-analysis of the literature and found that the incidence risk ratios for men to develop schizophrenia relative to women varied from 1.31 to 1.42 depending on what studies were included in the analysis; the sex difference was smaller in older (pre-1980) than in later studies; and they found no significant sex difference in reports from developing countries. The point prevalence (prevalence at a point in time) of broadly defined schizophrenia in inner London in 1991 was 5.1/1,000 of the population. Tsuang and Faraone (1997) give a prevalence range for schizophrenia of 0.6-17/1,000 people surveyed/year, most studies giving a range of 3-10/1,000. A generally agreed international figure is 0.5% or 1/1,000. According to Jeste and McClure (1997), the prevalence of schizophrenia is 7% in siblings and 3% in parents of probands with late-onset schizophrenia.

⁹¹⁶ Rendering studies alleging reduced incidence of schizophrenia based on reduced first admission rates difficult to interpret. A Finnish study (Salokangas ea, 2010) found that annual first admission rates (per 100,000) fell from 1980 to 1991 but increased slightly thereafter. They were higher using ICD-8 but lower with DSM-III-R or ICD-10. Bed number availability changes, admission policy, and diagnostic practice may explain most variation, and the authors wondered if increased use of illegal drugs and better treatment of depression might be reflected in the increased figures.

⁹¹⁷ The idea that the incidence of schizophrenia is the same around the world has been challenged. To some extent this depends on the diagnostic latitude employed. Earlier work tended to look for 'nuclear' (narrow) schizophrenia whereas 'broad' definitions yield greater differences between countries. The McGrath ea (2004) systematic review found up to fivefold differences internationally.

⁹¹⁸ Officially, 21% 19%, 20%, 19%, 20% and 20% of admissions to Irish psychiatric facilities in 1994/1995, 1999, 2001, 2002, 2004 and 2005 respectively suffered from 'schizophrenia'; 39% of inpatients attracted the same diagnosis during census day, 2001.(Daly & Walsh, 2002 – 38% in 2002) Admissions for schizophrenia to Irish psychiatric facilities in 2001 accounted for 9%, 20% and 23% of admissions to private, general hospital, and health board facilities respectively; the male rate for admission for schizophrenia per 100,000 (223.4) was higher than that for females (135.5).

⁹¹⁹ *Dementia tardiva*: later onset schizophrenia. Not surprisingly, a Danish study (Thorup ea, 2007) found that incidence rates for males significantly exceeded those for females in the age range 17-40 years but by the age of 72 years 1.59% and 1.17% of males and females respectively had developed schizophrenia.

*Morbid risk*⁹²⁰: Lifetime risk varies from 0.3 to 3.7%, a generally accepted figure being 1%. (Tsuang and Faraone, 1997) International consensus now accepts onset of schizophrenia even into old age. (Howard ea, 2000)

Social class and sex: Goldberg and Morrison (1963) found the social class distribution of the fathers of schizophrenics to be similar to the general population, i.e. schizophrenic offspring drift down the social ladder. Schizophrenia may not be directly caused by poverty but may lead to it⁹²¹. It may also delay presentation for treatment. (Mulvany ea, 2001) Upward paternal occupational mobility might place stresses on offspring with latent disposition to psychosis. (Mäkiö ea, 1997) Youthful onset is associated with a disorganised mental state and failure to climb the social ladder, whereas later onset is more often equated with paranoid delusions and a decline in social status. Peak age of onset of schizophrenia is in the third decade⁹²²; onset is 3-5 years later in females than in males⁹²³. (but see Kendler & Walsh, 1995 above) This sex difference does not appear to be artifactual and may relate to difference in brain maturation, or the condition may be more obvious socially in males. Oestrogens might offer a mild protective role in females. Relapse is more likely when oestrogen levels are low: during or just before menstruation⁹²⁴, the puerperium, and after the menopause. The illness may be milder in women. Long-term treatment with conventional antipsychotic drugs in women produces better outcomes and, even when controlling for body weight, lower doses are needed than in males. Chronic exogenous oestrogen treatment reduces DA transmission in animals. Attempts to equate puberty with age of onset of symptoms have suffered from small numbers and possible recall bias. One group (Cohen ea, 1999) found the earlier was puberty (menarche) in females the later were onset of psychosis and first hospitalisation, with men showing a trend in the opposite direction.

According to Murray (2008) it is difficult to induce psychosis before puberty. He points to the use of ketamine in children and wonders why methylphenidate does not induce psychosis in ADHD.

Not all studies support an equal sex incidence of schizophrenia, e.g. an Irish rural catchment area study of DSM-IV first-episode psychosis reported a 7.5-fold lower incidence of schizophrenia⁹²⁵ among women than among men. (Scully ea, 2002) However the incidence rate was low and incomplete case ascertainment was a possibility. A retrospective Chinese study (Phillips ea, 2004) suggests schizophrenia is more prevalent in women than in men, a finding criticised on methodological grounds by Ran and Chen. (2004) A systematic review (McGrath ea, 2004) found a male to female ratio for schizophrenia of 1.4. Inner city areas may attract people who already have, or will later develop, schizophrenia.

*Aetiology*⁹²⁶

'It is likely that schizophrenia is the final common pathway for a group of disorders with a variety of etiologies, courses, and outcomes.' (APA, 2002)

Psychology: Millon and Davis (1996) disagree with lumping dissimilar patients under the rubric of schizophrenia. Instead they suggest, without much in the way of evidence, that schizophrenia represents an end stage in which certain symptoms are shared and which is reached by a gradual decompensation of personality.

⁹²⁰ Probability that individual develops a disorder by a given age.

⁹²¹ Nevertheless, social adversity may contribute to psychosis among migrants. (Vanheusden ea, 2008)

⁹²² In the twenties, although the median age has been reported as being 19 years in America.

⁹²³ Hare ea (2009) found that age at onset of psychotic symptoms in schizophrenia was a function of genes and the patient's sex.

⁹²⁴ Irregular and absent menstruation is common with typical antipsychotics and there are many case reports incriminating risperidone. Bergemann ea (2007) reported significant improvement in psychotic (but not depressive) symptoms in females with schizophrenia during the luteal phase. Also, in a randomised double-blind study, Kulkarni ea (2008) found that adjunctive transdermal oestrogen reduced positive symptoms and general psychopathological symptoms in women with schizophrenia.

⁹²⁵ And 6.6-fold lower incidence of bipolar disorder.

⁹²⁶ The term *psychosis* was introduced by Ernst von Feuchtersleben (1806-1849) of Vienna in 1845. A fundamental problem with all attempts at finding a cause or causes for schizophrenia arises from the strong likelihood that 'schizophrenia' represents a heterogeneous group of disorders. (O'Shea, 1997) Andreasen (1999) believes that schizophrenia is related to maturational or developmental brain processes, such as neurite formation, synaptogenesis, excessive neuronal pruning, (Siekmeier & Hoffman, 2002) or apoptosis (programmed cell death – different from necrosis); the cause occurs therefore between the start of neurone formation and migration (*circa* second trimester) on the one hand and young adult life on the other hand.

Stress: For many years it has been noted that remissions in schizophrenia are often terminated by changes in the patient's environment. Roughly, four times as many patients from high expressed emotion (EE, a measure of criticality, hostility, intrusiveness, and overinvolvement) homes as those from low EE homes relapse during the first nine months at home following discharge from hospital after treatment of an acute episode. Young, single men, who are living with parents, are at very high risk from this type of ambient tension⁹²⁷ (Vaughn and Leff, 1976).

Expressed emotion (EE)

High EE – intolerance, intrusiveness, use of inappropriate and/or inflexible strategies

Low EE – tolerance, respecting personal space, sensitivity to needs

Expressed emotion and relapse rates as percentages (after Vaughn and Leff, 1976)

Low EE, on medication – 12%

Low EE, no medication – 15%

High EE, < 35 hrs. face to face contact*, on medication – 15%

High EE, < 35 hrs. face to face contact, no medication – 42%

High EE, > 35 hrs. face to face contact, on medication – 53%

High EE, > 35 hrs. face to face contact, no medication – 92%

High EE, < 35 hrs. face to face contact = 28% of patients

High EE, > 35 hrs. face to face contact = 69% of patients

*Face to face contact with family in hours per week.

Parents of offspring with schizophrenia often show a pattern of chronic grief.(Davis & Schultz, 1998) What is considered high or low EE will vary with culture. Many families do offer low EE environments to patients. Measures of EE may be inferior to the *relatives' attribution of responsibility for symptoms*: low EE relatives may see than as beyond the patient's control, whereas high EE relatives may blame the patient. Parents of children and adolescents with schizophrenia may manifest less EE than parents of adult schizophrenics.(Asarnow ea, 1994) perhaps because the former more easily conceptualise their offspring as being ill. Some researchers have failed to find an influence for EE on relapse rates. (McCreadie and Phillips, 1988)

People with schizophrenia may do better if they live in suburbs, if they are of high socio-economic status⁹²⁸, allegedly if they live in rural developing countries (Mojtabai ea, 2001; Ran ea, 2001), or if they perceive their relatives in a positive light. Stress may, of course, come from outside the family (occupational, social, etc). Various coping mechanisms, such as problem solving, and the neuroleptics, may prevent the effects of stress reaching the non-specific symptomatic stage. A high ambient tension may keep the subject close to the threshold for relapse, so that minor stresses (including a rise in EE) may precipitate the return of florid symptoms. There is evidence of an increase in EE levels in the three weeks before the onset of an episode of schizophrenia. The better caretakers are able to cope the less disruptive are their charges. Antipsychotic drugs reduce relapse rates in the presence of high EE, but only relatively so. A higher frequency of independent life events is probably required to initiate relapse in adequately medicated patients. If relatives can be trained to recognise non-specific symptoms, medication dose could be increased pending consultation. Relapse rates may be reduced by educating the family about schizophrenia and by conducting group sessions for those involved in the care of patients in the community.(Pilling ea, 2002a) Family intervention are usually conducted in the home by two therapists working together over a period of months.(O'Shea, 1997)

Falloon, Leff and others (Falloon ea, 1984) have done valuable work in this area. Whilst it makes sense to concentrate on improving the interpersonal coping skills of individual patients, focusing on the family unit may improve results.

⁹²⁷ Adolescent and young adult first degree relatives of people with schizophrenia or schizoaffective disorder may show physical anhedonia, and difficulties with/lack of peer/sibling/opposite gender relationships.(Glatt ea, 2006)

⁹²⁸ Low socio-economic status in schizophrenia arises because of poor work performance of self and/or parents, the latter being more likely than the general population to have schizophrenia or subclinical illness (including cognitive dysfunction/schizotypal characteristics).

While research has tended to concentrate of the stresses inherent in family life for the schizophrenic member, a schizophrenia relative can be difficult to live with.(Tantam, 1991) Patients with schizophrenia may be impaired in their ability to cope with normal levels of negative affect.(Bellack ea, 1992) It is debatable whether parental EE is a trait or a reaction. Relatives may dislike the idea of EE because it smacks of blame. It is important to emphasise positive aspects of EE reduction rather than negative aspects of high EE. EE levels may fall when carers feel less burdened and when there is less contact with the patient⁹²⁹.(Scazufca & Kuipers, 1998)

Life events lead to stress, which in turn leads to *non-specific symptoms* like insomnia⁹³⁰, and thence to a relapse in the illness.

Life events

Probably non-specific

Determine if a patient will fall ill, but not the illness itself

High EE and relapse is not specific to schizophrenia - also associated with mood and eating disorders

Meaning of the life event to an individual (*contextual threat*) has a major role in determining how that person will react

Time of life when an event occurs can influence what follows, e.g. asthma or acting out in a child, alcohol misuse or migraine in a young adult, or depression and confusion in the elderly

The woman with schizophrenia who is pregnant (Abel, 2007, pp. 646-7)

Increased likelihood of unwanted, unwelcome or unplanned pregnancy or pregnancy by rape

Symptoms may remain the same or worsen

Delayed presentation (for most of organogenesis)

Reduced cognitive capacity to self-monitor, adhere with antenatal care, or recognise labour onset

Pregnancy causes increased plasma volume, decreased antipsychotic drug absorption from GIT and entry to CNS, together with increased renal clearance: reduced drug efficacy

Increased likelihood of amniotomy, artificially induced labour, assisted vaginal delivery, caesarean section

As with other psychiatric disorders, more stillbirths, malformed offspring, and infant mortality

Fetal exposure to antipsychotic drugs: icterus, under/overactivity, blocked intestine, poor feeding, unstable vasomotor system

Reduced likelihood of longterm care of offspring and fear of loss of child custody

Steinberg and Durell (1968) found the frequency of schizophrenia to be particularly high in the months following conscription into the army. In a prospective Danish study, Khashan ea (2008) found an association between death of a relative of the mother during the first trimester of pregnancy and risk of schizophrenia in the offspring.

Van Os (2002) suggests that reduced cortical volume in schizophrenia is due to reduced social interaction, a phenomenon reported in animals⁹³¹, but this type of hypothesis ignores direction of causation. Rijdsdijk ea (2005), on the other hand, found that whole brain volume in schizophrenia was of genetic origin, while the size of the lateral ventricles was related to individual specific environment.

Post-traumatic stress disorder appears to be common in patients with schizophrenia or other severe mental disorders, prevalences ranging from 3.8% to 43% (mostly 29%-43%) being reported (compared to 8%-12% in the general population).(Combs & Mueser, 2007)

Immigrants: These have been reported to have an increased risk for 'schizophrenia'.

Possible reasons for excess of schizophrenia in immigrants/ethnic minorities (O'Shea, 1997; Cantor-Graae ea, 2005; Fearon ea, 2006; Veling ea, 2008a; Weiser ea, 2008)

⁹²⁹ Carer burden in cases of schizophrenia may relate to factors in the patient (symptoms, male sex, unemployment, marital status), the carer (coping powers, contact with patient, being the parent), and the country (worse in Britain than in Germany).(Roick ea, 2007)

⁹³⁰ Secondary to physiological arousal. Slow habituation to arousal is associated with delusional thinking and hallucination proneness.(Allen ea, 2007)

⁹³¹ The magnitude changes are much greater in the latter reports.

Professional *bias* against certain cultures⁹³²
 Poor *matching* for age with native controls
 Use of *tools* that have *not been validated* cross-culturally
 Stress of immigration
 Disadvantaged status⁹³³
 Differences in culture and appearance⁹³⁴
 Infection (e.g. poliovirus)
 Obstetric complications
 Excess *cannabis* abuse
 Tendency of *pre-psychotic* people to emigrate
 Living in a neighbourhood where they comprise a small *minority*⁹³⁵
 Increased risk for *all psychoses*⁹³⁶

Putative antecedents of schizophrenia such as *psychotic-like experiences*⁹³⁷ may be more common among children of Afro-Caribbean origin in the UK than among their white peers.(Laurens ea, 2008) Rates of mental hospital admission for immigrants to England and Wales tend to be higher for females. Many authors point to lower admission rates for schizophrenia in the countries of origin, (e.g. Selten ea, 2005) but this is open to many interpretations, such as ‘the dysfunctional or sick emigrate’, (Patino ea, 2005) ‘emigration makes you sick’, or ‘host countries imagine you to be sick’. Some studies show an excess of schizophrenia in second-generation immigrants but not in the actual immigrants, although others show an excess in first- and second-generation immigrants and in nationals with a history of foreign residence,(see Cantor-Graae ea, 2003) but it is difficult to explain such findings.(Cantor-Graae & Pedersen, 2007) Also, immigrants may have a better prognosis than the indigenous population of the host country,(McKenzie ea, 1995) probably because the illnesses are precipitated by social adversity.

Cantor-Graae and Selten,(2005) in a meta-analysis of the literature, found a mean weighted relative risk for schizophrenia among first- and second- generation migrants of 2.7 and 4.5 respectively. The risk was increased if migrants came from developing countries or if they hailed from countries where most people are black. Coid ea (2008) conducted an inner-East London population-based 2-year epidemiological study of first-episode psychosis in people aged 18-64 years. Black and minority ethnic subgroups all had increased incidence of affective and non-affective psychoses compared to white British people. Only black Caribbean second-generation individuals had a significantly increased risk compared to first-generation counterparts. Asian women (but not men) of both first-generation and second-generation were at increased risk for psychoses compared to white British people. Morgan ea (2008) looked at first episode psychosis cases and community controls in two English cities over three years. Cases were more socially disadvantaged and isolated, even when they confined the sample to affective diagnosis, a short prodrome, and short duration of untreated psychosis. The greater the disadvantage the more likely was psychosis to occur. The authors found similar patterns in White British and Black Caribbean groups, although the latter were more disadvantaged.

Psychodynamics/family theories: Freud, in 1911, published his analysis of Daniel Schreber, the presiding judge of the Dresden appeal court. This analysis (based only on Schreber's autobiography and the report of a Dr Weber) led Freud to conjecture that Schreber was unable to accept that he was a homosexual. Instead,

⁹³² More likely to be detained, brought by police, given emergency injections, less likely to be diagnosed as depressed or given psychotherapy.

⁹³³ It is difficult to disentangle cause and effect when studying minority groups, psychosis, and perceived disadvantage.(Cooper ea, 2008)

⁹³⁴ Israeli study in which Ethiopian immigrants had highest risk of later schizophrenia.(Weiser ea, 2008)

⁹³⁵ These results from Holland (Veling ea, 2008a) might be due to lack of social support or greater discrimination.

⁹³⁶ According to Fearon ea, (2006) African-Caribbeans and Black Africans in England are at especially high risk for both schizophrenia and mania.

⁹³⁷ About 15% of the population report such experiences (delusions and hallucinations), although clinical psychosis is much less prevalent. The importance of such symptoms is the subject of debate and opinion varies from normal variant to psychosis precursor. Zammit ea (2009) found an association in 12-year-olds between having definite symptoms and maternal infection during pregnancy, maternal diabetes, need for resuscitation, and 5-minute Apgar score. Bartels-Velthuis ea (2010) found a 1-year prevalence of auditory vocal hallucinations in 7- and 8-year-olds of 9%; 15% of these were reported to suffer significantly and to behave problematically; rural children had a higher prevalence but urban children were more functionally impacted by the experience; and there was little evidence of a role for developmental variables.

according to Freud, the following subconscious changes occurred: 'I love him' - 'I hate him' - 'It is not I who hates him but he who hates me' - 'I am persecuted by him' (denial with projection). This Freud would state was the basis for paranoid thinking. It is now thought Schreber may have suffered from either paranoid schizophrenia or encephalitis lethargica. Melanie Klein believed schizophrenia was caused in infancy (paranoid-schizoid position). There was a failure to realise people could have a number of characteristics, such as 'good' and 'bad', simultaneously.

Fromm-Reichmann, another psychoanalyst, coined the term 'schizophrenogenic mother' in 1948. This concept has completely fallen from favour⁹³⁸. Egeland and Sroufe (1981) state that the schizophrenic mother may be unable to offer secure attachment for her child, with resultant poor bonding, social incompetence and problem solving difficulties in the offspring. It is difficult to explain this phenomenon but it needs to be addressed.(Wan ea, 2007) Nevertheless, the offspring of mothers with psychotic disorders are at increased risk of several adverse outcomes, including early death.(Suvisaari ea, 2008) An affirmative answer to a query about depressed mood during mid-gestation does not increase the risk for schizophrenia in offspring but it might add to the pathogenic effect of a positive family history of psychosis.(Mäki ea, 2010)

Lidz, from uncontrolled psychoanalytic studies of a few, wealthy, families of schizophrenic patients suggested there were two types of abnormal families: marital skew⁹³⁹ and marital schism⁹⁴⁰.

Bateson and his colleagues, in 1956, spoke of the double bind wherein overt instruction is contradicted by covert instruction; the child can only give ambiguous and meaningless responses.

Weiser ea (2008) looked at responses of male adolescents to questions posed by the Israeli Draft Board and found an increased risk for non-affective/schizophrenic psychoses in those people reporting poor family functioning. However, this project does not tell us anything about direction of causality.

Bebbington ea (2004) reported an excess of various forms of victimisation⁹⁴¹ in the past histories of adult psychotics in private British households.⁹⁴²

Social: In a follow-up study of first episode schizophrenics (FES), Johnstone, ea, (1986) found most patients were not in high face-to-face contact with other members of the family; many lived alone; and EE (overinvolvement, hypercritical) was a weak predictor of liability of relapse. A short duration of symptoms prior to admission and neuroleptic treatment were significant predictors of good outcome.

Classification of life events

Uncontrollable: apparently imposed on the subject and outside his control

Controllable/possibly-independent: within his control, not associated with culturally sanctioned behavior, not due to illness

Controllable/probably-dependent events: within his control, objective evidence suggests they might have been brought about by behavior regarded locally as abnormal and possibly arising from the early stages of mental illness

Doane ea (1986) reported that a behaviourally-oriented, problem-solving family approach may have decreased the risk of relapse in the first nine months after discharge from hospital by teaching families concrete ways of solving problems and concomitantly reducing the amount of negative emotional relating between family members.

Historically, urban life was often considered to protect against insanity.(e.g. Hood, 1862, p. 52) In a Nottingham study (Giggs & Cooper, 1987), people with schizophrenia showed the expected concentration in central city areas of low socio-economic status, whereas a more varied distribution was found for affective psychosis. It is probable that the former seek out the low levels of social demands for performance and the relative anonymity of city centres, whilst the latter benefit from periods of normality, the manic

⁹³⁸ That being said, the schizotypal mother-schizophrenic offspring is a not uncommon and difficult to manage clinical situation.

⁹³⁹ One parent dominant, usually the mother, and the other partner yields to her whims.

⁹⁴⁰ Parents hold contrary views, leaving the child with divided loyalties.

⁹⁴¹ Especially **child sexual abuse**. Shevlin ea (2007) found that physical abuse predicted psychosis, rape being particularly predictive in males. Fisher ea (2009) looked at gender differences in the association between childhood abuse and psychosis and found that **physical** (even more than sexual) **abuse** was important in females but found no association in men.

⁹⁴² These cases were not identified by standardised clinical interview, reporting bias may have contaminated the results, and controlling for depression 'somewhat reduced the odds ratios for the individual experiences'.

drive, or other unknown associated factors. Sundquist *et al.* (2004) found in Sweden that the incidence of first admission psychosis and depression rose with increasing levels of urbanisation, although evidence from Denmark suggested that urban-rural differences in schizophrenia risk were unrelated to exposures that became more common in urban areas over time. (Pedersen, 2006) Murray (2003b) suggests that the increased risk for onset of schizophrenia in cities is due to social isolation. An association between vagrancy and schizophrenia has been noted in various parts of the world. (Harding, 1973) The 'drift hypothesis' holds that patients' fortunes decline as a result of illness so that they fall down the social scale into poverty, whereas the 'breeder' hypothesis holds that impoverished city centres are aetiologically related to schizophrenia.⁹⁴³ There was a significant movement of patients with schizophrenia from outer to inner London during the period 1986-1991. (McNaughton *et al.*, 1997) Those inner London schizophrenics who were relatively mobile were more likely to be male, have prominent hallucinations, and have no general practitioner contact. Kelly *et al.* (2009) found that the incidence of schizophrenia in males was higher in Irish urban than rural areas (incidence rate ratios [IRR] for males and females = 1.92 and 1.34 respectively) whereas the incidence of affective psychosis was lower in urban than rural areas for both sexes (IRR = 0.48 and 0.6). The drift-breeder controversy still attracts advocates to both sides of the divide. (O'Shea, 1997, 1998) One criticism of the breeder theory is that parents may have moved to cities because of their genetic predisposition to psychosis.

Reasons why cities might be inherently pathogenic

Complex⁹⁴⁴

Viruses

Malnutrition

Stress⁹⁴⁵

Noise⁹⁴⁶

Drugs like cannabis⁹⁴⁷

Head injury⁹⁴⁸

Pollutants like lead

Downward social drift has also been demonstrated for bipolar disorder. (Tsuchiya *et al.*, 2004)

Violence among schizophrenic patients

Violence by people who have schizophrenia may be slightly higher than in the general population but attracts a disproportionate level of media attention. (Dean *et al.*, 2008, p. 540) Alcohol and substance abuse is a far greater cause of violence than mental illness. (Elbogen & Johnson, 2009) An actively psychotic patient who misuses drugs and who is not being followed up by mental health services obviously represents a greater threat than a patient whose illness is under reasonable control, whose progress is monitored, and whose habits are temperate.

⁹⁴³ Of course, both poverty and illness may lead to drift in that rented accommodation tends to be cheaper in less attractive, run-down areas, this being one factor in the genesis of 'ghettoisation'. (Ramon, 2001)

⁹⁴⁴ Genetic predisposition → poor social and cognitive functioning → coping with urban life → increased risk of schizophrenia. (Weiser *et al.*, 2007) Polanczyk *et al.* (2010) followed up children from 5 to 12 years of age: self-reported hallucinations and delusions were familial and heritable and were associated with social risk factors such as urbanicity, domestic factors like maternal EE, behavioural/emotional/educational problems at age 5, and comorbidity, e.g. self-harm.

⁹⁴⁵ In the Schomerus *et al.* (2008) study, 10% and 19% of patients with schizophrenia were victims of violent and non-violent crimes; patients felt safer in rural than in urban areas; being a victim of violence was most strongly associated with alcohol/substance abuse and with criminal arrests by the patients themselves; and not feeling safe most clearly correlated with poverty and experience of being a victim. In a one-year study, Ascher-Svanum *et al.* (2010) looked at involvement in the US criminal justice system of people treated with antipsychotic drugs for schizophrenia and related disorders: 46% of 609 such people reported at least one criminal justice encounter (these were most likely to be substance users and relatively poorly adherent with medication); the 2 most common encounters were being victim of a crime (67%) and being on parole/probation (26%); such involvement is common and costly.

⁹⁴⁶ Prodromal schizophrenia-spectrum patients who are unmedicated extract message-like meaning from meaningless noise. (Hoffman *et al.*, 2007)

⁹⁴⁷ Boydell *et al.* (2006) found a greater increase in cannabis use in the year before presentation with schizophrenia compared to other psychiatric disorders in part of London.

⁹⁴⁸ Childhood head injury plus a strong familial predisposition to schizophrenia may be important. (AbdelMalik *et al.*, 2003)

Violence and schizophrenia

Tends to involve a minority of patients⁹⁴⁹

Mostly petty

May be serious and bizarre

Classically aimed at relatives and occurs at home

5-10% of people awaiting trial for murder in Western prisons have schizophrenia (e.g. Erb ea, 2001)

5% of homicide perpetrators in England & Wales have a diagnosis of schizophrenia (Swinson ea, 2007)

Schizophrenia is 10 times more common in prisons than expected by chance (Mullen, 2006)

May be associated with command hallucinations (Q.V.), longer pre-treatment illness, affectively charged delusions, delusions of being poisoned, attempts to confirm delusions, personality disorder, and alcohol or drug abuse (e.g. Walsh E ea, 2002, Moran ea, 2003; Foley ea, 2005; Friedman, 2006)

Threats to kill may lead to homicide (Warren ea, 2008⁹⁵⁰)

Predictors of violence were childhood conduct problems, drug abuse, victimisation, economic deprivation, and living situation; negative symptoms predict less violence; antipsychotics may only help when violence is related to acute psychopathology (Swanson ea, 2008)

Violent male forensic patients with schizophrenia had lower IQ and higher psychopathy scores than non-violent male forensic patients with schizophrenia (Fullam & Dolan, 2008)

Mullen (2006) suggests that psychiatrists have tended to underestimate the connection between violence and schizophrenia in order to assure the public and because they often do not see such offenders⁹⁵¹.

However, medical staff may be victims of such violence.(Vevera ea, 2005) The addition of antisocial personality disorder (Joyal ea, 2004) may modify homicidal acts committed by schizophrenics in that they may be more likely to assault non-relatives, to have used alcohol, and to have been involved in a row with the victim prior to the incident. Attentional problems in childhood may play a role in later criminality,(Cannon ea, 2002) although its specificity to schizophrenia requires further elucidation.

According to Hodgins and Müller-Isberner,(2004) schizophrenic men who break the law demonstrate long-standing antisocial behaviour, at least from mid-adolescence. Late-onset schizophrenia may be much less likely to be associated with violence than when onset occurs at an earlier stage in development.

Documented increases in violent acts committed by schizophrenics may reflect a general increase in community violence,(Wallace ea, 2004) although Vevera ea (2005) found little increase in violence from 1949 to 2000.

Schizophrenic patients who abuse cocaine may have less negative symptoms but more anxiety and depression.(O'Shea & Stokes, 2000) Alcohol abuse may be a risk factor for depression in first-episode schizophrenia.(Roche ea, 2010) Delusions of vampirism⁹⁵² is a rare cause of violence in schizophrenia.(O'Shea, 2000a)

Violence may be associated with cortical thinning in the medial inferior frontal and lateral sensory and motor cortex, especially on the right side, and surrounding association areas.(Narayan ea, 2007)

⁹⁴⁹ Based on patient interviews, Swanson et al (2006) found that the 6-month prevalence of violence was 19.1% (3.6% serious violence). Positive symptoms (e.g. persecutory thinking) increased the likelihood of all degrees of violence, negative symptoms having the opposite effect. Drug abuse was associated with minor violence! Serious violence was associated with psychotic and depressive symptoms, conduct disorder as a child (Hodgins ea, 2008), and victimisation. Dean ea (2007) looked at first episode psychosis and found 40% were aggressive at first service contact (half of these were physically violent) – youth, Afro-Caribbean ethnicity and history of past violence each contributed; aggressiveness was associated with mania and individual manic symptoms (for whole sample and for schizophrenia) – violent aggressive patients differed from those who were non-violently aggressive by being male, of a lower social class, and having offended before. However, Large ea (2009) conducted a systematic review and meta-analysis and found that rates of homicide by schizophrenia patients correlated strongly with total homicide rates; a pooled proportion of 6.8% of all homicide offenders had a diagnosis of schizophrenia; and factors associated with homicide in schizophrenia were likely to be the same as those in non-schizophrenia homicide, e.g. social disadvantage, substance abuse, and access to weapons.

⁹⁵⁰ The Warren ea (2008) study was based on people who were *convicted* of such threats.

⁹⁵¹ Elsewhere, Mullen and Sullivan (2007, p. 483-4) say that while there is a connection between psychiatric disorder and violence the risk is not that high, the lifetime chance of someone with schizophrenia committing homicide being 0.05% (similar to the risk in young males).

⁹⁵² Drinking own or others' blood. For a discussion of vampirism see Jaffe and DiCataldo (1994), Kelly ea (1999) and O'Shea (2000a).

The gene coding for COMT⁹⁵³ is located within the small (about 35 genes) region on chromosome 22 that is deleted in velo-cardio-facial syndrome (VCFS). (Blackwood & Muir, 2004, p. 163, *vide infra*) Reduced ability to breakdown catecholamines has been suggested as a factor in violence in schizophrenia, homozygosity for the low-activity COMT allele being commoner in violent cases and homozygosity for the high-activity form of the enzyme being commoner in non-violent cases, (Lachman et al, 1998) although other authors have found no evidence for a major role for the COMT gene in schizophrenia. (Chen et al, 1999) According to Meltzer (2003) COMT polymorphism predicts cognition in schizophrenia: the more COMT there is the more is DA removed and the poorer is cognition. In a meta-analysis, Glatt et al (2003) found a small risk for schizophrenia to be associated with the Val158/108 polymorphism of the COMT gene, but others disagree. (Williams et al, 2005) Stefanis et al (2007) found that army induction increased stress levels and that this stress exacerbated psychosis levels, and carriers of the COMT Val158Met Val allele were more susceptible to the effects of stress on the psychosis outcome than those with the Met-Met genotype. Thaker et al (2004) found a significant diagnosis by genotype interaction in that schizophrenic patients with the Met-Met COMT genotype showed poor predictive pursuit⁹⁵⁴.

In a prospective, two-year community-based American study of schizophrenic patients atypical antipsychotic drugs⁹⁵⁵ significantly reduced violent behaviour relative to conventional medications. (Swanson et al, 2004) The authors suggest that better adherence to prescribed treatment explained this difference, and better adherence was associated with less psychotic symptoms, substance abuse, and adverse medication side effects. Krakowski et al (2006) found clozapine superior to olanzapine, the latter being superior to haloperidol, in reducing violence associated with schizophrenia and schizoaffective disorder. McCue et al (2006) found haloperidol, olanzapine, and risperidone superior to aripiprazole, quetiapine, and ziprasidone in the treatment of acute schizophrenia.

Fertility and mortality: All psychiatric disorders carry an increased risk of premature death, the highest risk, from natural and unnatural causes, being associated with substance abuse and eating disorders. (Harris & Barraclough, 1998) The risk of premature demise from unnatural causes is especially pronounced in the so-called functional disorders, particularly schizophrenia and major depression. (O'Shea et al, 1983) Deaths from natural causes are particularly common in organic mental disorders, intellectual disability, and epilepsy. A disturbing report from Sweden found that the number of people with schizophrenia whose bodies were not discovered for some time after death increased in keeping with the decline in bed availability during 1952-2005 in Malmo. (Nilsson & Lögdberg, 2008)

Among people with schizophrenia in rural China all-cause mortality and suicide rates were greater in males than in females in a 10-year cohort study; male gender, earlier age at onset, older present age, longer illness duration, physical illness, inability to work, and no history of treatment were independent predictors of increased mortality. (Ran et al, 2007)

People with schizophrenia have been reported to have a reduced life expectancy by about 20% (males > females: Brown et al, 2000) and a reduced reproduction rate⁹⁵⁶. A Finnish study suggests that long-term antipsychotic treatment, especially clozapine⁹⁵⁷, is associated with lower mortality compared with the non-use of antipsychotics. (Tiihonen et al, 2009) Brown et al (2010) reported on the 25 year mortality of a community cohort with schizophrenia: mortality risk was 2 to 3 times that of the general population, mostly because of natural causes (unnatural deaths tended to occur during the first 5 years of the study), and the authors suggested that cardiovascular mortality may have increased compared to the general population. The steepest rise in cardiovascular mortality appeared to coincide with the introduction of the newer antipsychotic drugs although the authors felt unable to form any firm cause-effect conclusions from this observation.

However, schizophrenia seems to continue to occur at a similar rate to that in the past 50 years. Inbreeding does not seem to affect the incidence of schizophrenia. (Tsuang et al, 2002) Married status may delay onset of illness, especially in men. Alternatively, less vulnerable people marry and stave off breakdown for longer.

⁹⁵³ Catechol-O-methyltransferase (COMT) is an enzyme that catalyses catecholamine (including dopamine) in the brain. The gene (at 22q11) contains a functional polymorphism (Val^{108/158}Met) that affects enzyme activity.

⁹⁵⁴ Smooth pursuit eye movements based on internal representation of the target motion – unlike responses based on retinal motion processing.

⁹⁵⁵ Clozapine, risperidone, or olanzapine.

⁹⁵⁶ Although fertility may be improving and more cases are living freely outside institutions.

⁹⁵⁷ This study covered 1996-2006. Quetiapine was associated with the highest risk.

Never married persons of either sex are likely to be admitted earlier in life than those married.(Hart ea, 2007) Schizophrenic males rarely marry and reproduce⁹⁵⁸ and affected females have decreased rates of marriage and fertility.(e.g. Howard ea, 2002) Study of a Swedish birth cohort (MacCabe ea, 2009) found that, relative to the general population, people with schizophrenia had less children and grandchildren (partly due to lower marriage rates), their unaffected siblings had no more children than the population norm, there was a trend for offspring of schizophrenia patients to have more children, and patients with affective psychosis and their relatives resembled the general population regarding fertility measures. It seems, therefore, that either environmental factors are aetiologically important or that new mutations keep it going. An alternative hypothesis is that schizophrenia confers a biological advantage on the sufferer, although the evidence for this is not strong (e.g. Masterson & O'Shea, 1984; Feeley & O'Shea, 2001; Goldacre ea, 2005). Reduced fertility among Finnish schizophrenics is not compensated for by higher fertility among their siblings.(Haukka ea, 2003) Many studies attest to the high frequency of cigarette smoking (and drug and alcohol abuse: McCreadie ea, 2002a) among patients with schizophrenia. This is associated with increased lipid peroxidation in first-episode cases.(Scottish Schizophrenia Research Group, 2000) Cancer may be more common in schizophrenia than in the general population, mainly due to an excess of bronchogenic carcinoma.(Lichtermann ea, 2001) Breast cancer may be less common in Israeli schizophrenic females and in women with other serious mental illnesses.(Bark ea, 2008) Dalton ea (2004) found no evidence for a reduced risk of cancer in parents of schizophrenic patients, a finding opposite to that of Levav ea.(2007) A large, 11-year, prospective study (n = 3,470) found that schizophrenic patients had a standardised mortality rate (SMR) 4 times that of the general population with cancer being the second most frequent cause (global SMR of 1.5); there was an increased mortality by cancer, especially from breast cancer in women and lung cancer in men; and baseline duration of smoking and age greater than 38 years predicted lung cancer death.(Tran ea, 2009) Women with schizophrenia in Manitoba are less likely to get appropriate cervical cancer screening than are their peers⁹⁵⁹.(Martens ea, 2009) Although schizophrenics may have less rheumatoid disease than the general population they are not immune from it.(e.g. Feeley & O'Shea, 2001) Indeed, there is Danish⁹⁶⁰ evidence that suggests that autoimmune disorders may be more common in schizophrenia sufferers than in the general population.(Eaton ea, 2006) Chronic obstructive pulmonary disease is more common in people with serious mental illness than in the general population.(Himmelhoch ea, 2004) Various authors have speculated about whether schizophrenia is becoming milder with a better prognosis. The apparent decline in the frequency of some subtypes, such as catatonia⁹⁶¹ (Cf later), has been noted with interest, although some authors contest the validity of this decline on methodological grounds.

⁹⁵⁸ Although they may have more children when they do marry than do married schizophrenic females.

⁹⁵⁹ The authors suggest that their finding suggest a need for greater involvement by primary care services.

⁹⁶⁰ The rarity of such disorders makes interpretation of the Danish data problematic.

⁹⁶¹ Catatonia was seen as a 'schizophrenic' issue only until recent times.

Catatonia

Season of birth: There is a reported excess⁹⁶² of schizophrenic births in winter and spring from the northern (O'Shea, 1997; Davies *et al.*, 2003) but not the southern hemispheres, (McGrath & Welham, 1999) raising concerns of a possible viral aetiology and the possible role of obstetric problems.⁹⁶³ Season of birth effect is small, with differences of only 5-10% from expected rates. It may be important in some cases. O'Callaghan (1989) noted an excess of spring births in the general Irish population and he found that schizophrenics with a family history of schizophrenia followed the same pattern, but that schizophrenics with a negative family history had an excess of winter births. A survey of Norwegian psychiatric inpatients born from 1866 to 1939 revealed a striking excess of winter births, a tendency which was less marked in patients from the higher social classes. (Odegard, 1974) Retrospective Scottish work suggested a cold autumn might lead to the birth of people prone to developing schizophrenia during the following spring. (Kendell & Adams, 1991) Kirkpatrick *et al.* (2002; Messias *et al.*, 2004) found an association between summer births and deficit (negative symptom) schizophrenia⁹⁶⁴. Being born or reared in urban areas may add to the risk of viral infection *in utero*. Research on urban/rural place of birth, the relevance of being male/female, and the time of year when one is born is on-going. (O'Shea, 1997; Mortensen *et al.*, 1999; Lundberg *et al.*, 2009) Migration processes are a source of spurious findings in research into the relation between health and urban life. (Jablensky, 2003, p. 221) Boydell *et al.* (2003) described a large increase in broadly- and narrowly-defined schizophrenia, mainly in younger people, in part of south-east London (Camberwell). The authors were unable to state if this increase was due to a migration effect. Finnish work on birth cohorts suggest a move from rural to urban births over time, but there are still clusters that suggest possible genetic isolation. (Haukka *et al.*, 2001) Pedersen and Mortensen (2001) in Denmark found that the longer one lived in an urban area and the higher the degree of urbanisation the greater the risk of developing schizophrenia. Van Os *et al.* (2003, 2004) found both level of urbanicity and familial liability independently and synergistically increased risk for psychotic disorder.

Genetics: Schizophrenia often runs in families, the risk increasing with the number of affected relatives⁹⁶⁵. Various figures have been published stating the risk for different relatives. If both parents have schizophrenia the risk for their child is about 45%, compared to 1% in the general population. If one parent has schizophrenia the risk is 13%.⁹⁶⁶ If a parent and a sibling have schizophrenia the risk is 16%. If a

⁹⁶² Compared with controls.

⁹⁶³ Of course, there are other possible explanations, such as whatever psychosocial factors drive procreation practices in parents.

⁹⁶⁴ Also, there is some evidence that the same seasonal factor/s may affect brain development and personality characteristics of the general population. (Kirkpatrick *et al.*, 2008)

⁹⁶⁵ And with severity of illness in the proband.

⁹⁶⁶ Gottesman (1991) suggests that this relatively low risk reflects a milder form of parental illness, i.e. more severe illness may reduce the likely of parenthood in the first instance.

sibling has schizophrenia the risk is 9%. The risk for second-degree relatives is 3-4%. The genetic input is most likely polygenic⁹⁶⁷. There is no evidence for a single gene causing a large increase in risk. Various loci⁹⁶⁸ have been highlighted by research as possibly being important in schizophrenia.⁹⁶⁹ These results should be approached with caution until there is much more in the way of replication. (Harrison & Owen, 2003; Crow, 2008) Stefansson et al (2002) identified several markers in the neuroregulin 1 (NRG1)⁹⁷⁰ gene (8p) making up a core haplotype that showed a significant association (relative risk 2:1) with schizophrenia, and an almost identical pattern was found by the same group in a Scottish population. (Stefansson et al, 2003; Alaerts et al, 2009) While McGuffin (2003) was enthusiastic about neuroregulin 1, he was less enthused about dysbindin⁹⁷¹ (6p), G72 (13q32 – G72 is now known as DAOA, i.e. D-amino-acid oxidase activator⁹⁷²), proline hydroxylase (22q), and COMT (22q) as positional candidate

⁹⁶⁷ As in diabetes: additive effect of a number of minor genes, i.e. **quantitative trait loci** or **QTLs** (QTL = genomic region containing naturally occurring allelic variations affecting a quantitative phenotype). Linkage (detects linkage over fairly long distances) and association (requires that DNA marker be closely linked to disease gene) methods have been used to map human QTLs. Continuous outcome measures that are related to schizophrenia biologically (e.g. schizotypy) are another approach in QTL research.

⁹⁶⁸ At **chromosomes** 1p (Tamil Nadu, India: Holliday et al, 2009a), 1q (e.g. SELENBP1 [selenium-binding protein 1 at 1q21-q22 – involved in rapid cell outgrowth], RGS4 [regulator of G protein signalling at 1q23.3] and disrupted-in schizophrenia 1 [important for cognition and development of cortex] and translin-associated factor X alleles at 1q42: Cannon et al, 2005; NOS1AP or nitric oxide synthase 1 [neuronal] adaptor protein at 1q21-22: Wratten et al, 2009; NOS1 was found to be associated with clinically significant variation in cognition: Donohoe et al, 2009; 1q23-25 associated with negative symptoms in Taiwan: Holliday et al, 2009b), 2cen-q13 (MAL – myelin and lymphocyte protein, important for genesis and function of myelin), 2q (GAD1 or glutamase dehydrogenase 1 at 2q31.1 which has a role in cognition; MDH1 or maleate dehydrogenase at 2q13.3, involved in regulating metabolism), 2q32.1 (Zinc Finger Protein gene [ZNF804A]: In Irish and German patients [Walters et al, 2010] this genotype was associated with differences in episodic and working memory that were not found in controls, and exclusion of patients with lower IQ strengthened association between schizophrenia and ZNF804A), 2p (deletions of neurexin 1 gene reported in autism and some families with schizophrenia; Rujescu et al [2008] report that such deletions confer risk for schizophrenia if they affect exons), 3p, 5p, 5q (e.g. for abstraction and mental flexibility: Almasy et al, 2008), 6p (DTNBP1 [dysbindin] at 6p22.3 with role in formation of lysosomes [Kircher et al, 2009]), 6q23 (AHI1 or Abelson helper integration site 1 [Ingason et al, 2010]), 7q (GRM3; MET [mesenchymal-epithelial transition factor] proto-oncogene variation at 7q31; Burdick et al, 2010), 8p (PP3CC or protein phosphatase 3 at 8p21.3, involved in calcium signaling; NRG1 or neuregulin at 8p21-p12 with role in neuroplasticity/ErbB signaling), 10q (HSPA12A or heat shock 70kDa protein 12A at 10q26.12, involved in nerve cell development and maturation; 10q22.3 in Taiwan: Holliday et al, 2009b), 11q, 12p (CACNA1C: rs1006737), 12q (DAAO), 13q (G72; HTR2A or 5-HT2A receptor at 13q14.1-q32), 14q (AKT1 or RAC-alpha serine/threonine-protein kinase at 14q32.32 with role in nerve cell survival), 15q (CHRNA7), 17q (17q21 in families of Central American/Mexican origin), 19q (MAG or myelin-associated glycoprotein at 19q13.1; Almasy et al, 2008; Francks et al, 2008 – SNP of familial schizophrenia and familial bipolar disorder show peak suggesting shared susceptibility locus on 19q13), 20p, 22q (APOL or apolipoprotein gene cluster at 22q13.1-q12.3 with role in metabolism of lipids/fatty acids; COMT or catecholamine methyltransferase at 22q11.21 that has a role in cognition; PRODH2 or proline dehydrogenase at 22q11.21 which is involved in apoptosis) and Xq (PLP1 or proteolipid protein 1 [Hakak et al, 2001] at Xq21.3-q22 with role in myelination) according to different sources. An excess of sex chromosome aneuploidies (such as XXY and XXX based on the observation that among patients with schizophrenia sib-pairs are more often of the same than of the opposite sex); a translocation involving chromosome 11 (a large Scottish family with almost half having mental disorder, including schizophrenia, show a balanced translocation between chromosomes 1 and 11 [e.g. Millar et al, 2000]); various loci on chromosome 6 (e.g. 6p23); a modest effect for a vulnerability locus on chromosome 8p; linkage to 10q22.3; inheritance of susceptibility via the gene for the 5-HT2A receptor (or one in linkage disequilibrium with it) on chromosome 13 (however, the same variant allele is not confined to schizophrenia); linkage between failure to inhibit the P50 evoked potential (common in schizophrenics and their relatives: Louchart-de la Chapelle et al, 2005) and a dinucleotide polymorphism at chromosome 15q13-14 (same site as alpha-7-nicotinic receptor), and a 'dementia praecox'-like picture in Irish patients with linkage to the 8p22-8p21 region. Gurling et al (2006) found evidence for a link between **pericentriolar material 1 protein** (PCM1 – involved in maintenance of centrosome integrity and regulation of microtubule cytoskeleton) gene on 8p22 and susceptibility to schizophrenia with orbitofrontal gray matter volume deficits. PCM1 forms a complex at the centrosome with disrupted-in-schizophrenia 1 [DISC1 at 1q42.1] and Bardet-Biedl syndrome 4 protein [BBS4] which provides an essential cortical developmental pathway. Suppression of PCM1 during cerebral cortical development leads to defective neuronal migration. Such defects are phenocopied by suppression of DISC1 or BBS4 and made worse by suppression of DISC1 and BBS4. (Kamiya et al, 2008) DISC1 encodes a multifunctional scaffold protein involved in neurodevelopmental processes and has been implicated in the genesis of schizophrenia. (Schumacher et al, 2009) DISC1 variants affect the level of social anhedonia, i.e. they are important in determining our ability to enjoy social interaction. (Tomppa et al, 2009) McClellan et al (2007) argue for multiple rare highly penetrant mutations predisposing to schizophrenia.

⁹⁶⁹ For a recent review see Gill et al (2010)

⁹⁷⁰ Neuroregulin is a protein involved in directing neural stem cells to become neurones or glia. The connection between schizophrenia and NRG1 may involve a cell adhesion function. (Kanakry et al, 2007)

⁹⁷¹ **Dysbindin** = *dystrobrevin-binding protein 1* (DTNBP1). It has also been implicated in bipolar disorder, especially when accompanied by psychosis. The gene is at 6p22.3.

⁹⁷² According to Williams et al (2006) variation at the DAOA/G30 locus (chromosome 13) is not so much associated with schizophrenia/psychosis but rather with mood disorder episodes in both bipolar disorder and schizophrenia. Mood incongruent psychotic features in bipolar patients may be linked to 13q21-33. (Goes et al, 2007) Soronen et al (2008) suggest that the DAOA (aka G72) gene may play a role in predisposition to mixed psychosis and mania and visuospatial problems. Opgen-Rhein et al (2008) reported a

genes in schizophrenia. However, Williams *et al* (2004) using Cardiff and Dublin samples, produced evidence that variations in the dysbindin gene confers susceptibility to schizophrenia. Weickert *et al* (2004) found dysbindin mRNA expression to be reduced in schizophrenia. Fanous *et al* (2005) found that a haplotype for dysbindin may predispose to psychosis with high levels of negative symptoms. Kishimoto *et al* (2008) found preliminary evidence that the dysbindin gene is associated with risk of metamphetamine psychosis.

Copy-number variants⁹⁷³ (CNVs) may have a role in schizophrenia.(Vrijenhoek *et al*, 2008⁹⁷⁴; Kirov *et al*, 2009⁹⁷⁵; Guilmatre *et al*, 2009; Grozeva *et al*, 2010)

Genetic input is likely a graded matter in the general population. Murray and Dean (2008, p. 289) suggest that liability to psychosis (like hypertension) is a continuous trait in the population with schizophrenic patients lying at one extreme of this continuum. Schizophrenia, like criminality (Mednick & Finello, 1983), may have a genetic input but environmental influences are also important (see van Os *et al*, 2009). Up to one-third of schizophrenics have no known family history of schizophrenia.⁹⁷⁶ Also, schizophrenia may be associated with a far wider range of mental disorders than we have been apt to think,⁹⁷⁷ a fact that may influence studies of risk factors.(Mortensen *et al*, 2010) Onstad *et al* (1991) found that paranoid schizophrenics had a lower likelihood of having affected first-degree relatives than did other subtypes as well as having a lower concordance ratio between DZ and MZ twins. Nonfamilial cases may have an environmental aetiology because they were more likely to show cerebral abnormalities such as enlarged cerebral ventricles.⁹⁷⁸ Some authorities (e.g. McGuffin *et al*, 1994) suggest that schizophrenia can be explained entirely by genes or that non-genetic phenocopies account for very few cases. Seven (58%) of 12 adopted MZ twins were concordant for schizophrenia⁹⁷⁹ in a systematic review of twin studies, a point against an aetiological role for shared environment in the genesis of the disorder.(Gottesman & Shields, 1982) A meta-analysis of 12 twin studies (Sullivan *et al*, 2003) found the point estimate of heritability in liability to schizophrenia to be 81%⁹⁸⁰; there was evidence for environmental influences as well (joint estimate of 11%), but this work threw no light on the nature of such influences.

Crow (1990) favoured a 'continuum of psychosis' and suggested that we failed to genetically demarcate schizophrenia from affective disorder. Dalby *et al* (1986) described a case of MZ twins in which one had manic-depressive psychosis and the other had schizophrenia. Other authors have also reported overlap between affective disorders and schizophrenia in the families of patients with schizophrenia.(O'Shea, 1997; Knowles, 2003) Kendler *et al* (1998), working in Roscommon⁹⁸¹, found a familial tendency to develop a wide variety of psychotic syndromes rather than schizophrenia *per se*, but vulnerability to develop depressive and manic affective illness was found to be somewhat more specific.⁹⁸² McKenna (2007, p. 341) states that depression and elation in schizophrenia fails to reach the level of 'a full affective syndrome', i.e. low mood is not accompanied by biological and other accessory symptoms of major depression and mania is not accompanied by distractibility, overactivity, and overspending. However, there is evidence (Kasckow *et al*, 2009) that adding citalopram to antipsychotic medication in schizophrenia patients with subsyndromal depression does seem to improve their social and mental functioning as well as their quality of life. Anglin *et al* (2009) found that schizophrenia patients with a family history of affective illness performed relatively

significant effect of DAOA variation on risk for schizophrenia, and is also important in terms of neurocognitive function, e.g. semantic fluency. Overlap between schizophrenia and bipolar affective disorder may be linked to 2p11-q14.(Goes *et al*, 2007)

⁹⁷³ **Copy number variation** (CNV) refers to a segment of DNA for which copy-number differences have been found by comparing at least two genomes. Humans (diploid) usually have 2 copies of each chromosomal region, one per chromosome. This may vary because of deletion or duplication.

⁹⁷⁴ Affected genes in this report, all important in nerve cell functioning, were MYT1L, CTNND2, NRXN1, and ASTN2.

⁹⁷⁵ Deletions at 22q11.2 and 17p12, the latter known to cause hereditary neuropathy with liability to pressure palsies.

⁹⁷⁶ It should be recalled that one-third of cases of haemophiliacs has no family history of the disorder, but that does not make it an acquired disorder.

⁹⁷⁷ Are haplotypes shared across disorders or is shared environment important?

⁹⁷⁸ One possible cause for such 'sporadic' cases is periventricular haemorrhage.

⁹⁷⁹ Not dissimilar to twins reared together.

⁹⁸⁰ Owen *et al* (2000) estimated heritability for schizophrenia (80%), bipolar disorder (80%), alcohol abuse/dependence (60%), major depression (40%), panic disorder (40%), phobia (35%), and generalised anxiety disorder (30%).

⁹⁸¹ Irish county in Connaught.

⁹⁸² There were a number of problems with this study e.g. lack of consistency with the existence of discrete classes does not refute the existence of such classes.

well on measures of IQ and executive function, perhaps suggesting the existence of a distinct subgroup that is biologically nearer to severe affective disorder than to schizophrenia.

A very large (more than 2 million nuclear families) Swedish study (Lichtenstein *et al.*, 2009), using a multi-generation register the hospital discharge register, found evidence that schizophrenia and bipolar disorder partly share a common genetic aetiology – 63% of the co-morbidity between disorders was due to additive genetic effects common to these two conditions. This research shows that the first-degree relatives of probands with schizophrenia or bipolar disorder are at increased risk for both disorders, a slap in the face for Emil Kraepelin! (Owen & Craddock, 2009) Indeed, a meta-analysis of family studies of probands with schizophrenia and bipolar disorder found that they coaggregated in families. (Van Snellenberg & de Candi, 2009)

Population-based cohort study in Denmark (Gottesman *et al.*, 2010)

Both parents admitted to psychiatric facility with a diagnosis of scz: risk of scz in offspring = 27.3% (39.2% for scz-related disorders)

One parent admitted to psychiatric facility with a diagnosis of scz: risk of scz in offspring = 7%

No parent admitted to psychiatric facility with a diagnosis of scz: risk of scz in offspring = 0.86%

Both parents admitted to psychiatric facility with a diagnosis of BP: risk of BP in offspring = 24.9% (36% if UPD was included)

One parent admitted to psychiatric facility with a diagnosis of BP: risk of BP in offspring = 4.4%

No parent admitted to psychiatric facility with a diagnosis of BP: risk of BP in offspring = 0.48%

Risk of scz in offspring with 1 parent each with scz and BP = 15.6%

Risk of BP in offspring with 1 parent each with scz and BP = 11.7%

Maximal risks of having any psychiatric disorder in offspring of parents who both had scz = 67.5%

Maximal risks of having any psychiatric disorder in offspring of parents who both had BP = 44.2%

Note: scz = schizophrenia; BP = bipolar affective disorder; UPD = unipolar depressive disorder.

Niemi *et al.* (2004) followed up all women born between 1916 and 1948 and treated for schizophrenia spectrum disorders in Helsinki psychiatric hospitals and looked at their offspring born 1960-4 and at controls. The cumulative incidences of schizophrenia and schizophrenia spectrum disorders among the offspring were similar to those in first degree relatives of probands with schizophrenia and adoptees whose biological mothers had schizophrenia. Children of schizophrenic mothers were also at increased risk for non-psychotic disorders, especially mood and substance use disorders, and the fathers of these high risk offspring had increased rates of psychiatric disorders, especially alcohol and substance use disorders⁹⁸³. Rüdin⁹⁸⁴ performed the first systematic family study of schizophrenia. This was published in 1916 and reported an increased rate of dementia praecox among siblings of probands over the general population. Shur (1982) did a retrospective study from the case notes (and item sheets filled out by psychiatrists dealing with the subjects) of hospitalised schizophrenics. Those with a family history of psychiatric disorders were significantly more likely to have been born in the UK and to have older mothers. Those with relatives with psychiatric diagnoses other than schizophrenia were significantly more likely to have been diagnosed as schizoaffective. The author wondered if there was a constitutional trait in the parents of those patients with a family history of psychiatric disorders delaying child bearing.

Family studies: Lifetime expectancy of an individual in the general population for schizophrenia is about 1% but far higher figures are reported among relatives of schizophrenics. If both parents are schizophrenic the chance of one of their children developing the illness is about 25%; if there is only one schizophrenic parent the risk falls to around 12%. Only 5-10% of schizophrenics have a schizophrenic parent. (O'Flynn *et al.*, 2003, p. 82)

⁹⁸³ A Norwegian comparison of patients with schizophrenia and bipolar spectrum disorder found that the former were more likely to use centrally stimulating substances and used one or more non-alcoholic drugs more often, whereas bipolar spectrum disorder patients drank more alcohol and had a higher frequency of single use of cannabis. (Ringen *et al.*, 2008)

⁹⁸⁴ Ernst Rüdin (1874-1952), pro-Nazi, co-worker of Kraepelin.

Twin studies: MZ twins carry a 30%-40% risk⁹⁸⁵; a singleton has a 10% risk.⁹⁸⁶ There is some evidence to suggest that the rate of first admission to hospital for schizophrenia may be higher in DZ than in MZ twins⁹⁸⁷. (Klänning, 1999) In a follow-up study comparing schizophrenic MZ twins with their never affected monozygotic co-twins, the offspring of both groups were equally likely to develop schizophrenia, with age-corrected risks of 16% and 16.8% respectively, suggesting the possibility of incomplete penetrance in non-affected twins. Birchwood ea(1988) suggest that the majority of unaffected members of discordant schizophrenic MZ twin-pairs have abnormal personalities. Critics point out that twins share an intrauterine environment and may share perinatal hazards. Davis ea (1995) reported that MZ twins sharing a single chorionic sac (monochorionic) are more often concordant for schizophrenia than are dichorionic twins. Gottesman and Bertelsen (1989), among others, studied offspring of discordant MZ twins (only one had the illness) and found that the risk to children of the healthy twin was the same as that for the children of the affected twin, others putting the risk even higher. This suggests that the genotype for schizophrenia may remain unexpressed. The reason for this is not known. (See also Gottesman & Shields, 1982) Essentially similar findings have been reported for bipolar disorder.(Jones ea, 2002)

Adoption studies: A child of biological parents with schizophrenia adopted at birth by normal adoptive parents still retains more or less the same risk for the illness. If schizophrenic adoptive parents adopt the child of non-schizophrenic biological parents he carries the same risk for schizophrenia as anyone else (1%). Critics suggest that adoption agencies seek adoptive families resembling families of origin. The type of rearing a person genetically at risk receives in the adoptive home has a bearing on the likelihood of expression of schizophrenia spectrum disorder.(Tienari ea, 2004; Wahlberg ea, 2004)

*Pooled DNA and SNPs*⁹⁸⁸: In order to reduce cost, pooling of DNA has been used in a genome-wide study of schizophrenia in Cardiff.⁹⁸⁹ (Kirov ea, 2008) The Kirov ea (2008) study suggested that the SNPs rs11064768 (within a coiled-coil domain gene CCD C6O) and rs893703 (within a candidate gene for schizophrenia RBP1) may be important. However, Sanders ea (2008) carried out a large genetic association study of SNPs in 14 schizophrenia candidate genes and were unable to show that they accounted for a substantial proportion of genetic risk for schizophrenia, although small effects could not be outruled. A meta-analysis of 32 genome-wide linkage studies of schizophrenia (Ng ea, 2008) suggested that future work might concentrate on chromosomes 1, 2q, 3q, 4q, 5q, 8p, and 10q. Large scale studies using big patient numbers are needed to further our knowledge and this necessitates the combined efforts of many investigators.(Owen ea, 2010)

Chromosome studies are popular but have yet to pay major dividends. Narrowly defined schizophrenia with a constellation of physical abnormalities, and a piece of chromosome 5 on chromosome 1, thus giving a partial trisomy of chromosome 5, has been reported.(Sherrington ea, 1988) Crow's (1988) so-called *pseudoautosomal theory*, wherein he locates the genetic mechanism for psychoses at the tips of the short arms of the sex chromosomes, has been influential. Crow (2002, 2008) states that language is a human facility made possible by lateralisation, in turn made possible by material from the X-chromosome moving to the Y-chromosome (recombination during male meiosis) and thus escaping inactivation: attention has been focussed on the region of X-Y homology and specifically one gene, protocadherin XY,⁹⁹⁰ which Crow suggests explains, at least to some extent, both language and psychosis⁹⁹¹. However,(Weinberger & Marengo, 2003, p. 335-6) most morphometric work has reported bilateral alterations, anatomical asymmetries are found in other primates, and Crow fails to address the more generalised deficits found in schizophrenia. Nevertheless, there is fMRI evidence to suggest that increased language activity of the right

⁹⁸⁵ Figures vary, e.g. some sources give lifetime expectancies of 46% for a MZ twin where the co-twin already has schizophrenia or, for a singleton, if both parents have the disorder.

⁹⁸⁶ Twins in general are probably no more likely to develop schizophrenia than members of the general population.

⁹⁸⁷ Although this must be interpreted with caution for methodological reasons such as the use of registers, mailed questionnaires, and the attendant risk of misclassification.

⁹⁸⁸ Single nucleotide polymorphisms (SNPs or 'SNIPS': variations or polymorphisms in single bases/nucleotides in the DNA sequence.

⁹⁸⁹ 3 pools were used: unaffected controls, schizophrenic patients, and patients' parents. Highest ranked SNPs were individually genotyped.

⁹⁹⁰ Protocadherin is a cell adhesion molecule involved in axonal guidance.

⁹⁹¹ Burns (2006) suggests that schizophrenia is by-product of social brain evolution in humans, with problems in the 'social brain', i.e. frontotemporal and frontoparietal networks. So-called 'mirror neurones' in this part of the brain help us to read the intended actions of others. He suggests that the basic problem in schizophrenia relates to a sense of detachment and disembodiment from the social self and social world. This concept receives support from the work of Schürmann ea (2007) with twins discordant for schizophrenia.

hemisphere may play a role in precipitating psychosis.(Sommer ea, 2004) Also, Somers ea (2008) found that non-right-handed people have higher schizotypy that reflects a higher incidence of bilateral language lateralisation, potentially underlying loosening of associations; the authors suggest that decreased lateralisation is a vulnerability model for schizophrenia spectrum features.

Nicotine (incl. smoking) in schizophrenia

Transiently normalises the P50 deficit.

Nicotine receptor may regulate sensory gating⁹⁹² (Leonard ea, 2002)

More specifically, the alpha 7-nicotinic receptor gene may be involved in auditory sensory gating defect reported in schizophrenics⁹⁹³ (Freedman ea, 1997) – linkage of impaired P50 inhibition was reported to a locus adjacent to the alpha 7-nicotinic receptor gene on 15q

Do schizophrenic patients smoke to improve filtering of environmental stimuli?

fMRI work is consistent with nicotinic receptor mediation of neuronal dysfunction in schizophrenia (Tregellas ea, 2005; Tregellas ea, 2009a)

According to Sacco ea, (2005) cigarette smoking may improve visuospatial working memory and attention in schizophrenic patients, perhaps via nicotinic receptors

There is some evidence that ondansetron, a 5-HT₃ antagonist⁹⁹⁴, improves P50 auditory gating in medicated schizophrenia patients (Adler ea, 2005)⁹⁹⁵

George ea (2003, p. 87) suggest that schizophrenic subjects smoke tobacco in order to improve their cognitive functioning, although Netski ea (2003, p. 168) suggest that they abuse whatever is available and that data do not support the self-treatment hypothesis

Nevertheless, there is some evidence that DMXB-A⁹⁹⁶, a partial alpha 7-nicotinic agonist improves cognition in people with schizophrenia (Olincy ea, 2006; Freedman ea, 2008)

Nicotine replacement therapy plus motivational interviewing/CBT may have utility.(Baker ea, 2006)

Nicotine, in mice, may upregulate glutamic acid decarboxylase 67 (GAD₆₇) expression by activating nicotinic cholinergic receptors located on cortical or hippocampal GABAergic interneurons.(Satta ea, 2008)

DeLisi ea (2002) suggested that failure to consistently replicate linkage reports might reflect an epigenetic mechanism (gene expression) rather than an effect of sequence variation.(see also Crow, 2007)

The *velo-cardio-facial syndrome* (VCFS)⁹⁹⁷ is due to small hemizygous chromosomal deletions in chromosome 22q11.2. Although the sample size may have been inadequate, according to Ivanov ea (2003) the rate of VCFS in patients with psychosis without learning difficulties may be as low as 0.6%. There are cleft lip/palate, congenital heart defects, thymic dysplasia, hypocalcaemia, nasal speech, intellectual disability (in almost half – of various degrees of severity), long facies, bullous nasal tip, and an increased incidence of schizophrenia-like⁹⁹⁸ and bipolar disorder-like disorders. However, Baker and Skuse (2005) looked at adolescents and adults with the syndrome and found an excess of psychiatric morbidity⁹⁹⁹, i.e. there is a continuum of developmental disruption followed by a decline in mental health in early adulthood.

⁹⁹² Sensory gating = ability to ignore unimportant environmental stimuli.

⁹⁹³ Decreased muscarinic cholinergic receptors, specifically M1 and M4, have been reported in prefrontal cortex (Crook ea, 2001) and M1 in the caudate-putamen in schizophrenia.(Dean ea, 1996)

⁹⁹⁴ 5-HT, 5-hydroxytryptamine, serotonin.

⁹⁹⁵ The notion of a defective **filtering of environmental stimuli** goes back to **Broadbent**.(1958) Hemsley (1977) applied defective selective attention theory to negative symptoms – patients learn to cope with information overload by slowed thinking, poverty of speech and flat affect, apathy and withdrawal. However McKenna (2007, p. 192) suggests that disordered attention may be more reminiscent of mania than of schizophrenia.

⁹⁹⁶ 3-[(2,4-dimethoxy) benzylidene] anabaseine, a natural alkaloid derivative.

⁹⁹⁷ Shprintzen or catch 22 syndrome. Incidence = c. 1/5,000 births. The term catch 22 stands for **c**ardiac defects, **a**bnormal facies, **t**hymic hypoplasia, **c**left palate, **h**ypoglycaemia, and the involvement of chromosome **22**. A more severe form of VCFS, Di George syndrome, includes absent thymus and hypocalcaemia. In fact, many clinical syndromes have been described with this deletion.(Kobrynski & Sullivan, 2007)

⁹⁹⁸ 10-20% in adulthood – the phenotype can closely resemble schizophrenia.(Bassett ea, 2003) Adolescents with 22q11.2 deletion syndrome have poor ‘source monitoring’, i.e. impaired ability to identify the origin of mental events.(Debbané ea, 2008) In common with epilepsy and a number of congenital cerebral disorders, onset of psychosis is delayed until adolescence or early adult life.(Weinberger & Marengo, 2003, p. 340)

⁹⁹⁹ ADHD, depression, anxiety, transient psychotic episodes, inappropriate emotionality, disrupted social behaviour, as well as poor functional adjustment associated with schizotypal symptoms.

Such patients may be at increased risk for seizures when given antipsychotic drugs.(Sporn ea, 2004)
Reduced white matter volume on MRI was reported by van Amelsvoort ea.(2004)

VCFS

MRI in VCFS (abbreviated)¹⁰⁰⁰

One case of cavum septum pellucidum and hypoplastic vermis

Children with VCFS - 11% reduction in total brain volume, 16.3% and 7.5% reduction in white and grey matter volumes respectively, a relatively large frontal lobe, and a loss of normal parietal lobe asymmetry due to a reduction in grey matter on the left side

Childhood cases - relatively small lobe, superior temporal gyrus and hippocampus, the brain being small overall

Adult cases - increased prevalence of white matter hyperintensities, cavum septum pellucidum, widespread differences compared to controls in white matter bilaterally, and regional specific differences in grey matter in the left cerebellum, insula, and frontal and temporal lobes

Study reported reduced white matter anisotropy in frontal, parietal, and temporal regions as well as in tracts connecting the frontal and temporal lobes

Facial emotional processing task – reduced activation in right insula and frontal brain regions and increased activation in occipital regions

Prepulse inhibition (PPI)¹⁰⁰¹ is lower in 22q.11 deletion cases than in a sibling control group.(Sobin ea, 2005) Blackwood and Muir (2004, p. 163) point out that the gene coding for COMT is located within the small region on chromosome 22 that is deleted in VCFS. COMT genotype seems to affect brain development in VCFS.(van Amelsvoort ea, 2008) The TBX 1 gene is important in cardiac development, is involved in the deletion, and seems to be important in the development of the VCFS phenotype.

*Metachromatic leucodystrophy*¹⁰⁰² may be misdiagnosed as schizophrenia for a long time before neurological stigmata emerge.(Weinberger & Marengo, 2003, p. 340)

Paternal half-sibling studies: If paternal half-siblings (same father but different mothers) are separated early in life we can claim to have individuals who share neither intrauterine nor early maternal influences. Kety¹⁰⁰³ ea (1976) found that 13% of paternal half-siblings of schizophrenics were diagnosed as having this disorder compared with 1.6% (1 case) of 64 half-siblings of controls. These findings favour genetic transmission over other explanations.

Anticipation: This refers to increasing severity and earlier age of onset of a condition over successive generations. It has been suggested that a minority of cases of schizophrenia may have this characteristic. Di Maggio ea (2001) have reported a reduction in time of onset of psychotic symptoms and age at first hospitalisation in successive birth cohorts. Whilst reminiscent of the degeneration theories of the nineteenth century, it was hypothesised to be associated with unstable coding trinucleotide (triplet) repeat expansions.

¹⁰⁰⁰ It should be noted that reported findings are the result of comparisons with whatever controls are being employed for a particular study.

¹⁰⁰¹ Sensorimotor gating: PPI linked to haplo insufficiency of TBX1 gene (one of the genes affected in 22q11 deletion syndrome). Neonatal rats whose hippocampi are lesioned show impaired prepulse inhibition at puberty, suggesting that such an early lesion create a vulnerability to hormonal influences on neural circuits that accompany puberty.(Lipska ea, 1995)

¹⁰⁰² Aryl sulphatase deficiency.

¹⁰⁰³ Seymour Kety (1915-2000).

Work has been done on polyglutamine-expanded tracts, encoded by CAG repeats, in protein from lymphoblasts. This work has also suggested a role for a polyglutamine expansion in childhood-onset schizophrenia. These findings are reminiscent of those in Huntington's disease research. However, dynamic mutations resulting in variation trinucleotide repeats lacks convincing evidential support.(Fortune ea, 2003) *Parental age:* There is some evidence that an older father¹⁰⁰⁴ at the time of conception may be associated with increased risk for developing schizophrenia in the offspring.(Malaspina ea, 2001; Brown ea, 2002; Zammit ea, 2003a; Sipos ea, 2004) The literature does not offer a clear answer as to which offspring sex is more likely to be more affected. A Danish study found schizophrenia to be associated with having an older father; the authors speculated about new mutations, possibly X-linked.(Byrne ea, 2003) This finding receives support from Sipos ea (2004) who found that advancing paternal age¹⁰⁰⁵ increases the risk for schizophrenia in people with a negative family history. The same authors found paternal age is only weakly associated with non-schizophrenic non-affective psychosis. Fuller Torrey ea (2009) concluded that the effect of paternal age in increasing risk for schizophrenia in offspring is of 'intermediate magnitude' and applies when the father is at least aged 55 years. Rosenfield ea (2009) defined an older father as someone over 35 years of age and found that both sexes with 'paternal age-related schizophrenia' (PARS) shared the same age of onset and a similar preponderance of negative symptoms; non-PARS cases had the typical earlier age of onset and more severe negative symptoms in males; PARS cases had more severe symptoms than non-PARS cases when medication was stopped but the symptoms globally improved with antipsychotic treatment so that differences between the two groups were reduced; and the authors wondered if the aetiological pathology of PARS and non-PARS were distinct.

Other putative associations: According to Naguib (1991), paranoid schizophrenia has shown a 'consistent' association with HLA-A9. Naguib also reported 'early evidence' of an association of 'paraphrenia' with HLA-B37. The frequency of DRB1*04 alleles¹⁰⁰⁶ may be reduced in schizophrenia. In Japan, 16% of schizophrenics have DR1 (DRB1*0101) versus 10.5% of controls.(Sasaki ea, 1999) Radiation has been suggested as a possible cause of genetic mutation leading to schizophrenia.

*Obstetric complications*¹⁰⁰⁷ (OCs): A number of researchers, including O'Callaghan ea (1990), found that OCs were more common in the personal history of schizophrenic patients who had relatively early onset of illness¹⁰⁰⁸ and who lacked a family history of schizophrenia. OCs may be more important for males than females and for childhood-onset cases. An excess of pre-eclampsia and detention in care as a neonate have been reported in the histories of persons later developing schizophrenia.(Kendell ea, 1996; Jones & Cannon, 1998) The British Perinatal Mortality Survey data failed to support a connection between factors predicting perinatal mortality and the aetiology of schizophrenia.(Done ea, 1991) Others, such as McCreadie ea (1992) and Kendell ea (2000), also failed to find a connection between schizophrenia and OCs. Also, the question remains as to whether the foetus is genetically and/or environmentally predisposed to develop OCs, i.e. the direction of causation is unclear. Geddes and Lawrie (1995) speculated that selection and publication bias may inflate any connection between schizophrenia and OCs. Webb ea (2005), in a meta-analytic review, found an almost twofold higher risk of foetal death/stillbirth among offspring of women with psychoses. Harrison ea (2003), whilst finding an increased risk for non-affective psychoses for persons born in urbanised areas, were unable to incriminate OCs or parental educational status. Cannon ea,(2002) in a meta-analysis, whilst concluding that there was a small but important association between OCs and schizophrenia, pointed to the lack of statistical power to measure small and interactive effects and to a lack of detailed information about the prenatal period. Verdoux ea (1997) found an association between early onset of schizophrenia and OCs, but no connection between the latter and a family history of schizophrenia. Bersani ea (2009) found that OCs severity was significantly associated with magnetic resonance measures of ventricular enlargement, and greater OCs severity showed increased association with increasing ventricular size; these associations were independent of age at onset of schizophrenia, illness duration, and antipsychotic treatment; and OCs severity was significantly positively

¹⁰⁰⁴ And possibly an older mother.(Ekéus ea, 2006)

¹⁰⁰⁵ Advanced paternal age may also increase the risk for autism spectrum and bipolar affective disorder.

¹⁰⁰⁶ Encoding for class II HLA DR4, which is associated with rheumatoid arthritis which seems to be uncommon in schizophrenia, although the author has diagnosed just such a case.

¹⁰⁰⁷ There is room only to mention a sample of published research papers here. A major problem in this area is that a number of different OCs may turn up as relevant simply because they are interrelated.(Lewis & Zammit, 2004, p. 69) McKenna (2007, p. 185) states that this research would not stand up to the 'mildest statistical query'.

¹⁰⁰⁸ ? Foetal hypoxia → neurotoxicity → premature cortical synaptic pruning → early-onset schizophrenia.

associated with hallucinations. There is evidence that OCs may interact with genetic liability¹⁰⁰⁹ to 'produce' schizophrenia. (Kinney ea, 1998; Cannon ea, 2002) Stefanis ea (1999) found that people who experienced obstetric problems were especially likely to have a small hippocampus and we know that lesioning of neonatal rat ventral hippocampus reduces spine density in prefrontal cortex and accumbens nuclei and such animals, on reaching maturity, have excessive reactions to amphetamine. In a prospective birth cohort study, Waddington ea (2008) found a doubling of risk for schizophrenia spectrum disorder with craniofacial midline anomalies and related functional-neural impairments which might be explained by a common relationship with brain dysmorphogenesis resulting from genetic and environmental predisposition to schizophrenia.

Low birth weight (< 2,500 grams) has been reported in people who later develop schizophrenia¹⁰¹⁰. In males this may be associated with poorer premorbid social and cognitive abilities, and with impairment of adult cognitive function. In fact, low birth weight may be one factor in determining which MZ twin develops schizophrenia. (Stabenau & Pollin, 1993) Jablensky ea (2005) found increased risk for pregnancy, birth and neonatal complications¹⁰¹¹ among both schizophrenic and affective disorder¹⁰¹² patients. Schizophrenia in the mother was associated with heightened risk for placental abruption, small/light babies, and offspring with congenital cardiovascular anomalies. Neonatal complications were more common in winter, whereas low birth weight peaked in spring. OCs¹⁰¹³ more often succeeded diagnosis of psychiatric illness than preceded it. Rifkin ea (1994) suggested that neurodevelopmental impairment caused both poor foetal growth and later schizophrenia. Alvir ea (1999), in a small number study, found poor response to treatment in first episode schizophrenia to be associated with a history of OCs and larger lateral ventricles. When Kirov ea (1996) removed cases with a history of OCs (mainly males) from their series of 73 schizophrenics, they found that the sex difference in the age of onset disappeared! Interestingly, for reasons that are not fully understood, birth and delivery complications *in general* may be more common in boys. (Eogan ea, 2003)

There has been suggestions that schizophrenia may be associated with rhesus incompatibility. (Hollister ea, 1996)

First trimester maternal starvation retrospectively correlated with schizophrenia in offspring. (e.g. Susser & Lin, 1992) Poor nutrition might affect brain development¹⁰¹⁴, as might toxins¹⁰¹⁵ or diuretic drugs used to treat hypertension during the third trimester. (Sørensen ea, 2003) Sørensen ea (2004) reported an association between second trimester analgesic-taking and risk for schizophrenia in offspring.¹⁰¹⁶ Susser and Lin (1992) found an increased risk for schizophrenia after prenatal exposure to the Dutch Hunger Winter of 1944-1945. Similar findings were reported for the Chinese famine of 1959-1961. (St. Claire ea, 2005) However, there is also a reported increased risk for schizophrenia for people born in the Netherlands during 1940¹⁰¹⁷, relative to persons born during 1938-9 or 1941-43. (Van Os & Selton, 1998) Also, Neugebauer ea (1999) found an association between antisocial personality disorder in the offspring of mothers exposed to the same Dutch Hunger Winter.

Findings of an excess of schizophrenia from unwanted pregnancies (Myhrman ea, 1996) do not tell us why the pregnancies were unwanted. Other reported associations with later schizophrenia include maternal stress during pregnancy, vacuum extraction, prolonged labour, preterm delivery¹⁰¹⁸, low birth weight¹⁰¹⁹, smallness for dates, and foetal malformations. Hypoxia-ischaemia may be a common perinatal risk factor in the histories of both schizophrenic (Dalman ea, 2001) and other non-affective psychosis and this may apply

¹⁰⁰⁹ Indicated by eye tracking dysfunction or comparative gray matter and CSF abnormalities in schizophrenic patients, their siblings and normals.

¹⁰¹⁰ As has short gestation and depression in the mother during pregnancy.

¹⁰¹¹ Including placental abnormalities, antepartum haemorrhage, and foetal distress.

¹⁰¹² Scott ea (2006) reviewed the literature and found no reliable evidence for a connection between exposure to OCs and bipolar disorder.

¹⁰¹³ Other than low weight babies and congenital anomalies.

¹⁰¹⁴ Indeed MRI has shown reduced brain size and various abnormalities, such as white matter hyperintensities.

¹⁰¹⁵ Alcohol, amphetamine, retinoids, etc.

¹⁰¹⁶ Some of the drugs taken by mothers in the study are now generally obsolete, the study lacked statistical power in relation to the effects of individual chemicals, and information on dosage was unavailable.

¹⁰¹⁷ German invasion.

¹⁰¹⁸ Maternal distress in later pregnancy, as shown on the GHQ, has been shown to be a risk factor for preterm delivery in Danish non-psychiatric populations.

¹⁰¹⁹ A modest risk factor for schizophrenia.

to both sexes. Large population-based samples are needed to clarify the relationship between OCs and schizophrenia.(Thomas ea, 2001) Caution is required in interpreting results (Jablensky, 2003, p. 218) and reliance on maternal recall alone is susceptible to bias.(McIntosh ea, 2002)

Cannon ea (2002) classify three groups of **complications** that may have significant associations with schizophrenia. These were derived from a meta-analysis of prospective studies and are:

- complications of pregnancy (bleeding, diabetes, rhesus incompatibility, preeclampsia),
- abnormal foetal growth and development (low birth weight, congenital malformations, reduced head circumference), and
- delivery complications (uterine atony, asphyxia, emergency Caesarean section).

Breastfeeding: There is no convincing evidence¹⁰²⁰ of an association between been breastfed or not and developing schizophrenia.(Mukherjee & Galanis, 2001)

Dermatoglyphics: A number of authors (e.g. Mellor, 1992) have reported differences in the skin ridge pattern¹⁰²¹ between schizophrenic patients and controls, the latter including co-twins in MZ pairs. The relatives of schizophrenics may also have such abnormalities.(Avila ea, 2003)

Neuropathology and neurophysiology: The second trimester is a critical period for massive neuronal migration to the cortex¹⁰²² and there is evidence to suggest that this does not occur normally in at least some cases of schizophrenia, e.g. the finding of heterotopic clusters of neurones in the entorhinal cortex, or selective displacement of interstitial frontal white matter neurones.(e.g. Akbarian ea, 1996) However, attempts to replicate cell disarray have been problematic.(McKenna, 2007, p. 134) Gogtay ea (2008) used tensor-based morphometry to study 12 cases of childhood-onset schizophrenia and 12 healthy controls over a 5-year period and found that childhood-onset schizophrenia was associated with up to 2.2% slower annual growth rates in white matter, especially in the right hemisphere.

Popken ea (2000) reviewed the literature and reported certain consistent findings: smaller cortical neurones, diminished arborisation of axons and dendrites, and a diminished number of thalamic neurones (especially in mediodorsal nucleus and especially the subnucleus projecting to dorsolateral prefrontal cortex).

Polysialic acid-rich neural adhesion molecule is involved in regeneration and plasticity of neurones and may be reduced in schizophrenic patients' hippocampi; mice who are depleted in polysialic acid-rich neural adhesion molecule isoform 180 (PSA-NCAM-180) show neuronal migration and cytoarchitectural problems.(Lipska & Weinberger, 2003, p. 395) Synaptic density peaks in childhood in the human frontal cortex, decreasing by 30-40% during adolescence because of progressive elimination of synaptic connections. Excess pruning has been suggested as a cause of hallucinations, as has abnormal co-activation of white matter tracts leading to confusion as to the source of inner speech¹⁰²³.(Hubl ea, 2004; Shergill ea, 2004) Schizophrenia might be a cortical or a subcortical disorder, the latter involving such structures as the basal ganglia or thalamus where integration and co-ordination of neural function is undertaken.

Bogerts ea (1985) reported that the brains of schizophrenic patients who died before modern treatments¹⁰²⁴ became available had reduced size of the amygdala, hippocampus, and parahippocampal gyrus and globus pallidus. McDonald (2004, p. 189) states that the morphology of schizophrenia and bipolar disorder are distinct but overlapping: the former is associated with subcortical and frontotemporal volumetric deficits, but grey matter volume is normal in psychotic bipolar disorder; and both conditions are characterised by volumetric deficits in white matter, with temporoparietal overlap. Other research findings are listed in the box.

¹⁰²⁰ And methodological problems, e.g. lack of statistical significance, small sample size, poor information on the general population.

¹⁰²¹ Since dermal ridges appear in the third to fifth months of gestation, the inference is that the cause of these abnormal dermatoglyphics preceded those dates.

¹⁰²² And migration of dermal cells to form skin ridges.

¹⁰²³ However, Langdon ea (2009) found no significant difference between healthy controls and schizophrenic subjects with auditory verbal hallucinations in terms of inner speech and the phenomenology of the hallucinations (e.g. third-person) did not relate to inner speech. Nevertheless, Simons ea (2009), using fMRI with 15 patients with schizophrenia and 12 healthy controls who listened to sentences and imagined sentences, found attenuated deactivation of the left superior temporal gyrus in schizophrenic patients whilst they processed inner speech, suggesting a problem with self-monitoring (i.e. my thoughts or extraneous words?).

¹⁰²⁴ Including ECT and insulin treatment.

Neuropathological findings in schizophrenia¹⁰²⁵

Reduction in all cell types in the mediodorsal thalamic and accumbens nuclei
 Smaller (than in controls) neurones in hippocampal areas (e.g. entorhinal cortex) thought to maintain two-way connections with the cerebral cortex
 Reduced numbers of small neurones in the superficial lamina and increased numbers of larger numbers in deeper layers of the prefrontal and cingulate cortices
 Increased neuronal density in the cerebral cortex and in areas of right hippocampus
 Cytoarchitectural asymmetry between hippocampi
 Increased CSF and reduced frontal lobe tissue
 Affected MZ twin had larger cerebral ventricles and smaller hippocampi bilaterally than unaffected twin
 Reduced density of the largest cortico-cortical projection neurones of sublayer IIIc of the prefrontal cortex
 Cognitive deterioration in older schizophrenics did not correlate with age-related degeneration
 Most cases of cognitive impairment not due to Alzheimer's disease, but mild Alzheimer-like pathology might reduce cognitive reserve in chronic schizophrenia (scz)
 Significantly smaller L superior temporal gyrus in both sexes in scz; total volumes of temporal lobe grey and white matter also significantly smaller, especially on L
 Altered dopaminergic innervation of prefrontal cortex area 9 (did not seem to be due to medication)
 Levels of the synaptic vesicle protein synaptophysin and the presynaptic protein SNAP-25, but not their mRNAs (other studies have found reduction in this mRNA in some brain regions), are reduced in scz, suggesting 'hypofrontality' might be due to abnormal structure or function in prefrontal cortex
 Levels of L1 and Thy-1 cell adhesion molecules (CAMs) normal in prefrontal cortex
 Increased fibre density in fornix of male scz
 Increased mononuclear phagocytes/macrophages in CSF during acute psychotic episode, cytology normalising during conventional neuroleptic therapy

Dendritic spine density reduced in layer 3 of dorsolateral prefrontal cortex (DLPFC) in scz
 Mean gyrification index (a ratio involving line of gyral surface and inner line of skull) on R side increased in M scz only
 Scz of both sexes had reduced volumes of L parahippocampal and fusiform gyri; normal L>R volume asymmetry reversed for both structures in scz; and degree of anomaly of asymmetry for both gyri increased with age of onset in M but not F scz
 Reduced spine density of subicular apical dendrites in scz and mood disorders (in latter case it is related to strong family history of major psychiatric disorders)
 Reduced levels of glycogen-synthase kinase-3 (protein kinase involved in signal transduction and in neurodevelopment) in frontal cortex in scz (*antipsychotic drugs may treat psychotic symptoms, at least partly, by modulating levels and activity of Akt/glycogen-synthase kinase-3 [GSK-3] and wingless (Wnt)-related intracellular signalling*: Freyberg et al, 2010)
 Having found changes in mitogen¹⁰²⁶ activated protein (MAP) kinase in scz after death, then found increase in protein levels of ELK-1, CREB and ATF-2 in cerebellar vermis; given critical role of MAP kinase pathway in memory consolidation and long term neuronal plasticity, and the role of the cerebellum in memory, the results are no surprise (small Purkinje cell size in vermis in scz has also been reported)
 Transcriptional and post-transcriptional glutamate receptor expression reduced in thalamus in scz
 No volumetric abnormalities of frontal in scz (TJ Crow's group)
 MRI and postmortem evidence of R hypergyria in family with multiple cases of scz
 Decreased somal size of prefrontal cortex in scz and smaller deep layer 3 pyramidal neurones
 Fewer projections from mediodorsal thalamic nucleus to prefrontal cortex
 Abnormal densities and ratios of olfactory epithelium in scz
 Scz have smaller and less than normal numbers of neurones in some thalamic nuclei
 Consistent volume reduction of amygdala not consistent finding in scz
 No evidence of a primary alteration of the hippocampus in schizophrenia
 Increased phosphate-activated glutaminase and glutamic acid decarboxylase activities in DLPFC in scz suggests dysregulated glutamatergic/GABAergic state
 Examination of single neurones in entorhinal cortex in scz for gene expression found marked differences from controls in various G-protein-coupled receptor-signalling transcripts, glutamate receptor subunits, synaptic proteins, etc
 DARPP-32 reduced in DLPFC in scz (DARPP-32 is localised to neurones with DA receptors. It is a strong inhibitor of protein phosphate 1, which plays an important role in dopaminergic and glutamatergic signalling and in integrating these two pathways.)
 Compared to normals, scz at postmortem only had significant smaller (12% difference) frontal gray matter volume
 Monoclonal antibody against microtubule-associated protein MAP2 (a dendritic protein) to label interstitial white matter neurones in anterior parahippocampal gyrus: suggests abnormality in residua of cortical subplate (? migration problem or problem with pattern of programmed cell death)
 No differences in cerebellum between DSM-III male scz and male controls
 Amyloid β -peptide levels in scz without Alzheimer's disease do not differ from normals (measured using antibodies)
 Reduced NR1 subunit (of NMDA receptor) transcript expression restricted to exon 2-containing isoforms; increased expression of NMDA receptor-associated postsynaptic density proteins NF-L, PSD95, and SAP102 detected in thalamus in scz

¹⁰²⁵ Roughly in order of publication. It should be noted that Elmer Ernest Southard (1876-1920) of Boston reported ventriculomegaly in deceased schizophrenic patients (no controls used) in the *American Journal of Insanity* in 1915 (January, p. 639).

¹⁰²⁶ A *mitogen* is an agent that induces mitosis and cell proliferation.

Decreased thalamic expression of homeobox gene DLX1 (required for production, migration, and differentiation of neocortical, hippocampal, and olfactory bulb GABA-ergic interneurons in mice; DLX1 and DLX2 in humans are closely linked at chromosome 2q32) in patients with scz and in bipolar patients with a history of psychosis

Relatively small sample failed to find any change in hippocampal pyramidal neuronal cell size in scz

Glial cell loss in anterior cingulate cortex in scz

Density of GABA interneurons expressing NMDA NR2A subunit is decreased in ant cingulate cortex in scz and bipolar disorder (note: GABA interneuronal activity is modulated by glutamatergic input from pyramidal cells)

Normal Heschl's gyrus found in scz

Scz patients had lower levels of spinophilin (neurabin II, a dendritic spine marker) mRNA in CA4 (hilus), CA3, subiculum, and entorhinal cortex than did normal hippocampal formations; mood disorder group had similar findings to scz; MAP2 and cyclophilin mRNA (housekeeping gene control) did not differ between scz, mood disorder, and normals: evidence for abnormal dendritic spines in scz and mood disorders (spines are target of most glutamatergic synapses)

Increased neuronal density and reduced interneuronal **neuropil**¹⁰²⁷ in primary visual area in scz

Abnormal DNA methylation of genes related to neurodevelopment and synaptic plasticity in occipital cortex in scz

High levels of H3-(methyl)arginine 17 associated with downregulated metabolic gene expression in prefrontal cortex (PFC) of some cases of scz: histone modifications may contribute to PFC dysfunction (4 core histones together with base pairs of genomic DNA wrapped around them compose the basic units of chromatin [nucleosomes]; chromatin fibres consist of arrays of nucleosomes connected by histones and DNA)

Thalamic dopaminergic abnormalities in scz are at level of intracellular integration of DA signalling with other neurotransmitter systems, probably including glutamate

Greater exposure to typical antipsychotics leads to thicker ant cingulate gyrus

Small study of DLPFC at postmortem in scz showed no increase in neuronal density but there was loss or reversal of asymmetry in cortical layer 3

2-dimensional electrophoresis of DLPFC in scz, bipolar affective disorder (BAD) and mentally normal controls to look for abnormal proteins: scz and BAD had differences from controls; mass spectrometry identified 15 scz-associated and 51 BAD-associated proteins; most affected were synaptic proteins in scz and metabolic and mitochondrial proteins in BAD; majority of abnormally expressed synaptic-associated proteins in BAD were isoforms of the septin family; findings are evidence for synaptic pathology in scz and metabolic dysfunction in BAD

MRI evidence of prefrontal volume deficits in scz that mainly affect areas (orbitofrontal) needed to think socially

GABA transmission appears to be decreased in cortex of cerebellum in scz

Antibody testing of post-mortem brain in scz found increased glutamate carboxypeptidase (GCP II) expression and low mGluR3 (a group II metabotropic glutamate receptor) expression in DLPFC suggesting that N-acetyl-aspartyl-glutamate (NAAG, a specific endogenous mGluR3 agonist) –mediated signalling is impaired; also, mGluR3 receptor appears to be involved in antipsychotic action of mGluR2/mGluR3 agonists

Postmortem study of anterior cingulate brain sections (BAD, major depressive disorder [MDD], schizophrenia, and controls) determined oxidative stress by analysing 4-hydroxynonenal (4-HNE), a major product of lipid metabolism; 4-HNE levels raised by 59%, 47% and not at all in BAD, schizophrenia, and MDD respectively; oxidative damage may contribute to BAD and schizophrenia

In a post-mortem study case-control study, schizophrenic subjects had large increases in chondroitin sulphate proteoglycans (CSPGs¹⁰²⁸)-positive glial cells in amygdala and entorhinal cortex (CSPG changes were negligible in bipolar disorder)

Reveley ea (1982) suggested that cerebral ventricular size might be under genetic control: where only one of a pair of twins has schizophrenia it is the one with the larger ventricles who has the illness. These findings find support from other workers.(e.g. Suddath ea, 1990). BDNF Met allele carriers have significantly greater decreases in frontal grey matter volume with reciprocal increases in the lateral ventricles and sulcal CSF than Val homozygous patients.(Ho ea, 2007)

Lateral ventriculomegaly in schizophrenia seems to be more marked in males.(e.g. Flaum ea, 1990)

Crow (1990) suggested that enlargement of the temporal horn of the lateral ventricle in schizophrenia is selective to the left side of the brain.

Knable ea (1998) point to the non-progression of abnormal findings in schizophrenia¹⁰²⁹ and the absence of gliosis as evidence for a neurodevelopmental¹⁰³⁰ (versus neurodegenerative¹⁰³¹) process. However, Pantelis ea,(2003) in an MRI study, examined people with 'prodromal signs of psychosis' and re-examined them after 12 months: at baseline, those who would develop psychosis had less grey matter in right medial temporal, lateral temporal and inferior frontal cortices and in cingulate cortex bilaterally, while after developing psychosis grey matter was reduced in left parahippocampal, fusiform (occipitotemporal), orbitofrontal and cerebellar cortices and cingulate gyri; in those not becoming psychotic changes over the

¹⁰²⁷ Neuropil: blood vessels, glia, axons, and dendrites.

¹⁰²⁸ CSPGs are an important part of brain extracellular matrix that is involved in regulating developmental and adult neural functioning.

¹⁰²⁹ Big cerebral ventricles, small medial temporal lobe structures, aberrant function of prefrontal cortex.

¹⁰³⁰ Ziermans ea (2009) performed MRI on young adolescents at ultra high risk for psychosis and were unable to demonstrate any gross neuroanatomical changes! They wondered if changes were present but too subtle to see or if they develop later.

¹⁰³¹ See McWilliams and O'Callaghan.(2007)

year were restricted to the cerebellum; therefore, it was concluded, some grey matter changes precede and others develop in association with first expression of psychosis¹⁰³². In another MRI study, with a mean of 3 years between scans, Ho ea (2003) found progressive reduction in frontal lobe white matter (and increases in cerebrospinal fluid volume) during the early stages of schizophrenia. Cahn ea (2006) found that progressive brain volume changes on MRI, especially of grey matter, were associated with clinical and functional outcome five years after a first-episode of schizophrenia. Also, Brans ea (2008a) repeated MRI after a 5-year interval and found excessive whole brain and cerebral grey matter volume decrease in schizophrenia patients¹⁰³³ compared to their same-sex siblings and healthy matched controls. The same group (Brans ea, 2008b) used MRI in a 5-year follow-up of MZ and DZ twins discordant for schizophrenia and healthy comparison twin pairs: patients with schizophrenia and their unaffected co-twins showed significant decreases over time in whole brain and temporal and frontal lobe volumes and such changes could at least partly be explained by illness-related genetic factors.

Treatment-resistant schizophrenia has been described in association with cerebral hemiatrophy¹⁰³⁴. Other associations with schizophrenia include an excess of midline brain malformations, e.g. cavum septum pellucidum (found at all stages of schizophrenia and, less commonly, in affective disorders and schizotypal disorder¹⁰³⁵, and, less commonly again, in about 13% of normals), agenesis of corpus callosum, and aqueductal stenosis.

According to Nasrallah and Smeltzer, (2002, p. 134) against the idea that schizophrenia represents a 'static encephalopathy' are unpredictability of clinical course, great differences in outcome, a tendency for positive (productive) symptoms to be replaced by negative symptoms¹⁰³⁶ over time, characteristics of the cognitive deficit, and a tendency to 'burnout'¹⁰³⁷ after years of progression. They suggest that there may be a neurodegenerative process superimposed on faulty neurodevelopment. They also suggest that atypical antipsychotic drugs may have a neuroprotective effect that inhibits degeneration. Murray (2008) states that increased striatal D2 receptors in mice may cause schizophrenia-like deficits in behaviour and cognition that could represent a model for negative symptoms. Keefe ea (1999) reviewed fifteen efficacy studies and found that, despite methodological problems, there was support for improvement in verbal fluency¹⁰³⁸, digit-symbol substitution, fine motor function and executive functions in patients treated with atypicals. However, despite such gains, the performance of schizophrenic patients failed to reach normal levels. Krabbendam and Jolles (2002) have reviewed the claim that conventional antipsychotic drugs have a negative effect on cognition and found any such action to be minor (Similarly, atypical drugs have a modest positive effect on neurocognition¹⁰³⁹, with little difference between individual drugs: Keefe ea, 2007; Cuesta ea, 2009). Nevertheless, they correctly point out that the anticholinergic actions of drugs may be a real problem¹⁰⁴⁰. Importantly, Davidson ea (2009) examined the effects of haloperidol versus four atypical drugs¹⁰⁴¹ on cognition in schizophreniform patients and first-episode schizophrenia patients and found that all the drugs moderately and equally improved performance and that such improvement was weakly related to changes in the PANS scores.

There may be reduced *cerebral laterality* in schizophrenia. Evidence for this comes from linguistic analysis¹⁰⁴², chimeric stimuli¹⁰⁴³, EEG studies¹⁰⁴⁴, dichotic listening tests¹⁰⁴⁵, dopamine studies, and

¹⁰³² This is, of course, not a very long follow up period and a 'prodrome' is not always easily distinguishable from early symptoms

¹⁰³³ Mean duration of illness = 19.6 years (s.d. = 11.5).

¹⁰³⁴ Dyke-Davidoff syndrome.

¹⁰³⁵ From Rado's 1950 'schizotype', short for 'schizophrenic phenotype'. McKenna (2007, p. 435) states that Spitzer adopted Kety's 'borderline schizophrenia' and renamed it schizotypal personality for DSM-III.

¹⁰³⁶ Which may represent the core symptoms of the disorder. (Ho ea, 2003, p. 382)

¹⁰³⁷ Reaching a plateau without further deterioration.

¹⁰³⁸ A meta-analysis (Henry & Crawford, 2005) suggested that verbal fluency problems in schizophrenia are but part of a generalised intellectual dysfunction.

¹⁰³⁹ Because studies of the effects of antipsychotic drugs differed due to the use of different memory tests the NIMH introduced the MATRICS Measurement and Treatment Research to Improve Cognition in Schizophrenia initiative aimed at developing a common test battery. (see Harvey & Cornblatt [2008] for an introduction)

¹⁰⁴⁰ Drimer ea (2004) withdrew chronic anticholinergic drugs from older schizophrenic patients: extrapyramidal symptoms did not worsen and cognition improved. See also Vinogradov ea (2009b) who found that anticholinergic load interferes with cognitive training in schizophrenia.

¹⁰⁴¹ Amisulpride, olanzapine, quetiapine, and ziprasidone.

¹⁰⁴² Schizophrenics have less syntactically complex speech that contains more errors than either manics or controls – healthy controls, unlike schizophrenic patients, activate the posterior part of the right middle temporal and left superior frontal gyri when forming complex sentences. (Kircher ea, 2005)

neuroimaging¹⁰⁴⁶. Different authors suggest that the ‘problem’ may be in the right or the left cerebral hemisphere, and some studies found no evidence for a laterality problem at all. Crow (1995; see also above re protocadherin XY) hypothesised that psychoses are a product of human evolution, because of variation in genes controlling hemispheric asymmetry; he had earlier stated that psychosis may be related to increased complexity of neocortical structures associated with the evolution of language; and he would later describe the nuclear symptoms of schizophrenia as ‘language at the end of its tether’. Because of callosal constraints, language evolved by a process of hemispheric specialisation. ‘Phonological output sequence’ became localised to the dominant (for language) hemisphere, whereas its associations or ‘signfields’ were lateralised in part to the other half of the brain. Concepts (thoughts) are translated via a bi-hemispheric interaction into phonemes (speech) by the speaker in frontal association areas, and decoded back into concepts (meanings) by the hearer in occipito-temporal-parietal areas. According to Tim Crow, the psychotic person cannot distinguish the phonemic signals generated by the hearer from his own thoughts, or from signals that he receives from an interlocutor. Put more simply, his brain interprets his own thoughts as foreign. The question arises about the heritability of first rank symptoms, put at zero by some; but Loftus ea,(2000) who extracted nuclear/Schneiderian symptoms from case notes of and interviews with sibling pairs with DSM-III-R schizophrenia or schizoaffective disorder, found that some such symptoms ‘show a degree of familiarity and therefore perhaps heritability’. According to Ceccherini-Nelli and Crow,(2003) the *Clinical Language Disorder Rating Scale* (CLANG)¹⁰⁴⁷ is a reliable and valid instrument for assessing language disturbance in psychosis, and language disturbance is more specific than first-rank symptoms in the diagnosis of ICD-10 schizophrenia. However, the controls used were non-psychotic depressives, so no attempt was made to distinguish schizophrenia from mania; it was a non-blinded study; and instruments other than the CLANG were not employed.

Liddle (2001, p. 94) finds that human minds have become relatively independent of outside influence, allowing for a more flexible response to an ever-changing external world by utilising stored memories to construct theories about the future. He believes that reality distortion ultimately emanates from a confusion of ‘mental representations triggered by current external circumstances’ with ‘representations of past situations and representations of hypothetical situations’.

The *developmentally reduced synaptic connectivity* (DRSC) theory suggests that schizophrenia results from reduced synaptic connectivity due to perinatal and adolescent disturbances that lead to too few dendrites and synapses. Tissue loss, according to this theory, represents a loss of neurophil¹⁰⁴⁸ rather than neurones. Electrophysiological studies using a number of perceptual tasks have shown changes in auditory event-related potentials that distinguish schizophrenic patients from controls. The P3 component is a positive deflection recorded from the vertex about 300 milliseconds after a stimulus. Blackwood ea (1987), from their controlled studies, suggest that a prolonged P3 latency and reduced P3 amplitude indicate an impairment of auditory processing in some patients with schizophrenia which is independent of the presence of acute psychotic symptoms and is not influenced by neuroleptic treatment. There is some evidence that auditory P3 amplitude may decrease with illness duration.(van der Stelt ea, 2004) It should be noted that, despite the fact that the P3 component of the visual evoked response is often spared in these patients, there is a disturbance of visual attention also in schizophrenia as evidenced by reduced frontal P2a and posterior N2b event related components.(Potts ea, 2002) Work with event-related potentials suggest a neurophysiological impairment in the maintenance of selective attention and the cognitive processes associated with target detection in schizophrenia, probably due to dysfunction of frontostriatal pathways.(O’Shea, 1997; Mathalon ea, 2004 – work using visual target and competing visual stimuli were

¹⁰⁴³ Faces are presented with one side showing one emotion and the other side showing a different emotion.(e.g. Gooding & Tallent, 2002)

¹⁰⁴⁴ E.g. failure to show the normal left-sided superiority for phonetic processing as measured by event-related potentials; EEG and MEG combined point to left hemisphere dysfunction as being strongly related to auditory sensory gating deficit in schizophrenia.(Thoma ea, 2003)

¹⁰⁴⁵ If confined to testing for consonant-vowel or fused word tasks.

¹⁰⁴⁶ E.g. fMRI differences: controls activate both sensorimotor cortices during thumb opposition whereas schizophrenics show decreased activation of these areas; and MRI differences: amount of speech produced when talking about inkblots correlates with left and right superior temporal gyri respectively in controls and patients.

¹⁰⁴⁷ CLANG: 17 observer-rated items, such as unclear links and excess or lack of details, anchored on a four-point severity scale.(Chen ea, 1996)

¹⁰⁴⁸ Dendrites, axons, and synapses.

interpreted by the authors as suggesting anterior cingulate dysfunction [Yücel ea, 2002]) Other workers have reported reduced P3 amplitude¹⁰⁴⁹ in the close relatives of schizophrenics and in people with schizotypal (personality) disorder, while still others suggest that reduced amplitude of the P3 component on the left side only may characterise early schizophrenia. According to Butler ea (2005) deficits in early-stage visual processing predict higher cognitive deficits. Myles-Worsley (2002), looking at multiplex families, found impaired auditory sensory gating (independent of treatment, including doses) in schizophrenia patients (67% had abnormal P50 ratios) and their first-degree relatives (51.8%) compared to normals (10.3%) as measured by P50. According to Hall ea, (2007) event-related potential indices are potentially valid endophenotypes¹⁰⁵⁰ for schizophrenia, with P50 suppression and P300 amplitude showing the closest genetic relationship to schizophrenia. Greenwood ea (2007) looked at 183 families containing probands with schizophrenia and calculated heritability for pre-pulse inhibition of startle response, P50 event-related potential suppression, antisaccade task for eye movements, *Continuous Performance Test*, *California Verbal Learning Test* (second edition), and *Letter Number Sequencing Test*; all showed significant heritability but also significant environmental correlations. Sánchez-Moria ea (2008) found evidence supporting the presence of a P50 sensory gating deficit in both schizophrenia and euthymic bipolar disorder, implying that this deficit represents vulnerability to psychosis across diagnoses. Decreased neuregulin 1-induced activation of phosphoinositide 3' kinase (PI3K)/AKT system has been reported in association with impaired sensory gating in first-episode schizophrenia (Kéri ea, 2010), neuregulin 1 being involved in intracellular signalling. This finding may be important because antipsychotic drugs may ameliorate psychotic symptoms, at least in part, by modulating levels and activity of Akt/glycogen-synthase kinase-3 [GSK-3].

Using EEG coherence measures, Norman ea (1997) found a relationship between left fronto-temporal connectivity and reality distortion, especially in males. Slewa-Younan ea (2004) employed a conventional auditory odd-ball task in men and women with chronic or first-episode schizophrenia and matched controls; phase synchronous gamma (40 Hz) activity was extracted from the EEG: chronic cases, especially females, showed decreased global functional connectivity (lower gamma phase synchrony); while first-episode cases showed a general decrease in the speed of frontal connectivity, the speed of global connectivity was faster in female patients; the results suggest that female schizophrenics experience further breakdown in cerebral network connectivity as the disease becomes chronic. Symond ea (2005) reported that first-episode schizophrenia patients had decreased magnitude and delayed latency for global gamma 1 synchrony relative to controls, but no difference to controls in gamma 2 synchrony. Wynn ea (2005) found decreased gamma activity and failure of lateralisation of activity to the right hemisphere during masking. A decrease in EEG-evoked responses in the gamma band when transcranial magnetic stimulation was applied to directly stimulate frontal cortex suggested a possible intrinsic dysfunction in frontal thalamocortical circuits in schizophrenia.(Ferrarelli ea, 2008)

Other EEG findings include

Reduced delta sleep in unmedicated schizophrenic patients
 Greater negativity of the N400 on the EEG in both schizophrenia and schizotypy in response to reading or hearing sentences
 Reduced N400 in schizophrenic patients to unprimed words
 The P50 wave following the second of two auditory clicks is suppressed or 'gated' in normals whereas patients with schizotypal personality disorder or schizophrenia (and the latter's relatives) have much less P50 suppression than do healthy controls
 Findings suggestive of a disturbance in processing relevant and irrelevant information
 Reversed P300 temporal area asymmetry (smaller on the left) in first-episode schizophrenia that may be explained by reduced gray matter volume of left posterior superior temporal gyrus on MRI

Light ea (2000) found that conventional neuroleptics failed to normalise P50 suppression in people with schizophrenia, whereas risperidone, olanzapine and clozapine were able to do so. Adler ea (2004) found that clozapine improved P50 gating more than did olanzapine, risperidone, quetiapine or typical antipsychotic drugs. It should be noted, however, that Arnfred ea,(2003) in a controlled study of auditory evoked potentials in 12 unmedicated schizophrenic outpatients, found P50 gating to be normal.

¹⁰⁴⁹ Or temporoparietal reduction and frontal increase.(Winterer ea, 2003)

¹⁰⁵⁰ According to Martin ea (2007) P50 ratio and frequency of leading saccades identified subjects with schizophrenia and bipolar disorders with high sensitivity (95%) and specificity (83%) with some schizoaffectives being being classified with schizophrenia and others with bipolar.

The visual system has two main components: a dorsal¹⁰⁵¹ and a ventral¹⁰⁵² stream. Doninger *et al.* (2002) tested the ability of schizophrenic patients to recognise complete objects based on fragmentary information (i.e. perceptual closure, e.g. recognising a face behind an open venetian blind). Nc1 (closure negativity, an index of perceptual closure generated in the visual cortex), and the preceding positive (P1) and negative (N1) event-related potentials (ERPs) were examined. The patients were significantly impaired in this ability; there was impaired generation of the Nc1, significantly reduced amplitude of visual P1 (especially over dorsal stream sites), and intact generation of visual N1. Work in Dublin by Yeap *et al.* (2006) demonstrated a deficit in early visual processing (P1 amplitude reductions) in well first-degree relatives of people with schizophrenia. Kéri *et al.* (2005) suggest that multiple visual information processing deficits derive from dysfunction of the magnocellular pathway, leading to impaired attentional modulation of perceptual organisation and of natural image organisation.

Hong *et al.* (2008) found that gating of the theta-alpha-band responses of controls were significantly different from schizophrenia patients and their first-degree relatives. Furthermore, heritability of this band (0.49-0.83) was at least four times higher than the P50 heritability estimate. Thus, the authors suggest that this measure may be a superior one for genetic studies of the gating deficit in schizophrenia.

Excitatory lateral connections in early stage visual cortical processing may be specifically impaired in schizophrenia, but not in bipolar disorder. (Kéri *et al.*, 2005) This may contribute to complaints such as unclear seeing, partial or skewed sight, disrupted rectilinearity, and abnormal figure-ground segregation.

In chronic schizophrenia there is some evidence of increased skin conductance activity at rest, and in socially demanding conditions the skin conductance level and variability was increased in the right hand. Asymmetry of skin conductance may therefore be a characteristic of the chronic form of the illness (White *et al.*, 1987). A number of authors have produced evidence for impaired autonomic habituation in schizophrenia; in fact, it has been suggested (Zahn *et al.*, 1997) that in childhood-onset cases a combination of low elicited skin conductance activity (SDA) and high levels of spontaneous SDA may be specific for schizophrenia. Holt *et al.* (2009) reported increased neural response to innocuous stimuli and increased arousal levels in schizophrenic subjects.

Eye-tracking¹⁰⁵³ (smooth pursuit of a spot) abnormalities are not specific to schizophrenia, having been reported in depression, bipolar disorder, OCD and in delusional disorder. (Campana *et al.*, 1998; Lencer *et al.*, 2004; Gooding *et al.*, 2004) although they appear to be inherited with schizophrenia. (O'Shea, 1997) Such studies have been criticised on methodological and interpretational grounds. Over 80% of people with schizophrenia do however have abnormal smooth pursuit tracking with about one in three of their relatives having similar problems. (e.g. Kathmann *et al.*, 2003) Saccadic abnormalities¹⁰⁵⁴ are also reported in schizophrenia. (O'Shea, 1997) Both these and smooth pursuit abnormalities seem to be present from the start of the disorder. The fundamental problem may be one of poor sensory integration in general.¹⁰⁵⁵ There may be an abnormal frontostriatal network that normally suppresses automatic eye movements (Raemaekers *et al.*, 2002) and/or an abnormality of the frontal eye field. (Lencer *et al.*, 2004) Saccadic abnormalities seem to be more common in schizophrenics than in their relatives but more common in the latter than in affective states, who in turn are more affected than healthy people. (Csernansky, 2002) Saccadic task performance is more stable over time in schizophrenia than in bipolar cases, which supports a trait-like phenomenon in the former group. (Gooding *et al.*, 2004) Indeed, saccade and smooth pursuit dysfunction may be endophenotypes of schizophrenia¹⁰⁵⁶. (Kallimani *et al.*, 2009) Harris *et al.* (2006) found that deficits in the voluntary control of spatial attention persisted after treatment in antipsychotic-naïve first-episode schizophrenia but that the deficits were worse whilst the patients were acutely ill. Lencer *et al.* (2008) found that second generation (atypical) antipsychotic drugs impaired already abnormal smooth pursuit performance in antipsychotic-naïve patients with schizophrenia. There was some partial normalisation at one year. In a study conducted by Landgraf *et al.* (2008) schizophrenic patients and their siblings showed

¹⁰⁵¹ Input from magnocellular division of lateral geniculate nucleus and extends from early visual areas through the occipitoparietal cortex.

¹⁰⁵² Input from parvocellular division of lateral geniculate nucleus and extends through the occipitotemporal cortex.

¹⁰⁵³ This gives information about integrity of neural networks mediating motion perception, sensorimotor transformation, and cognitive processes such as prediction. (Lencer *et al.*, 2008)

¹⁰⁵⁴ Subject fixates central dot that steps randomly to right or left. When target steps into periphery, subject has to look to side opposite to target.

¹⁰⁵⁵ Abnormal proprioception in schizophrenia has been recognised since the 1950s. (Rado, 1953)

¹⁰⁵⁶ However, active fixation may be state-dependent. (Kallimani *et al.*, 2009)

elevated memory-guides saccade¹⁰⁵⁷ error rates relative to controls, reflective failed inhibition of reflexive saccades to a visible target. Not all studies support saccadic problems in relatives of patients of schizophrenic cases (de Wilde ea, 2008) or an association with genetic risk rather than disorder status.(MacCabe ea, 2005)

In *backward masking* a target stimulus is presented followed shortly by a 'mask', i.e. a second stimulus. This has the effect of hampering (masking) detection of the target. The interference seems to work backwards in time, hence the name. Schizophrenic individuals find it more difficult than do normals to identify the first (target) stimulus (Del Cul ea, 2006) and this may be due to failure to adequately activate the lateral occipital complex.(Green ea, 2009) Backward masking is also found in some chronic mania patients.

Murray (2002) has suggested that schizophrenic patients are 'developmentally impaired manics', i.e. mania modified by an abnormal brain. Liddle (2001, p. 198) suggests that the essential pathology in schizophrenia is abnormal development of long-distance connections within the brain leading to impaired regulation of modulatory monoamine neurotransmitters; stress then leads to florid psychosis. Frontal projections might normally prevent excessive DA transmission in the basal ganglia during stressful circumstances; if this is not possible, then there may be excessive positive feedback to the cortex that leads to psychosis. Such impaired connectivity might also explain negative and persistent cognitive symptoms.(Liddle, 2001, p. 199) *Neuroimaging*: In general decreased blood flow to the dorsolateral prefrontal cortex correlates with negative symptoms while fronto-temporal abnormalities correlate with positive symptoms including thought disorder (Horn ea, 2009).

Neuroimaging is best confined to the investigation of atypical cases (Lawrie, 2006) and for research. Variations in the type of patients (and control subjects: Blakemore, 2002) employed and their medication status between studies complicate interpretation, as does the state versus trait dilemma. The relative enlargement of the lateral and third ventricles and cortical sulci that is found in some schizophrenics on CT has been deemed by many authors to be static and to represent a neurodevelopmental rather than a neurodegenerative disorder. CT findings also suggest smaller brain volume and length, especially left-sided and in males.(see O'Shea, 1997) In particular, such findings seem independent of duration of psychosis or medication. Young ea (1991) using MRI reported that the normally smaller left amygdala was not a feature of schizophrenia; the latter had an excessively small left parahippocampal gyrus; ventriculomegaly and cerebral atrophy were related to symptom severity; small caudate nuclear heads correlated with severity of negative symptoms; and marked positive symptoms were associated with larger ventriculo-brain ratios (VBR).¹⁰⁵⁸ Twins affected by schizophrenia may have smaller anterior hippocampi than have their co-twins.(Weinberger ea, 1992) Chakos ea (2005) used MRI to examine the hippocampi of young male schizophrenics, older chronic patients, and matched controls. Schizophrenics had relatively smaller hippocampi, more so in chronic cases. Younger patients had larger hippocampi if they were treated with atypical antipsychotics rather than haloperidol. The authors concluded that the hippocampus of male schizophrenics is progressively reduced in size. They also speculated that atypicals might protect against this. Hurlmann ea (2008) found, relative to healthy controls, bilaterally reduced MRI hippocampal volumes in subjects thought to be in a prodromal schizophrenic state; only in those thought to be in the late stages of the prodrome did such reductions correlate with poorer performance on the *Rey Auditory Verbal Learning Test* delayed recall. Schobel ea (2009) used fMRI and found abnormal cerebral blood volume (CBV) increases in the CA1 subfield of the hippocampal formation and the orbitofrontal cortex and abnormal CBV decreases in the dorsolateral prefrontal cortex; baseline CA1 CBV abnormalities predicted progression to psychosis from the prodromal state; CBV in CA1 correlated with psychotic symptoms; and the findings were not influenced by antipsychotic drugs.

Various abnormalities in relaxation times have been reported in MRI studies of schizophrenic subjects, e.g. prolonged T2 values, especially in the left temporal cortex and white matter. Siegel ea (1993) used PET to study unmedicated male schizophrenics and found low metabolic rates in the medial frontal cortical regions and in the basal ganglia; there was loss of the normal lateralisation patterns; and correlations with negative symptoms and group differences (from normal controls) were more prominent in the medial and lateral frontal cortex.

¹⁰⁵⁷ A memory-guides saccade paradigm requires a person to inhibit reflexive saccades and to programme a delayed saccade towards a remembered target.

¹⁰⁵⁸ Increased VBR has also been reported in depressives.

There are many problems of interpretation in neuroimaging studies, e.g., presuming the effects of medication¹⁰⁵⁹, alcohol dependence¹⁰⁶⁰, age¹⁰⁶¹ and sex are controlled for, reports of small structures in chronic cases could mean either progression of atrophy with duration of illness or that smallness predicts chronicity. In their review/perspective, Weinberger and McClure (2002) found that while early CT studies favoured a neurodevelopmental (no progression) for schizophrenia, more recent MRI work suggested neurodegeneration (progression)! They suggest caution in interpreting MRI data: changes could be secondary (adaptive/neuroplastic) to psychosis, MRI changes are so big that we should be finding more gross postmortem changes, and cognitive studies are in general against progression. In fact, most MRI studies that show progressive changes also record clinical improvement!(Weinberger & Marengo, 2003, p. 332)

McDonald *et al.* (2004), using MRI, found that genetic risk for schizophrenia was specifically associated with distributed grey matter volume deficits in bilateral fronto-striato-thalamic and left lateral temporal regions. Genetic risk for bipolar affective disorder was specifically associated with grey matter deficits only in the right anterior cingulate gyrus and ventral striatum. Genetic risk for both disorders was associated with reduced volume of white matter in left frontal and temporo-parietal regions. This was interpreted as representing a common fronto-temporal disconnectivity. Pérez-Iglesias *et al.* (2010a) examined first episode schizophrenia patients and matched controls with diffusion tensor imaging (DTI) and reported that voxelwise analysis revealed four clusters where fractional anisotropy values were significantly lower among the patients; these were localised bilaterally to regions of white matter corresponding to superior and inferior longitudinal fasciculus, forceps major¹⁰⁶², anterior and superior thalamic radiation, and corpus callosum; and the authors concluded that decreased white matter integrity is present early and is localised in fascicle that connect brain regions implicated in schizophrenia. Koch *et al.* (2009) found that schizophrenia was associated with increased fractional anisotropy in corpus callosum, cerebral peduncle, left inferior fronto-occipital fasciculus, anterior thalamic radiation, right posterior corona radiata, middle cerebellar peduncle, and right superior longitudinal fasciculus; increased fractional anisotropy was detectable in inferior sections of the cortico-pontine circuit; and the authors suggest that their findings indicate extended cortical-subcortical changes in white matter integrity in schizophrenia and that their results corroborate earlier work that demonstrated white matter structural deficits in mainly long-ranging association fibres. Pérez-Iglesias *et al.* (2010b) employed DTI and neurocognitive assessment in first-episode schizophrenia patients and found that executive and motor deficits were associated with reduced white matter integrity in the main bundles connecting frontal and temporal cortices and in cortico-subcortical pathways. Because the illness was at an early stage and because medication received was minimal Pérez-Iglesias *et al.* (2010b) felt that such findings were not due to chronicity or treatment. Honea *et al.* (2005) performed a meta-analysis of voxel-based morphometry studies (15 studies, 390 schizophrenic patients, 364 healthy volunteers) and found that the most consistent differences were relative deficits in the left superior temporal gyrus (see Kuroki *et al.*, 2006) and the left medial temporal lobe. Takahashi *et al.* (2009a) used longitudinal MRI (baseline and mean of 1.8 years later) in very high risk people, first episode psychosis cases, and community recruits. Their results suggest progressive gray matter reductions of the superior temporal gyrus during transition to psychosis. However, Takahashi *et al.* (2010), while finding smaller superior temporal gyri on MRI in those at risk of psychosis, found no difference between those who did and those who did not eventually become psychotic.

Various tasks have been used to test brain function. Using the Wisconsin Card Sorting Test (WCST) to activate prefrontal areas, most (e.g. Weinberger *et al.*, 1992) but certainly not all authors have found diminished blood flow in these areas while the task is being performed ('hypofrontality'¹⁰⁶³). The normal reaction to the WCST is an increased blood flow to the DLPFC. According to Molina *et al.* (2005) hypofrontality is easily missed if the patient is assessed whilst at rest and is best performed during an

¹⁰⁵⁹ Sullivan *et al.* (2003) found that atypical, but not typical, drugs were associated with bilateral thalamic volume deficits on MRI. Typical neuroleptics have been associated with larger caudate nuclei, reversing with a switch to atypical drugs. (Jernigan, 2003, p. 57) Lieberman *et al.* (2005) reported that haloperidol, but not olanzapine, were associated with a decrease in grey matter volume in first-episode psychosis.

¹⁰⁶⁰ Sullivan *et al.* (2003) found that comorbid alcohol dependence was associated with pontine deficits. Alcohol dependence on its own was associated with volume deficits in thalamus and pons.

¹⁰⁶¹ Including age of onset.

¹⁰⁶² The occipital radiation of the corpus callosum.

¹⁰⁶³ This has also been described in depressives.

attention task, e.g. in first-episode schizophrenia sufferers. However, Hill *et al.* (2004) in their meta-analytic study found no hypofrontality in first-episode/illness-duration-under-2 years cases but that it became more evident in studies looking at mixed acute and chronic subjects and even more so in chronic patients. Ablation of prefrontal cortex and destruction of dopaminergic (mesocortical) input to the same area produce similar behavioural deficits in animals, and D-amphetamine, an indirect DA agonist, partially alleviates impaired ability to activate prefrontal cortex in patients suffering from schizophrenia. (Liddle, 2001, p. 29) Kellendonk *et al.* (2006) showed that mice that are genetically modified to over-express D2 receptors in the striatum developed problems in working memory and behavioural flexibility.

'Disordered functional connectivity' is a modern term that suggests a possible disruption of interaction between frontal and temporal regions of the brain. Liddle (2001, p. 196) summarised functional imaging studies in schizophrenia and found that, in general and under diverse circumstances, there was a failure to activate the frontal cortex despite adequate engagement in a task; however, during certain tasks (such as paced word generation) the patient can activate the prefrontal cortex (PFC), but there is abnormal co-ordination between PFC and other parts of the brain. Failure to activate the PFC during the WCST appears to be related to low HVA levels in the CSF, suggesting a role for dopaminergic underactivity. (Weinberger *et al.*, 1988) Increased plasma HVA levels during a metabolic stress condition in schizophrenic subjects was interpreted by Marcelis *et al.* (2004) as reflecting an illness-related effect rather than an inherited phenomenon. Blakemore (2002) discussed the evidence for a temporo-frontal disconnection or a dysfunctional cortico-cerebellar circuit in schizophrenia and concluded that whilst the evidence is largely indirect there may be a basis in reality for such findings. Meyer-Lindenberg *et al.* (2005) found evidence for altered hippocampal formation-dorsolateral prefrontal cortex connectivity during working memory activation in schizophrenia. Achim and Lepage (2005) conducted a meta-analysis of 18 studies and found that schizophrenia is associated with abnormal patterns of brain activation during both encoding and retrieval of memories; the prefrontal cortex and hippocampus, amongst other regions, are implicated in the abnormal memory functions. Another meta-analysis (Ragland *et al.*, 2009) found prefrontal activation deficits during episodic encoding and retrieval in patients with schizophrenia. In a meta-analysis of 41 functional neuroimaging studies of executive function in schizophrenia published before February 2007 (Minzenberg *et al.*, 2009) found that healthy adults and schizophrenic patients activate similar networks (DLPFC and anterior cingulate cortex [ACC]) but that patients show changed activity with deficits in DLPFC, ACC, and mediodorsal thalamic nucleus; increases in activity in other PFC areas may be attempts to compensate for deficits.

Using diffusion tensor imaging (DTI: MRI), Burns *et al.* (2003) demonstrated reduced white matter tract integrity in the left uncinate and arcuate fasciculi in schizophrenia. Andreone *et al.* (2007) found microstructural disruption of white matter in frontal, temporal and occipital white matter. Skelly *et al.* (2008) reported diffuse deficits in a number of types of white matter tracts and an inverse relationship of DTI fractional anisotropy values with positive symptom scores in association fibres, interpreted as supporting a disconnection explanation for positive symptoms in schizophrenia. Widespread structural dysconnectivity, including the subcortical region, was found in neuroleptics-naïve, first-episode, Chinese schizophrenic patients using DTI. (Cheung *et al.*, 2008) Kubicki *et al.* (2008) used DTI and structural MRI in both schizophrenic subjects and controls and found a relative reduction of fractional anisotropy in those parts of the corpus callosum that connect both frontal regions. Friedman *et al.* (2008) used DTI cross-sectionally and found only trend-level lower (than controls) fractional anisotropy (affecting inferior longitudinal fasciculus) in first-episode schizophrenia whereas chronic cases had either significant or trend-level lower fractional anisotropy, suggesting progression. However, the authors admit that their findings will require to be tested by following such cases. Sussmann *et al.* (2009) used DTI and found the same white matter abnormalities¹⁰⁶⁴ in bipolar and schizophrenic patients compared to controls. Kanaan *et al.* (2009), in a relatively large study comprising 76 patients with schizophrenia and 76 matched controls, found widespread clusters of reduced fractional anisotropy affecting most major white matter tracts in patients and these were not associated with duration of illness or duration of treatment. In one study (Kyriakopoulos *et al.*, 2009), adolescent-onset schizophrenia was associated with decreases fractional anisotropy in parietal regions but adult-onset cases also had such decreases in frontal, temporal and cerebellar areas.

¹⁰⁶⁴ Reduced fractional anisotropy in anterior limb of internal capsule, anterior thalamic radiation, and in region of uncinate fasciculus.

Liddle and Pantelis (2003) reviewed brain imaging in schizophrenia and came to the following conclusions: diverse brain areas subtle volume decreases; abnormal gyrification suggests a neurodevelopmental defect but some studies suggest progressive changes; widespread functional (dynamic) dysfunction; abnormal increases and decreases in activities in various areas¹⁰⁶⁵; abnormal connectivity between areas¹⁰⁶⁶; and many inconsistencies in the literature. Therefore, they warn against interpreting individual studies uncritically.

A full listing of neuroimaging findings in schizophrenia (incl. MRS and magnetoencephalography) is beyond the scope of this book. CT scans are now rarely used for research in the area of schizophrenia.

Sample of (mainly recent) neuroimaging findings in schizophrenia

(DL) PFC = (dorsolateral) prefrontal cortex; scz = schizophrenia

Chua and McKenna (1995) reviewed CT, MRI, postmortem and functional imaging studies and concluded that the only well established abnormality in scz was a modest enlargement of the lateral ventricles, with considerable overlap with the normal population.

Lawrie and Abukmeil (1998) reviewed volumetric MRI studies. The 40 relevant studies revealed an overall decrease in whole brain by 3%, temporal lobe by 6% on left and 9.5% on right, and amygdala-hippocampal complex by 6.5% on left and 5.5% on right. There was increased size of the lateral ventricles (44% left, 36% right), being greatest in the body and occipital horns. Segmental studies suggested reduced grey matter and possibly increased white matter. Males had substantially reduced amygdala and hippocampus, with the largest reductions being in the parahippocampus (14% left, 9% right). Few studies gave figures for women only.

Nelson ea (1998) used meta-analysis of MRI studies and found that scz was associated with bilateral smaller (than controls) hippocampi and, probably, amygdala. A systematic review and meta-analysis of MRI studies in first-episode scz patients conducted by Steen ea (2006) whole brain and hippocampal volume are reduced and that ventricular volume is increased relative to healthy controls. Wright ea's (2000) meta-analysis of MRI publications confirmed bilateral reduction in volume of medial temporal lobe structures.

Zakzanis ea (2000) conducted a meta-analysis of CT, MRI, SPECT and PET studies of the temporal lobe in scz. Most cases were normal, a minority had reduced values, and some had increased function and structure rather than a deficit.

Sommer ea's (2001) meta-analysis concluded that overall there is reduced cerebral lateralisation in scz with reduced asymmetry of the planum temporale and the Sylvian fissure, but no reduction in asymmetry of the temporal horn.

Goldstein ea, (2002) in an MRI study, reported that the effects of scz on the brain appear to depend on sex, especially in the cortex (esp. frontomedial cortex, basal forebrain, cingulate and paracingulate gyri, and planum temporale); the normal asymmetry of the planum was disrupted in men and women with scz. In other words, factors producing sexual brain differences may modulate insults causing scz.

Neither duration of illness or MRI measures showed any significant relationship to treatment responsiveness in the paper by Robinson ea.(1999)

In a two-year follow-up MRI study in scz, Westmoreland ea (1999) found that the basal ganglia became bigger with typical neuroleptic use (see also Navari & Dazzan, 2009), but smaller with atypical drug use. This has been demonstrated by Scheepers ea (2001) for clozapine responders (but not for non-responders).

Reduction in volume of white matter near left fronto-occipital fasciculus on follow up of patients who developed (retrospectively) frank psychosis.(Walterfang ea, 2008)

Using a combination of PET (¹⁸F-fluorodeoxyglucose), MRI and a spatial attention test in never-medicated scz (8 m, 5 f, mean age 28.5 years) and normal volunteers, Lehrer ea (2005) found that the patients had diminished glucose metabolism in the medial dorsal nucleus, posterior thalamus, and prefrontal cortex, interpreted as reflecting deficits in interactions between frontal executive areas and thalamic sensory and association processes.

PET study found dopamine overactivity during scz prodrome (especially in associative striatum) that correlated with symptom severity and neurocognitive dysfunction.(Howes ea, 2009)

In a meta-analysis of 25 MRI studies, Boos ea (2007) found that first-degree relatives of scz patients (compared to normal controls) had smaller hippocampi, less grey matter, and larger third ventricles.

Unaffected relatives of patients with scz had significantly larger pituitary volumes on MRI compared to controls; the pituitary was even bigger in relatives of patients with familial scz; there was no significant difference between relatives of bipolar patients and controls; and, patients with scz had relatively large pituitary if receiving antipsychotic drugs that increase prolactin.(Mondelli ea, 2008)

MRI of first-episode and chronic scz (meta-analysis of 27 articles): both groups had grey matter reductions in thalamus, left uncus/amygdala region, insula bilaterally, and anterior cingulate; only in first-episode cases were there decreases in grey matter in both caudate heads; and decreases in cortical regions were more widespread in chronic cases.(Ellison-Wright ea, 2008)

MRI of first-episode, antipsychotic-naïve scz patients found volume loss in right superior and middle temporal gyri and right anterior cingulate gyrus; functional networks involving right superior and middle temporal gyri were associated with symptom severity.(Lui ea, 2009)

New episode psychosis (mostly scz) treated for 3-4 weeks with antipsychotic medication was associated with enlarged (by 10%) caudate nuclei bilaterally.(Chua ea, 2009)¹⁰⁶⁷

¹⁰⁶⁵ Frontal and medial temporal, basal ganglia, thalamic.

¹⁰⁶⁶ Possibly involving long myelinated axons as well as synapses and dendrites.

¹⁰⁶⁷ These were compared with first episode psychosis (again mainly schizophrenia). Note that in another study that first-episode cases had decreases in grey matter in both caudate heads.(Ellison-Wright ea, 2008)

Longitudinal MRI of 35 ultra-high risk for psychosis cases of whom 12 experienced psychosis (converters) by 12 months follow-up found significantly greater brain contraction (cortical volume loss) in right prefrontal region in converters.(Sun ea, 2009)

Patients with scz fail to activate and to deactivate anterior prefrontal/anterior cingulate cortex (part of 'default mode network' involved in maintain sense of 'self') on fMRI during performance of a working memory task.(Pomarol-Clotet ea, 2008)

Compared with controls, people with scz or schizoaffective disorder marked prefrontal and temporal cortical thinning (on MRI), regardless of age, and this is independent of medication.(Nesvåg ea, 2008)

Authors compared cortical thickness in normals, scz patients, and unaffected siblings with MRI and and calculated heritability: patients had widespred thinning (mainly frontal and temporal) but unaffected siblings did not differ significantly from normal controls, arguing against cortical thickness being an intermediate phenotype for scz.(Goldman ea, 2009)

Patients with scz had reduced grey matter volume on MRI in middle and inferior frontal gyri, the inferior frontal gyri volume also being reduced in unaffected siblings.(Harms ea, 2010)

Pajonk ea (2010) found that hippocampal volume (MRI) increased in scz patients and in healthy controls after 3 months of cycling (aerobic exercise) but not in a non-exercise group; short-term memory improved if hippocampal volume increased; the patients (but not controls) who hippocampi increased in size showed (MRS) an increase in hippocampal N-acetylaspartate to creatine ratio.

Cross-sectional comparison using fMRI of prodromal symptoms ('at-risk'), first-episode schizophreniform psychosis, and healthy volunteers during an overt verbal fluency task and an N-back working memory task: activation was intermediate in 'at-risk' group relative to the 2 other groups in inferior frontal and anterior cingulate cortex during verbal fluency task and in inferior frontal, dorsolateral prefrontal and parietal cortex during working memory task.(Broome ea, 2009)

Using fMRI (while listening to mixtures of urban noise, i.e white noise) and testing P50 evoked response to paired-click sensory gating task, outpatients with scz showed greater activation than controls of hippocampus, thalamus, and prefrontal cortex (PFC) and evoked responses correlated with haemodynamic responses in hippocampus and PFC; such findings suggest involvement of these areas in gating deficits.(Tregellas ea, 2009b)

Stroop test during fMRI in scz (and controls) showed significant attenuation of activity in anterior cingulate gyrus, left pre-/postcentral gyrus and left inferior frontal junction (LIFJ); at follow-up there was a significant increase in activation in LIFJ associated with reduction in positive symptoms, suggesting that LIFJ is important in development of positive symptoms.(Krabbendam ea, 2009)

Drug-naïve and drug-free scz patients and matched controls underwent fMRI to look at neural responses to feedback of successful and unsuccessful monetary gain or avoidance of loss; functional connectivity was assessed between medial prefrontal cortex (MPFC) and ventral striatum (VS), areas known to be activated by feedback of reward and loss; results suggested differential impairment and reduced connectivity between MPFC and VS.(Schlagenhauf ea, 2009)

Immediate contextual signals do not sufficiently bias the caudal lateral PFC activity needed to to select appropriate behavioural representation in patients with scz (MRI) and, to compensate, patients inefficiently use temporal episodic information through higher activation in rostral lateral PFC regions.(Barbalat ea, 2009)

Using fMRI and Hayling sentence completion test, Whalley ea (2009) found that unmedicated subjects at high genetic risk for scz developed activation increases in left middle temporal gyrus when they developed symptoms.

In a controlled PET (18 FDG) study involving facial emotion recognition, it was found that right-handed non-acute patients with scz showed left amygdala hyperactivation in both emotional and control tasks and the right amygdala showed no differential activation in any of the tasks: scz is associated with non-task specific amygdalar hyperactivation during a continuous emotional and non-emotional task compared to healthy controls.(Fernandez-Egea ea, 2009)

Non-psychotic offspring of patients with scz have relatively small caudate nuclei bilaterally.(Rajarethinam ea, 2007)

MRI study in first episode scz showed that cognitive deficits are related to brain volume abnormalities in inferior parts of DLPFC.(Minatogawa-Chang ea, 2009)

At baseline MRI, adolescent offspring of scz parents showed decreased gyral surface area in fronto-parietal lobes and increased sulcal curvature and parietal gyral cortical thinning compared to healthy subjects; after a year there were shrinkage of total surface area in bilateral frontal and occipital regions and preservation of cortical thickness whereas controls had preserved or increased surface area and cortical thinning; the findings led Prasad ea (2010) to suggest that they were observing a divergent neurodevelopment trajectory and they suggested that cortical surface measures may be more sensitive to genetic liability to scz compared to volume measures.

In a controlled fMRI study of scz, Henseler ea (2009) looked at 3 brain systems underlying maintenance-related subprocesses of working memory: patients showed less activation of fronto-opercular, intraparietal and anterior cingulate cortex during non-articulatory maintenance of phonological information as well as attenuated hippocampal deactivation, and prefrontal activation depended critically on current symptom status; during visuospatial maintenance patients had impaired activation of superior parietal, temporal and occipital cortex, and increased activation of frontal eye fields and inferior parietal cortex; and activation was normal during articulatory rehearsal task.

Low IQ subjects at increased risk for scz differed on MRI from low IQ subjects without this risk – reduced amygdala volume in the former may be associated with negative symptoms.(Welch ea, 2010)

Ultra-high risk (UHR) subjects who transition to psychosis (UHR-P) had reduced fractional anisotropy (FA) bilaterally in medial frontal lobes and, compared to those not becoming psychotic (UHR-NP), had lower FA lateral to right putamen and in left superior temporal lobe and they increased FA in left medial temporal lobe; among UHR-P positive PANSS negatively correlated to FA in left middle temporal lobe; among all UHR positive PANSS negatively correlated to FA in right superior temporal lobe.(Bloemen ea, 2010)

Using an affective face recognition paradigm and fMRI Satterthwaite ea (2010) found that patients with scz performed slowly; comparison subjects recruited expected cortical areas more than did patients, and more severely symptomatic patients showed relatively diminished recruitment; increased symptoms correlated with excess amygdala and orbitofrontal cortex response to threatening faces; and comparison subjects showed a negative relationship between amygdala and cortical areas involved in cognition, while patients exhibited weakening of this relationship: i.e. the limbic system is over responsive and the cortical facial recognition memory response is decreased.

Patients with auditory hallucinations (AH) have reduced interhemispheric connectivity in both primary and secondary auditory cortices on fMRI compared to both non-AH patients and healthy controls whilst passively listening to words.(Gavrilescu ea, 2010)

Prata ea (2009) examined the effect of a polymorphism in the dopamine transporter gene (variable number of tandem repeats in 3' untranslated region) on brain function in scz patients and healthy comparison subjects: variations in the dopamine transporter gene normally modulates insular, cingulate and striatal function but its effect on activation in DLPFC is altered in scz.

PET after pharmacological depletion in untreated scz patients and healthy controls showed a larger increase in associative striatum D2 receptor availability in the former group (suggesting increased synaptic dopamine concentration), especially in pre-commissural dorsal caudate, and no differences were found between the two groups in the limbic and sensorimotor striatum: absence of group differences in limbic striatum questions the therapeutic importance of mesolimbic selectivity of 'atypical' antipsychotics.(Kegeles ea, 2010)

PET and fMRI and working memory task in outpatients with prodromal signs of psychosis showed direct correlations between altered PFC function and subcortical DA synthesis capacity.(Fusar-Poli ea, 2010)

MRS studies (see O'Shea, 1997 for an introduction) reported reduced levels of membrane phospholipids at all stages of scz and increased breakdown products of membrane phospholipids in the early drug naïve patient; a reduction in signal intensity in the hippocampal region and the DLPFC; increased glutamine levels in medial prefrontal cortex in neuroleptic-naïve patients, probably due to diminished glutamatergic activity locally; a gross deficit in cortical grey matter; both early- and adult-onset scz patients have less than normal regional N-acetylaspartate (NAA) relative signals, suggesting neuronal damage or malfunction in the hippocampi and DLPFC; first episode drug-naïve Japanese scz sufferers had disturbed membrane phospholipid metabolism in both temporal lobes and reduced energy demands in the left temporal lobe; DS patients have lower ratios of NAA to creatinine plus phosphocreatine than healthy controls of non-deficit cases, suggesting neuronal loss in medial prefrontal cortex in deficit cases; decreased NAA in both (medio-dorsal) thalami in male scz patients but not in healthy males; first degree relatives of scz sufferers compared to controls had greater phospholipid breakdown, even in youth; lower prefrontal NAA predicted more severe negative symptoms; and mainly left-sided NAA reduction in scz. Jensen ea (2002), using a small sample of chronic, medicated patients, confirmed altered membrane phospholipid metabolism in all regions implicated in scz. Bustillo ea (2002) found high choline levels in the caudate nucleus in scz that could not be due to medication.

Flycht ea (2001) looked at *skin fibroblasts* and tyrosine transport across cell membranes in first-episode and chronic scz: lower maximal transport capacity (Vmax) and affinity of tyrosine binding sites (Km) were compatible with a cell membrane disturbance; and, as changes were transmitted through several cell generations of cultured fibroblasts, it was interpreted as a genetic trait.

Patients with scz showed deficits in hippocampal activation during a memory task compared to bipolar patients (Hall ea, 2010) and there were differences in PFC activation between the two diagnostic groups.

Water intoxication: Many psychotic patients, especially those with schizophrenia, drink excessive fluids. This might possibly be based either on delusional beliefs or on an inappropriate ADH secretion (SIADH). Polydipsic chronic schizophrenics may have less suppression of cortisol in the DST test, although depressed schizophrenics may have a particularly low rate of non-suppression of cortisol in response to dexamethasone.(Q.V.) Perhaps hypothalamic dysfunction causes both polydipsia and cortisol dysregulation. Water intoxication can be fatal and primary polydipsia (no medical cause) in psychiatric patients foreshortens life.(Hawken ea, 2009). The early features of the condition are headache, blurred vision, polyuria, vomiting, tremor, and a worsening of the psychosis. More severe manifestations are muscle cramps, ataxia, delirium, stupor, coma and convulsions. Various treatments have been advocated, such as frusemide, urea, or water restriction. Incidentally, there is a report of an exaggerated ACTH response to acute metabolic stress exposure in the form of 2-deoxy-D-glucose in schizophrenia.(Elman ea, 1998)

Transmethylation hypothesis: This old theory holds that schizophrenia may be due to an excess of methylated biogenic amines. DMT (dimethyltryptamine), for example, was used on Haiti to induce mystical states. It is taken as a snuff. DMT by injection causes a transient schizophrenia-like psychosis. Mescaline is a methylated substance chemically related to dopamine and noradrenaline (NA). Its effects do not closely resemble schizophrenia. LSD is a methylated derivative of indoleamine. Methionine, a methyl donor, appears to exacerbate schizophrenic symptoms. It is possible that all one is seeing here is a toxic state superimposed on chronic schizophrenia.

Many, but not all, reports suggest low values for *platelet MAO* in schizophrenia. This finding has been reported in other psychiatric disorders, and neuroleptic drugs can produce this effect. Should the findings be relevant, they could have relevance for the transmethylation and dopamine hypotheses. Less MAO could result in excess monoamines or their abnormal metabolites becoming available.

Carbonyl stress¹⁰⁶⁸: Glycoxalase 1 (involved in detoxification of reactive carbonyl compounds) deficits and carbonyl stress may have a role in the pathogenesis of some cases of schizophrenia.(Arai ea, 2010)

Dopamine¹⁰⁶⁹: The dopamine hypothesis has been reviewed by O'Shea (1997) and Moncrieff¹⁰⁷⁰ (2009). Typical antipsychotics all block D2 receptors. The alpha isomer of flupenthixol blocks dopamine receptors

¹⁰⁶⁸ Accumulation of advanced glycation products (e.g. pentosidine) follow carbonyl stress, a situation involving an increase in reactive carbonyl compounds and their attendant protein modifications; vitamin B6 detoxifies reactive carbonyl compounds. A carbonyl group consists of a carbon atom double-bonded to an oxygen atom: C=O.

(equally blocks both D1 and D2) and is therapeutic in schizophrenia; the beta isomer does not block dopamine receptors and has no such therapeutic value. (Johnstone *et al.*, 1978) Selective/preferential D2 antagonism (e.g. sulpiride, haloperidol) work as well as non-selective agents¹⁰⁷¹. (Seeman, 1980) However, the degree of DA receptor blockade as assessed by PET does not distinguish neuroleptic responders from non-responders. Connell, in 1958, described amphetamine psychosis, a condition thought to resemble paranoid schizophrenia. However, amphetamine psychosis is characterised by over-responsiveness rather than emotional blunting, thought disorder is rare, and tactile and olfactory hallucinations are more common than in schizophrenia. In one study of healthy individuals, (Krystal *et al.*, 2005) ketamine and amphetamine produced positive symptoms and euphoria, but perceptual changes¹⁰⁷² were caused only by ketamine whereas only amphetamine caused hostility, grandiosity, and somatic concern; both drugs produced conceptual disorganisation but only ketamine induced concrete thinking and strange mannerisms. A reduction in circulating plasma levels of homovanillic acid¹⁰⁷³ over a period of weeks that correlates with clinical response to antipsychotic drugs can be interpreted as being in favour of a role for dopamine in schizophrenia in particular, psychosis in general, or simply as something that these drugs do. Increased interleukin-2 (which increases DA neurotransmission) in the CSF of neuroleptic-free schizophrenics, has been reported. Amphetamines also exacerbate true schizophrenia, even if the patient is compliant with his medication. (Curran *et al.*, 2004) Amphetamine challenge leads to greater release of DA in schizophrenic patients than in healthy controls. (Laruelle *et al.*, 1999) This may represent a mechanism whereby stress leads to excess DA release in schizophrenia. (Stefan *et al.*, 2002, p. 61) PET and SPECT studies have not consistently demonstrated increased numbers of D2 receptors in drug-naïve schizophrenia. Also, efforts to link schizophrenia with the D2 dopamine receptor gene region of chromosome 11 have mostly failed. The same applies to the D3 receptor gene. Seeman *et al.* (1993) found the D4 receptor increased in schizophrenic's brains. Nevertheless, SPECT and PET studies suggest that D2 receptors may be overactive in some cases of schizophrenia, particularly during periods of psychosis, and such cases may be more likely to respond best to antipsychotic drugs. Hirvonen *et al.* (2005) based on twin studies, have suggested that D2 receptor upregulation in the caudate is related to genetic risk for schizophrenia.

Methamphetamine users who become psychotic tend to have a familial tendency to develop schizophrenia and are more likely to have schizotypal features during childhood; also, these two factors determine duration of psychosis. (Chen *et al.*, 2003)

One modern reformulation of the dopamine hypothesis reads as follows: negative symptoms are due to hypodopaminergic activity in the mesocortical system, and positive symptoms are a consequence of hyperdopaminergic activity in the mesolimbic system¹⁰⁷⁴. It has been suggested that positive symptoms are 'release phenomena' in the Jacksonian sense. Put another way, there may be increased D2 and D4 activity in the limbic system and increased 5-HT₂ and reduced DA activity in the frontal area and all of these may be reversed by atypical neuroleptics.¹⁰⁷⁵ Animal work suggest that 5-HT₂ blockade could increase DA activity in the frontal cortex. (Kapur & Remington, 1996) Perhaps DA may exert its malign effects during

¹⁰⁶⁹ Dopamine is needed for many reasons, including attaching **salience** (and hence paying attention) to things, for reward (pleasure), and to prevent Parkinson's disease. Kapur (2003) suggested that mesolimbic DA gave meaning/salience to external stimuli and inner thoughts and that excess DA release in psychosis causes otherwise insignificant events to be imbued with great significance, e.g. a trivial remark by a radio announcer about the weather becomes a personal comment about the patient. According to Murray (2008) excess DA leads to aberrant assignment of salience (imbues events with significance) to external and internal stimuli: 'birds sing more loudly, flowers are of a deeper colour, I must be more important, strange things are afoot, a battle between Good and Evil is going on', etc. Excess DA (increased synthesis, release, or D2 receptor occupancy) leads to an increase in the positive symptoms of psychosis. Murray (2008) states that there is increased DA synthesis in the caudate and putamen of both prodromal cases of psychosis and in patients' relatives compared to controls.

¹⁰⁷⁰ Moncrieff (2009) is highly critical of the hypothesis: the results are contradictory; antipsychotics may reduce symptom severity simply by causing neurological suppression; post-mortem findings (DA and DA receptors, HVA) are negative or inconclusive; prior medication may influence some results; and confounding factors (e.g. movement, arousal, attention, stress, and smoking) are rarely studied.

¹⁰⁷¹ Block D1 and D2: e.g. flupenthixol, fluphenazine.

¹⁰⁷² Ketamine produced perceptual distortions but not hallucinations in another study of healthy volunteers. (Pomarol-Clotet *et al.*, 2006)

¹⁰⁷³ The major DA metabolite.

¹⁰⁷⁴ One version has it that reduced prefrontal DA, itself a product of preexisting prefrontal pathology, causes upregulation of subcortical DA activity leading to psychosis. Rodent prenatal lesion studies suggest that release of excess DA may be delayed until adulthood. (Laurelle, 2003, pp. 376 and 378)

¹⁰⁷⁵ It should be noted that haloperidol has a higher affinity for D4 receptors than does clozapine, and D4-selective drugs have not demonstrated antipsychotic activity.

adolescence by affecting the balance of excitatory and inhibitory inputs to cortical pyramidal cells or by influencing cortical information processing around the time of puberty.(Lewis, 1997)
One formulation of the DA hypothesis is illustrated in the box.

Dopamine and schizophrenia (VTA = ventral tegmental area)

Genes and/or prenatal insults to mesocortical pathway

↓

Decrease in DA in cortex, especially in frontal areas

↓

Loss of cortico-limbic glutaminergic transmission *and* loss of inhibitory feedback of VTA by cortex

↓

Loss of inhibition of mesolimbic system

↓

Increased mesolimbic DA transmission

Notes: It has been suggested that clozapine reduces negative symptoms by blocking 5-HT with a resulting increase in DA in the mesocortical system. Phencyclidine given to monkeys reduces DA turnover and clozapine then normalises dopaminergic turnover in the prefrontal cortex.(Elsworth ea, 2008)

The dopamine hypothesis fits less well for clozapine¹⁰⁷⁶ than for the older, ‘typical’ agents. Interestingly, amphetamine challenge has been noted to improve cognitive functioning in schizotypy without affecting other symptoms of psychosis.(Maier ea, 1999; O’Flynn ea, 2003, p. 92)

Overall, many linkage studies have been performed but there is no definite linkage between schizophrenia and any DA receptor.

It is commonly believed that antipsychotic drugs produce a delayed response in schizophrenic patients but it is probably truer to say that the response is a progressive one.(e.g. Agid ea, 2003)

Serotonin: The activity of 5-HT₂ cortical receptors decreases with age. The 5-HT partial agonist m-CPP exacerbates the positive symptoms of schizophrenia. Serotonin modifies DA release.

PCP induces symptoms resembling negative and positive schizophrenic symptoms¹⁰⁷⁷. The latter is accompanied by decreased dopaminergic terminal activity in the frontal cortex that can be normalised by giving 5-HT₂ antagonists. Therefore, 5-HT₂ antagonism indirectly activates midbrain dopaminergic activity and increased DA release in frontal cortex. Using a combination of 5-HT₂ and DA receptor antagonists causes selective enhancement in prefrontal cortex with resulting correction of the regional imbalance between cortical and midbrain dopaminergic mechanisms. 5-HT₂ antagonism may at least partly explain the beneficial effects of clozapine on negative symptoms¹⁰⁷⁸. The addition of an SSRI to an antipsychotic drug may improve negative symptoms and various mechanisms have been proposed as to how this might happen¹⁰⁷⁹.(Chertkow ea, 2009) Addition of the 5-HT_{1A} partial agonist to atypical antipsychotics in patients with schizophrenia or schizoaffective disorder led to no improvement in either cognition or symptoms¹⁰⁸⁰.(Piškulic ea, 2009)

Schizophrenics who never received neuroleptics or who did not receive them in the recent past show no difference from controls of similar age in 5-HT₂ receptor status on PET scanning.(Lewis ea, 1999)

Neuroleptic-naïve schizophrenics have reduced 5-HT_{2A} receptors in the parietal and frontal cortex on PET.(Ngan ea, 2000; Rasmussen ea, 2010)

Glutamate: According to Carlsson (1988), healthy mesolimbic glutaminergic neurones inhibit the mesolimbic dopaminergic pathways. PCP, a non-competitive inhibitor of NMDA receptor-mediated

¹⁰⁷⁶ Aripiprazole is a partial agonist at D₂ receptors.

¹⁰⁷⁷ Additionally, McCarron ea (1981) described a catatonia-like syndrome with PCP.

¹⁰⁷⁸ The blood-brain barrier may hold the key to the superiority of clozapine. **P-glycoprotein** (Pgp) is a drug efflux transporter. It binds most antipsychotic drugs as well as certain anti-cancer drugs and antibiotics. Oncologists know that inhibition of Pgp can reverse multi-drug resistance in malignant cells. Clozapine is relatively independent of transport by Pgp, which may at least partly explain its effectiveness in drug-resistant schizophrenia.(Loscher & Potschka, 2005)

¹⁰⁷⁹ I.e. 5-HT receptors, tyrosine hydroxylase, glutamate decarboxylase 67, protein kinase C beta, receptor for activated C-kinase 1 (Rack 1), various transcription and neuroprotective factors, calcium signalling, and cytokine receptors for IL-8 and chemokines. The present author was introduced to the augmentation of antipsychotic drugs with clomipramine for negative symptoms by the late Dr Aidan J McGennis at St Brendan’s Hospital, Dublin, in 1981!

¹⁰⁸⁰ This 6-week study of chronic patients might have been too short **or** intrinsic 5-HT_{1A} receptor activation by atypical drugs might have interfered with the effects of the putative augmenting agent.

transmission, may block this controlling effect. Ketamine, an NMDA receptor antagonist, may produce thought disorder similar to that found in schizophrenia when employed in subanaesthetic dosage. Drugs potentiating dopaminergic activity may induce or exacerbate schizophrenic activity.

Glutamate in schizophrenia

- Specific loss of mRNA that encodes for non-NMDA glutamate receptors reported in hippocampi of schizophrenic patients (Harrison ea, 1991) - authors suggested this might be due to reduced glutamate production
- Théberge ea (2007) looked at never-treated first-episode schizophrenic patients and found increased glutamate levels in anterior cingulate and thalamus; thalamic glutamate was significantly decreased after 30 months; some grey matter reductions seen at 10 months, becoming widespread at 30 months; parietal and temporal lobe grey matter loss correlated with loss of thalamic glutamate; authors speculate about neurodegeneration or plastic response to decreased subcortical activity
- In mice, a reduction in glutaminase¹⁰⁸¹ may have antipsychotic-like properties (Gaisler-Salomon ea, 2009)

Neuroleptics may increase glutamatergic activity. Complexins I and II are markers for inhibitory and excitatory neurones respectively. They are presynaptic proteins involved in the fusion of storage vesicles with cell membranes. There is early evidence of an excessive loss of complexin II in the medial temporal lobe in schizophrenia.(Harrison & Eastwood, 1998) D-cycloserine is a partial agonist at the glycine modulatory site of NMDA receptors and might improve negative symptoms in schizophrenia, as might the adjuvant use of glycine.(Heressco-Levy ea, 2002) These substances may have the opposite effect, an increase in negative symptoms, when added to clozapine! Hashimoto ea (2003), using high-performance liquid chromatography, found significantly lower serum levels of D-serine in schizophrenia than in controls. Neeman ea (2005) found plasma glycine levels and glycine-serine ratios were lower and homocysteine levels were higher in schizophrenia than in normals, low glycine levels correlating with more negative symptoms. Buchanan ea (2007)¹⁰⁸² found no significant difference between placebo and either glycine or D-cycloserine in terms of change in negative or cognitive symptoms of schizophrenia. Elevated maternal homocysteine levels in the third trimester increases risk for schizophrenia in offspring at least two-fold.(Brown ea, 2007) According to Lane ea,(2005) N-methylglycerine (sarcosine), a potent endogenous inhibitor of glycine transporter 1 (Gly T-1), added to stable antipsychotic drug regimens, may improve negative and cognitive symptoms of stable chronic schizophrenia; D-serine¹⁰⁸³ and sarcosine can improve positive symptoms in chronic schizophrenic cases on stable antipsychotic drug regimens; and sarcosine (more than D-serine) may also benefit acutely ill patients with schizophrenia when added to antipsychotic drug treatment.

LY2140023¹⁰⁸⁴ is a highly selective agonist at group II metabotropic glutamate receptors¹⁰⁸⁵ and no significant affinity for dopamine receptors. There is preliminary evidence that LY2140023 has antipsychotic activity.(Patil ea, 2007)

Hypoxia seems to render neurones susceptible to glutamate-induced damage. Early damage of this sort might cause schizophrenia in adolescence or later when abnormal circuitry comes under increased cortical control with resultant increased dopamine activity. Alternatively, the original hypoxia/glutamate insult reduces NMDA receptor availability with diminished inhibitory modulation via glutamate-dependent GABA activity, causing over stimulation of certain brain pathways.

Gao ea (2000), using in situ hybridisation, reported a decrease in the NR1 subtype of the NMDA receptor in the hippocampus. There is no evidence of an association between schizophrenia and the 2664C/T polymorphism of the NR2B subunit (of NMDA) gene. According to Owen ea,(2005) the genes likely to be

¹⁰⁸¹ Synaptic glutamate is chiefly taken up by the surrounding astrocytes and converted into glutamine by glutamine synthetase. The glutamine is then taken up by neurones and converted back into glutamate by **glutaminase**. Glutaminase-deficient mice display parahippocampal hypoactivity, insensitivity to pro-psychotic drugs and potentiated latent inhibition.

¹⁰⁸² This was a 16-week multi-site, double blind, double-dummy, parallel group, randomised trial of adjunctive glycine, D-cycloserine, or placebo.

¹⁰⁸³ Full agonists at glycine site of NMDA receptor include D-serine, D-cycloserine being a partial agonist.

¹⁰⁸⁴ A pro-drug that is metabolised to the active compound (but low bioavailable) LY404039.

¹⁰⁸⁵ Made up of mGluR2 and mGluR3.

involved in schizophrenia code for proteins that may impact, in one way or another, on glutamate receptor function: dysbindin-1, neuregulin-1, D-amino acid oxidase and its activator DAOA, and regulator of G protein signalling 4. It is possible that changes in cortical glutamatergic transmission lead to dopaminergic changes as a secondary phenomenon, but, as the authors admit, the truth is often more complicated than any simple theory. Neuregulin-1 (at chromosome 8p) is highly expressed in brain and signals through tyrosine kinase receptors, thereby being involved in neurodevelopment. Neuregulin-1¹⁰⁸⁶ seems to play a role in influencing susceptibility to schizophrenia and bipolar disorder,(Green ea, 2005) although not all studies are positive.(Duan ea, 2005) There may be an association of neuregulin-1 with schizotypal personality.(Lin ea, 2005)

The resemblance of phencyclidine psychosis to schizophrenia has been questioned.(O'Shea, 2000b)
GABA: Akbarian ea (1995) found a pronounced reduction in glutamic acid decarboxylase (a key enzyme in GABA synthesis) mRNA levels in schizophrenic prefrontal cortex (PFC) in the absence of significant cell loss. Others have confirmed this finding. It did not seem to be a treatment effect. Maldonado-Avilés ea (2009) found lower levels of mRNA for the delta subunit¹⁰⁸⁷ of the GABA-A receptor in the dorsolateral prefrontal cortex in schizophrenia and suggested that this may contribute to deficient tonic inhibition and prefrontal cortical dysfunction. The density of chandelier neurone axon terminals¹⁰⁸⁸ immunoreactive for the GABA membrane transporter (GAT-1) is reduced in most patients with schizophrenia. There may be down-regulation of glycoproteins secreted preferentially by cortical GABAergic prefrontal neurones in schizophrenia and psychotic bipolar affective disorder. Treatment of chronic schizophrenia with MK-0777¹⁰⁸⁹, a benzodiazepine-like drug undergoing trials for the treatment of anxiety showed some promise in alleviating cognitive deficits.(Lewis ea, 2008)

The reader is referred to the hippocampal glutamic acid decarboxylase (GAD) mRNA study of Heckers ea.(2002)

*Acetylcholine*¹⁰⁹⁰: Acetylcholine is important in cognition. Lieberman ea (2008) point out that muscarinic and nicotinic receptor numbers may be reduced in schizophrenia, that a functional polymorphism of the alpha-7 nicotinic receptor has been linked to this condition, that acetylcholine modulates striatal and cortical dopamine, that people with schizophrenia smoke heavily, and that clozapine's muscarinic receptor agonism may be important for its effects on positive and negative symptoms. Xanomeline is an M1 and M4 agonist and M5 antagonist but it also has other agonist (5-HT_{1A} and 1_B) and antagonist (5HT₂) properties. It may have a role in improving verbal learning and short term memory in schizophrenia.(Shekhar ea, 2008) DMXB-A is a cholinergic nicotinic partial agonist for the alpha-7 receptor that may improve negative symptoms.(Freedman ea, 2008)

*Free radicals*¹⁰⁹¹: Enzymes such as superoxide dismutase and other substances¹⁰⁹² defend against oxidative injury. Caloric restriction reduces injury from oxygen free radicals. Starvation, heavy cigarette smoking, and excess alcohol consumption all increase oxidative tone with the production of oxyradicals. Studies suggest that oxidative injury may be present at the start of non-affective psychosis, whether or not the patient has received antipsychotic drugs. Vitamins E and C supplements and fats from fish or vegetables rather than from animals or birds may be of some protection.(Mukherjee & Mahadik, 1997) However, there is some animal work suggesting that nicotine may be neuroprotective (Belluardo ea, 2000) and Zammit ea,(2003b) looking at Swedish conscripts, found that cigarette smoking at ages 18-20 was associated with a lower rate of developing schizophrenia!¹⁰⁹³

¹⁰⁸⁶ With its gene on 8p12. Dysbindin (6p) may play a similar role.(Breen ea, 2006)

¹⁰⁸⁷ This was unrelated to medication use, whereas alpha-4 levels were related to medication at time of death.

¹⁰⁸⁸ Called cartridges: these distinctive arrays of axon terminals provide inhibitory input to the initial axonal segment of pyramidal cells.

¹⁰⁸⁹ MK-0777 has selective activity at GABA-A receptors containing alpha-2 or alpha-3 subunits.

¹⁰⁹⁰ See also smoking.

¹⁰⁹¹ These are chemical species with an unpaired electron in one of their orbits. The most toxic is the hydroxyl ion.

¹⁰⁹² Examples are urate, glutathione, vitamins E and C, β-carotene, and quinones. Glutathione is important in the phospholipid pathway and there has been some benefit from giving the glutathione precursor **N-acetyl-cysteine** adjunctively to people with schizophrenia.(Berk ea, 2008) N-acetyl-cysteine is the specific antidote for paracetamol: a toxic breakdown product of paracetamol is scavenged by glutathione and when the body runs out of glutathione, as in common in the alcoholic, the paracetamol metabolite attaches itself to liver cells and kills them.

¹⁰⁹³ However, this study only had data on exposure and confounders for one point in time, i.e. commencement or cessation of smoking after conscription was not controlled for.

Heat shock proteins: Heat shock proteins may be involved in various neuroprotective mechanisms. There is some evidence that antibodies to these proteins are increased in schizophrenia. (Schwarz ea, 1999)

Viruses: Are patients with schizophrenia genetically predisposed to infection? Do the peaks of schizophrenic births in winter and early summer increase the likelihood of an infectious aetiology? In a 25-year-long Russian study of a block of flats, using uncertain diagnostic criteria, there did appear to be some evidence for a 'spread' of schizophrenia! Viruses may alter cell function without killing the cell.

*Viruses and other infectious agents*¹⁰⁹⁴

Leask ea (2002) - data from UK National Child Development Study – unable to implicate common childhood viral illnesses in aetiology of adult psychotic illness.

Against horizontal transmission of schizophrenia: Cooper ea (1987) - no greater an incidence of schizophrenia in psychiatric nurses 1955-1979 than in general nurses during same period

Mednick ea (1987) - rates of schizophrenia in young adults exposed during foetal life to influenza epidemic in Helsinki in 1957 - those exposed during *second trimesters* had increased risk of later schizophrenia

Similar findings reported in the northern and southern hemispheres in some (e.g. Sham ea, 1992) but not all (e.g. Crow & Done, 1992) studies (see O'Shea, 1997)

Interferon levels failed to distinguish between FES and healthy controls (Becker ea, 1990)

Brown ea (2004): significant association between maternal interleukin-8 level during second trimester and risk of schizophrenia spectrum disorders in offspring.

Brown ea (2004): used archived maternal serum assayed for influenza antibody in pregnancies - risk of schizophrenia in offspring 7-fold for exposure during *first trimester*, with no increased risk for exposure at other pregnancy stages

Brown AS ea (2000): rubella exposure during first trimester may be a factor in some non-affective psychoses

O'Callaghan (2001): other suggested viruses that might have a role in schizophrenia include Borna disease virus, the cause of 'crazy disease' (equine encephalitis) and retroviruses

Rasmussen ea (2006): a common non-functional allele of the CCR5 gene with deletion of 32-bp segment in open reading frame confers resistance to infections with macrophage-infecting strains of HIV, and there is some evidence that this deletion may be a susceptibility factor in late-onset schizophrenia

Dickerson ea (2003a): serological evidence of herpes simplex type 1 infection independently predicted cognitive dysfunction in people with schizophrenia

Jablensky (2003, p. 219) - arguing that having older siblings increases risk of developing schizophrenia may be explained in many ways, e.g. children bringing viruses into the home, sample/statistical artefact, or a birth order effect - PCR has not revealed viral nucleic acids to suggest a persistent or latent viral infection - retrospective recall correlates extremely poorly with serology

Dickerson ea (2003b): valacyclovir¹⁰⁹⁵ 1 G twice daily significantly improved scores on the Positive and Negative Syndrome Scale in outpatients with persistent schizophrenia and who were seropositive for cytomegalovirus (21 or 32.3% of the sample were seropositive for cytomegalovirus – interestingly, the drug didn't affect scores in herpes simplex type 1-seropositive patients[see Dickerson ea, 2003a above] or in patients seropositive for herpes simplex type 2¹⁰⁹⁶, Epstein-Barr, varicella-zoster, or human herpes virus 6)

Fatemi ea (1999): infection of mice with human influenza virus on day nine of pregnancy leads to thinner neocortex and hippocampus and reduced cortical reelin¹⁰⁹⁷ immunoreactivity in offspring

Brown ea (2005): high, but not moderate, maternal Toxoplasma IgG antibody titres associated with risk for schizophrenia spectrum disorders in offspring in US study

Babulas ea (2006): used obstetric records and found significantly increased risk of schizophrenia and other schizophrenia spectrum disorders in offspring of mothers who had genital infections periconceptually

¹⁰⁹⁴ For a review see Brown and Derkits.(2010)

¹⁰⁹⁵ Valacyclovir is rapidly converted to acyclovir after ingestion.

¹⁰⁹⁶ Brown ea (2006) found no support for a relationship between prenatal herpes simplex virus 2 type exposure and risk of schizophrenia.

¹⁰⁹⁷ Reelin: extracellular matrix glycoprotein secreted by GABA interneurons during development and in adults; probably involved in synaptic plasticity/morphological changes involved in learning.

Dalman ea (2008): follow up of Swedes found a *slight* increase in non-affective psychosis and schizophrenia in those with a history of CNS viral (but not bacterial) infection during childhood (especially mumps or cytomegalovirus)

Brown (2008) reviewed the literature on infection and schizophrenia and pointed out the difficulty of timing infection (e.g. T gondii¹⁰⁹⁸), the likely interaction of susceptibility (genes, development) and microorganisms, and the need for more rigorous research design (e.g. increasing statistical power)

Sørensen ea (2008): looked for maternal infections in Denmark; used broad and narrow definitions of schizophrenia; first trimester exposure was associated with increased risk for broad and narrow schizophrenia whereas second trimester exposure was associated with increased risk for schizophrenia but only in unadjusted analyses; the findings were especially strong for narrow (ICD-8) schizophrenia with earlier onset; post-hoc analysis found that upper respiratory infection and infection with gonococci were associated increased risk for schizophrenia; and the authors surmised that the effects of infection are mediated by transplacental passage of maternal cytokines in response to bacterial infection

Brown ea (2009): adult schizophrenia exposed (serologically documented) in utero to influenza and toxoplasmosis had impaired performance on WCST and Trail Making Test part B (Trails B) compared to those not so exposed

Hospital treated pyelonephritis in Finland may add to the effects of genes in increasing risk for schizophrenia in offspring (Clarke ea, 2009)

If viruses cause schizophrenic illnesses they probably only account for a minority of cases. (O'Shea, 1997; Westergaard ea, 1999) Also, influenza exposure¹⁰⁹⁹ in utero has been linked to later affective disorder in the Finnish population. (Machon ea, 1997)

Krause ea (2010) measured antibody titres to CMV, herpes simplex virus, Epstein-Barr virus, mycoplasma, Chlamydia, and toxoplasmosis in 31 patients with schizophrenia and 30 healthy matched control subjects.

There was a significant increase in positive antibody titres in patients with schizophrenia only for Chlamydia trachomatis ($p = 0.005$) and a trend to significance for Herpes simplex virus ($p = 0.055$).

Combining the different agents, patients with schizophrenia had a significantly higher rate of positive titres to infectious agents as compared to controls ($p = 0.04$). The authors suggest that schizophrenia is not caused by a specific infectious agent but is due rather to an immune reaction in the CNS.

There appears to be a shift from Type I (cellular) to Type II (humoral) immune response in schizophrenia.

Evidence for impaired Type I response comes from a small study (Freudenreich ea, 2010) where IFN- γ and TNF- α expression was relatively reduced in schizophrenia.

Secondary schizophrenia-like disorders

Some conditions that may be associated with a schizophrenia-like illness¹¹⁰⁰

Paralysis agitans¹¹⁰¹

Encephalitis lethargica and other forms of encephalitis

Cerebral syphilis

Sydenham's chorea

Temporal lobe epilepsy¹¹⁰²

Brain injury

Brain tumour¹¹⁰³

Wilson's disease¹¹⁰⁴

¹⁰⁹⁸ Niebuhr ea (2008) found a significant positive association between T gondii IgG antibody schizophrenia in discharged US military personnel.

¹⁰⁹⁹ 1957 epidemic.

¹¹⁰⁰ An ICD-10 disorder, not to be confused with DSM-IV schizophreniform disorder; syn. symptomatic schizophrenia. The symptoms of 'schizophrenia' in cases with organic brain disease are often of a paranoid-hallucinatory type, with retention of rapport and warmth, and a more benign course than that associated with 'true' schizophrenia. (McKenna, 2007, p. 383)

¹¹⁰¹ Some authors found a lower than expected incidence in Parkinson's disease.

¹¹⁰² 15% after 15 years of TLE.

¹¹⁰³ Cerebral gliomas, pituitary adenomas.

¹¹⁰⁴ Rare autosomal recessive (ATP7B gene on chromosome 13) disorder of copper metabolism. (Ala ea, 2007) McKenna (2007, p. 383) concluded that the frequency of something resembling schizophrenia in Wilson's disease was likely to be low.

Huntington's disease
 Narcolepsy¹¹⁰⁵
 Cerebrovascular disease
 Frontotemporal dementia¹¹⁰⁶
 Familial idiopathic basal ganglia calcification¹¹⁰⁷
 Demyelinating disorders¹¹⁰⁸

Some drugs that can precipitate paranoid-hallucinatory psychoses

Anticholinergics
 Bromocriptine
 L-dopa
 Psychostimulants like amphetamine
 Hallucinogens like LSD and PCP
 ACTH and steroids
 Disulfiram¹¹⁰⁹
 Indomethacin
 Digoxin
 Anti-malarials
 Anti-tuberculosis drugs
 Vigabatrin¹¹¹⁰

The hypotheses of a shared genetic basis between some cases of schizophrenia and coeliac disease and an abnormal intestinal permeability in some schizophrenics that might allow the passage of exorphins leading to behavioural problems is intriguing. (Dohan, 1966; Eaton ea, 2004) Does gluten precipitate schizophrenia in a minority of cases? One female with schizotypy known to the author has harassed many physicians, despite negative testing, in an effort to prove that her schizophrenic son has coeliac disease. A genetic marker (6p23-p22.3) in coeliac disease is very close to the dysbindin locus, which has been implicated in schizophrenia. (Straub ea, 1995)

Clinical features

'If one cannot hold information online or select what is relevant for task performance, then serious disruption in mental processes is likely to ensue.' (Banich, 2002)

(a) Premorbid findings

[1] This work is still at too early a stage to allow accurate prediction in individual cases.¹¹¹¹ Substance abuse is a confounder in such research and needs to be controlled for. A 1946 British birth cohort was followed up. Sitting, standing, walking and talking were delayed at 2 years. (Wadsworth, 1991) Foerster ea (1991) found that schizophrenic males had greater premorbid impairment than schizophrenic women or men with mood disorder. Poor premorbid adjustment predicted early age at first admission. Videos of schizophrenic patients taken during childhood have been interpreted as showing an excess of negative affect (Walker ea, 1993) or differences on measures of sociability and general neuromotor function from controls. (Schiffman ea, 2004) Perrin ea (2007) looked prospectively at a birth cohort of individuals with

¹¹⁰⁵ Must outrule effects of amphetamines. (Hyde & Lewis, 2003, p. 190) Amphetamine-induced psychosis in narcoleptics may require a change to modafinil.

¹¹⁰⁶ See Velakoulis ea (2009) and Schoder ea (2010). The two conditions share some symptoms (e.g. emotional blunting) but differ for others (e.g. delusions are rare in frontotemporal dementia). The risk for schizophrenia is increased in the close relatives of patients with frontotemporal dementia.

¹¹⁰⁷ Fahr's disease: an autosomal dominant condition.

¹¹⁰⁸ Is schizophrenia a disorder of myelin and oligodendroglia? (Davis ea, 2003) Microarray studies report downregulation of genes related to oligodendrocyte function and myelination in schizophrenic brain. (Peirce ea, 2006)

¹¹⁰⁹ Inhibits dopamine-beta-hydroxylase, increasing DA availability: may exacerbate schizophrenia, especially at > 250 mg/day.

¹¹¹⁰ Sabril, a GABA transaminase inhibitor.

¹¹¹¹ See *Dialogues in Clinical Neuroscience* 2005;7(1). The complete issue is dedicated to the early stages of schizophrenia.

and without schizophrenia spectrum disorder and found slower early, but not late, growth in females but not males who developed the disorder. In a study using both twins and siblings, Picchioni *et al.* (2010) found that schizophrenia was significantly associated with deficits in social adjustment and personality during childhood and adolescence and additive genetic effects best explained these phenotypic correlations. Johnstone *et al.* (2005) examined high risk young adults with a strong family history of schizophrenia and found that those who later developed schizophrenia were socially anxious, withdrawn, and had other schizotypal features. Jones *et al.* (1994) prospectively studied over 5,000 people born in one week in 1946. Thirty cases of schizophrenia arose between ages 16 to 43 years, giving a cumulative risk of 0.63%. The latter reached milestones, especially walking, later, had more speech problems, low educational test scores¹¹¹², solitary play preferences, less social confidence, and more social anxiety. Health visitors rated their mothers as having below average mothering skills and understanding of their children. Reports of less syntactically complex speech in premorbid children are contradictory, positive reports perhaps detecting state characteristics. In a 45-year follow-up study in Denmark (Sørensen *et al.*, 2010) people who developed psychiatric diagnoses other than schizophrenia reached most developmental milestones earlier than did those with a diagnosis of schizophrenia but later than did controls (people who were never admitted to a psychiatric department) and the two patient groups differed significantly for the age at which they could walk unsupported. Kremen *et al.* (1998), in their follow-up study, found that a decline in IQ during childhood was associated with later schizophrenia. This finding is supported by a Finnish report of a failure to progress in education despite early academic normalcy. (Cannon *et al.*, 1999) Morgan *et al.* (2008) point out that intellectual disability and schizophrenia often co-occur. A study of draftees in Israel (Davidson *et al.*, 1999) found that adolescents who later received a diagnosis of schizophrenia had poor social and intellectual functioning, as well as low organisational ability. Despite IQ scores within the normal range, apparently healthy Israeli adolescents who later manifest schizophrenia have intellectual decline. (Reichenberg *et al.*, 2005) Gunnell *et al.* (2002) in a cohort study of Swedish male conscripts, found that poor intellectual performance at age 18 years was associated with an increased risk of developing schizophrenia and other non-affective psychoses in early adult life. They attributed this phenomenon to the prodromal effects of psychotic illness rather than to problems encountered in utero or around the time of birth. It is likely that young people at high genetic risk for schizophrenia perform poorly on all tests of intellectual function and memory. (Byrne *et al.*, 1999) Hollis (2003a, p. 35) states that premorbid IQ appears to be lower in child and adolescent onset schizophrenia relative to adult onset cases and that this results from a downward shift of the whole distribution of IQ. Woodberry *et al.* (2008) found, in a meta-analytic review of 18 studies, that the mean IQ of people who developed frank psychosis years later was a one-half of a standard deviation below healthy controls and that IQ fell significantly when they fell ill. Cannon *et al.* (2001) found that suspiciousness, sensitivity, and peer relationship problems among attendees at a child psychiatric department to be predictive of schizophrenia in adulthood. A follow-up of the 1966 birth cohort from Northern Finland to age 34 (Isohanni *et al.*, 2006) found that impaired performance (e.g. delayed motor/intellectual development) or adverse exposures (such as pregnancy/birth complications, diseases of CNS) increased risk for schizophrenia; and, at least in the early phase, less flexibility and poor coping may precede schizophrenia.

Zammit *et al.* (2004) in a 27-year follow up, found that lower IQ was associated with increased risk for schizophrenia, severe depression, and other non-affective psychoses, but not bipolar disorder. Joyce *et al.* (2005) looked at community patients with first episode schizophrenia and found that half had preserved IQ in the normal range but with impaired spatial working memory; 40% had generalised cognitive decline; and low premorbid IQ was associated with earlier illness onset.

Combining high-risk status with cognitive disturbance may prove useful in predicting transition to psychosis. (Ruhmann *et al.*, 2010)

Low pre-morbid IQ may predispose people to psychiatric patienthood across a range of diagnoses. (Urfer-Parnas *et al.*, 2010)

An Australian follow-up study found that young adults who screened positive for 'non-affective psychosis' (Welham *et al.*, 2009) or 'delusional-like experiences' (Scott *et al.*, 2009) demonstrated psychopathology during

¹¹¹² Poor school performance in all domains at age 16 was strongly associated with risk for schizophrenia and other psychoses in a Swedish national cohort study. (MacCabe *et al.*, 2008)

childhood and adolescence and that the psychopathological trajectory of children destined to develop schizophrenia anticipated the heterogeneous nature of the full disorder.

The *Bonn Scale for the Assessment of Basic Symptoms* has been used to detect prodromal schizophrenia. Absence of BSABS prodromal symptoms excluded the development of a first psychotic episode, with a probability of 96%, with the percentage of false negatives being only 1.3%.

[2] In cases of *childhood-onset schizophrenia*¹¹¹³, failure of predisposed children to progress normally may occur instead of regression, there may be markedly uneven development and an insidious onset of symptoms, there may be a delay in language¹¹¹⁴ and social development¹¹¹⁵, and visual hallucinations are more common than in adult cases. A decline in full-scale IQ during adolescence has been recorded in such cases that may reflect an inability to acquire new information and abilities rather than a dementia *per se*. The child can be requested to describe TV shows or movies in order to test their organisation and synthesis of information. In one study (Werry *et al*, 1991) only 61% of childhood onset cases of schizophrenia retained this diagnosis on follow up, the others being rediagnosed as bipolar disorder, schizoaffective disorder, or other psychoses. Insidious onset, poor premorbid functioning, and absence of prominent affective symptoms were found to predict diagnostic continuity as schizophrenia. Positive symptoms failed to tell schizophrenic from affective cases. Hollis (2000) found that a diagnosis of DSM-III-R schizophrenia in childhood and adolescence had good predictive validity, suggesting aetiological continuity with adult cases, but with a worse course and outcome. Hollis (2003b) reported that premorbid social impairment was more common in early-onset schizophrenia than in other early-onset psychoses; overall, impaired premorbid development, enuresis and incontinence during psychosis were specifically associated with the negative psychotic symptom dimension. Childhood-onset schizophrenia is associated with the same eye-tracking dysfunction as that reported in adult schizophrenia. (Kumra *et al*, 2001) The parents of such cases have a significantly higher morbid risk for schizophrenia spectrum disorders (24.74%) relative to parents of adult-onset cases (11.35%) and parents of community comparison subjects (1.55%). (Nicolson *et al*, 2003) Adolescent schizophrenics with childhood-onset schizophrenia may have excess loss of cortical grey matter in frontal, parietal, and temporal regions. (Rapoport *et al*, 1999; Gogtay *et al*, 2004) The rate of reduction in cerebral grey matter is related to premorbid impairment and baseline symptom severity. (Sporn *et al*, 2003) One MRI study has demonstrated lateral ventricular enlargement, smaller mid-sagittal thalamic areas, but no reduction in the volume of temporal lobe structures. However, a controlled MRI study of adolescent-onset schizophrenia reported reduced total and gray matter volumes in the right superior temporal gyrus. Collinson *et al* (2003), using MRI in 'early-onset' schizophrenics and normal controls, found smaller brains in the former group, especially affecting the left hemisphere in males; female and male cases had reduced rightward and leftward asymmetry relative to same-sex controls; and decreased left hemisphere volume in males and decreased rightward asymmetry in females correlated with reduced IQ. Owever, Bakalar *et al* (2009) followed up 49 right-handed childhood onset cases of schizophrenia (mean baseline age 14.72 years \pm 2.63) with MRI and compared them matched, healthy controls: no significant asymmetry differences were found.

MRS has shown increased ventricular size¹¹¹⁶, and midcallosal, posterior cingulate, caudate and thalamic abnormalities.

¹¹¹³ *Dementia precocissima*: prepubertal schizophrenia. Childhood-onset schizophrenia affects < one in 10,000 children. Less than one in a hundred people with schizophrenia had this diagnosis as children. Commoner causes of psychosis in childhood are major depressive disorder, bipolar affective disorder, and severe cases of dissociation, as may be found in posttraumatic stress disorder. (Khurana *et al*, 2007)

¹¹¹⁴ Including verbal memory.

¹¹¹⁵ Poor attention and motor skills.

¹¹¹⁶ Especially posterior horns of lateral ventricles.

(b) Schizotypal disorder (F21 in ICD-10)¹¹¹⁷

These people are eccentric, aloof, and have thinking reminiscent of schizophrenia¹¹¹⁸, but nothing definite and characteristic of schizophrenia has been manifested. There may be suspiciousness, paranoid thinking, unresisted obsessiveness, illusions (including somatosensory), depersonalisation/derealisation, and occasional transient quasi-psychotic episodes¹¹¹⁹ with little or no external provocation. Working memory is impaired. (Mitropoulou et al, 2005; Nienow & Docherty, 2005) The course, while fluctuating in intensity, is chronic. It only sometimes evolves into schizophrenia. (Kendler et al, 1991) A family history of schizophrenia is not uncommon. Nevertheless it is often viewed as part of a 'schizophrenic spectrum', along with (very variably) schizophrenia, schizoaffective disorder, paranoid personality disorder (Hans et al, 2004), other non-affective psychoses, and psychotic affective illness. It resembles a personality disorder, and is designated as such in DSM-IV. Features of this disorder can be found in relatives of patients with disorders other than schizophrenia or schizotypal (personality) disorder, especially in association with affective disorder, although schizotypal symptoms appear to be particularly common in the relatives of schizophrenic patients. (Kendler et al, 1995)

In a Northern Finnish birth cohort study (Lahti et al, 2009), schizotypal traits in adulthood (age 31 years) lower placental weight, lower birth weight and smaller head circumference at one year predicted increased positive schizotypal traits in females, and higher gestational age, poorer childhood family circumstances, an undesired pregnancy, birth in winter or autumn, higher birth order and a mother who smoked whilst pregnant predicted some schizotypal traits in both sexes.

Neuroimaging studies using schizotypal patients suffer from various methodological shortcomings (e.g. small sample size and a bias toward using male subjects) and therefore have to be interpreted with caution. (Parnas et al, 2005, p. 35) However, there is evidence for bilaterally reduced neocortical grey matter volume and larger sulcal CSF volume in schizotypal personality disorder in both sexes. (see Koo et al, 2006) A smaller left Heschl's gyrus¹¹²⁰ gray matter volume has been reported from Boston on MRI in schizotypal patients than in controls. (Dickey et al, 2002) Takahashi et al (2009b) found MRI evidence suggesting that a reduction in gray matter in the superior temporal gyrus (including Heschl's gyrus) may be specific to schizophrenia in an MRI study of patients with a first episode of one of a number of types of psychosis. The sexes should be studied separately because an MRI study of community-based females comparing schizotypal personality disorder and comparison subjects by the same authors found no superior temporal gyrus volume differences. (Dickey et al, 2003) People with schizotypal disorder show a relatively decreased activation of key frontal regions on fMRI while performing a visuospatial working memory task. (Koenigsberg et al, 2005)

Schizoid personality disorder does not appear to be as closely related to schizophrenia as was once thought. (Fulton & Winokur, 1993)

(c) 'Acute'

About one year passes on average between onset of psychotic symptoms and getting into treatment. The onset is often insidious¹¹²¹, the person becoming more withdrawn and introverted, avoiding friends, losing drive, dropping out of activities, and developing an interest in subjects like psychoanalysis, occultism or

¹¹¹⁷ Once labelled as having 'latent' or 'borderline' schizophrenia (as were schizoid personalities).

A related concept is that of *schizotaxia*, (Meehl, 1962) an old idea that has been modified over the years. Genetically vulnerable individuals are exposed to early adversity, such as birth anoxia, leading to abnormal development of certain brain structures. In childhood, the presentation of this liability to schizophrenia presents as 'schizotaxia' as shown by various degrees of cognitive, neurobiological and social deficits. It has been suggested that 20-50% of first-degree relatives of schizophrenics are schizotaxic. Most cases remain schizotaxic but some will develop schizotypal disorder or schizophrenia. There is some evidence for improved function in people with schizotaxia who are given low-dose risperidone. (Tsuang et al, 2002)

This is an old concept that has been modified over the years. Genetically vulnerable individuals are exposed to early adversity, such as birth anoxia, leading to abnormal development of certain brain structures. In childhood, the presentation of this liability to schizophrenia presents as 'schizotaxia' as shown by various degrees of cognitive, neurobiological and social deficits. 'Delusional proneness' (e.g. feeling conspired against, telepathic thinking, or hearing voices) may be more common in first-degree relatives of schizophrenics or bipolars. (Schürhoff et al, 2003)

¹¹¹⁸ Magical, cold, odd, peculiar, circumstantial, metaphorical, overelaborative, stereotyped, no gross incoherence.

¹¹¹⁹ Intense illusions, hallucinations, and delusion-like ideas.

¹¹²⁰ Like the planum temporale, **Heschl's gyrus** is a component of the superior temporal gyrus. Heschl's gyrus and other superior temporal areas (including primary and secondary auditory cortices) may be involved in auditory hallucinations in schizophrenia. (Nenadic et al, 2010)

¹¹²¹ Perhaps this is so in a majority of cases.

astrology. Delusions¹¹²² and hallucinations eventually appear. Some cases come on more abruptly, perhaps following a stressful event; they are floridly ill, feel that they are the object of special attention, attach abnormal significance to the mundane, have bizarre (completely implausible) ideas, may be mute, and may have first rank symptoms (FRS). Any sensory modality may be affected by hallucinations, but most commonly these are auditory. Auditory hallucinations may be in any person, speaking to or about the patient. Their content is very variable and is not always clear to the sufferer. They tend to be persistent. The time-honoured differentiation between true and pseudo-hallucinations can be very difficult to make in practice. Affect is usually abnormal. There may be perplexity (ideas of reference, persecution or grandiosity may be fleeting), depression or elation¹¹²³, flattening or blunting of affect, anger, or incongruous emotional display (e.g. fatuous giggling when sadness would be more appropriate). Behaviour may be characterised by withdrawal, bizarre activity, or catatonia (*vide infra*). Full-blown catatonia is more likely to be seen today in people coming from the Third World or in people from isolated localities. However, catatonia has many causes other than schizophrenia and more subtle manifestations should be actively sought.(Fink & Taylor, 2009) Deaf schizophrenic patients may show evidence of thought disorder in their sign language¹¹²⁴.

(d) 'Chronic'

Positive symptoms such as hallucinations and delusions become less dominant. There may be a 'defect state' with lack of vivacity and enthusiasm, emotional unresponsiveness, apathy, poverty of speech, inability to form more than fleeting interpersonal ties, anhedonia, loss of employment or marriage, and impaired effectiveness in social roles, including parental responsibilities. Most cases will have recurrent episodes with positive symptoms, often without any prodrome. Many will develop depression.

(e) Thought disorder¹¹²⁵

Not all cases demonstrate this. It is not confined to schizophrenia, being found, e.g. in mania. Abstract thinking is more a function of low intelligence than thought disorder. The interviewer finds it difficult to get straightforward answers to simple questions. Answers are vague and irrelevant. There is a tendency to slip off the theme when talking. There is poor continuity between sentences. Unlike the dysphasic, the schizophrenic has no idea that he is difficult to understand. He is preoccupied with abstruse ideas. Quantity of speech declines and there is deterioration in sentence construction. Less words than normal are employed, words, phrases and even syllables are repeated. Constructs are unstable and idiosyncratic. An excess of thought disorder has been found in relatives of schizophrenics and interpreted as being due to shared genes rather than rearing.(Kinney ea, 1997) Using a test of *sensorimotor gating* called *prepulse inhibition*¹¹²⁶, Perry ea (1999) found a close association between gating difficulties and thought disturbance – trivia cannot be filtered out from conscious awareness. Others have found profound deficits of prepulse inhibition of the acoustic startle response in early- but not late-onset schizophrenia, while others found evidence for defective prepulse inhibition, probably genetically transmitted, in schizophrenia spectrum disorders, including schizotypal personality disorder (Hazlett ea, 2003) and the relatives of patients with schizophrenia. A reduction in prepulse inhibition is found in a number of disorders, e.g. OCD, Huntington's disease, and Tourette syndrome.(Ellenbroek & Cools, 2002) Prepulse inhibition levels are influenced by sex (higher in males), people on atypical antipsychotics, and smoking status (higher in smokers).(Swerdlow ea, 2006) Prepulse inhibition may be regulated by dopamine neurotransmission in the prefrontal cortex and its levels seem to depend on the COMT Val158Met gene polymorphism.(Roussos ea, 2008)

(f) Early onset schizophrenia

Alagband ea (1997) examined children and adolescents with onset of schizophrenia before age 12 years. Males more often had an insidious onset. Smaller cerebral volumes on MRI were associated with negative symptoms. The authors felt that their findings supported continuity between early and later-onset cases.

¹¹²² Patients with schizophrenia tend to justify abnormal beliefs in an illogical fashion.

¹¹²³ **Elation** can occur in a number of psychiatric disorders, e.g. acute schizophrenia, mania, and drug-induced states.

¹¹²⁴ Interestingly, in a small study, Mason ea (2008) found an odds ratio of recorded middle-ear (especially left-sided) disease pre-dating schizophrenia of 3.68 – auditory hallucinations were associated with middle-ear disease but not with deafness. The idea that ear disease causes insanity by brain irritation is old.(Bryant, 1906)

¹¹²⁵ Some authorities prefer 'speech disorder'.

¹¹²⁶ Reduced P50 suppression and prepulse inhibition do not necessarily occur together.(Hong ea, 2007)

Kendler et al (1994) found no evidence from a familial perspective to support an aetiological distinction between the modern subtypes of schizophrenia. The ICD-10 description of schizophrenia is outlined in the box. DSM-IV is also discussed in the same box. DSM requires 6 months for the diagnosis, ICD only one month. The former insists on deterioration in functioning whereas the latter does not. Each symptom is present in some patients, but none is found in all. DSM-IV schizophrenia is basically a diagnosis by exclusion; individual symptoms are not confined to schizophrenia, being found in conditions such as affective disorders and dementia; the condition is over-simplified and reduced to the smallest common denominator; and it is more suitable for an experienced psychiatrist doing research than for the newcomer. (Maj, 1998)

Schizophrenia

(a) ICD-10, F20

There are fundamental distortions of thinking and perception, and inappropriate or blunted affect. Onset can be acute with disturbed behaviour, or insidious with gradual development of odd ideas and conduct. Course is variable and specifiable (by 5-character categories) as continuous, episodic with progressive/stable defect, episodic remittent, incomplete/complete remission, other, and observation less than a year. In some cases, there may be complete or virtual recovery. It affects the sexes equally, onset being later in females. There are no strictly pathognomonic (read: diagnostic) features. *Symptoms must be present for at least one month* (except for simple schizophrenia where at least one year is required). Otherwise, diagnose *acute schizophrenia-like disorder* (F23.2) until and if a month elapses with symptoms. The one-month criterion only applies to certain symptoms: thought echo, delusions of control, commenting hallucinatory voices, culturally inappropriate and completely impossible persistent delusions, persistent hallucinations in any modality, breaks/interpolations in train of thought, catatonic behaviour, and negative symptoms such as blunt affect or self-absorption. It does not include a retrospective recognition of a prodrome: loss of interest, social withdrawal, poor hygiene, anxiety, mild depression, preoccupation, etc. (Relatives and friends may minimise or rationalise prodromal symptoms.) Schizophrenic symptoms must antedate affective ones during the first month of the illness proper; if they commence simultaneously and are evenly balanced the diagnosis is schizoaffective disorder (F.25). Avoid a diagnosis of schizophrenia in the presence of overt brain disease or during drug intoxication/withdrawal. Similar conditions developing in the presence of epilepsy or other brain disease are coded under F06.2, and those induced by drugs under F1x.5.

Subtypes:

- F20.0, paranoid¹¹²⁷ (includes paraphrenic schizophrenia) – relatively stable, often paranoid, deluded, usually hallucinated – especially auditory, perceptually disturbed; disturbances of affect, volition, and speech, and catatonic symptoms are not prominent; onset usually relatively late.
- F20.1, hebephrenic (includes hebephrenia and disorganised schizophrenia) – usually starts 15-25 years of age; poor prognosis; prominent affective changes; fragmentary delusions/hallucinations; irresponsible, unpredictable behaviour; mannerisms are common; grimacing; pranks; mood shallow and inappropriate, with giggling or self-satisfied, self-absorbed smiling, or a lofty manner; hypochondriacal; reiterated phrases; disorganised thinking; rambling/incoherent speech; loss of drive.
- F20.2, catatonic – nowadays uncommon in the West; prominent psychomotor disturbances; can alternate between hyperkinesis and stupor, or automatic obedience and negativism; constrained attitudes and postures held for long periods; may show violent excitement; may have oneiroid state (Q.V.) with vivid scenic hallucinations; perseveration of words/phrases; transient and single symptoms can occur in other subtypes of schizophrenia; catatonic symptoms not diagnostic of schizophrenia, as will be discussed later.
- F20.3-9, undifferentiated (can't be subtyped), post-schizophrenic depression (some, non-dominating schizophrenic symptoms still present), residual (chronic negative symptoms; more or less synonymous with 'chronic schizophrenia'), simple (uncommon, insidious, odd, socially incompetent, declining

¹¹²⁷ Some say this is the commonest type but others would say that undifferentiated schizophrenia is the most common.

performance, progressive, no positive symptoms at any stage, aimless, idle, self-absorbed, may be vagrant), 'other', and 'unspecified'.

(b) DSM-IV

'Schizophrenia and other psychotic disorders' include disorders that have psychotic symptoms as their defining feature. According to DSM-IV, other conditions, such as Alzheimer's disease, psychotic mood disorders, and substance-induced delirium, do have psychotic symptoms but not as their defining feature.

- *Schizophrenia*. The disturbance has lasted at least 6 months, including at least 1 month of active-phase symptoms: 2 or more delusions, hallucinations, disorganised speech, grossly disorganised or catatonic behaviour, negative symptoms. The subtypes are: paranoid¹¹²⁸ (preoccupation with 1 or more delusions or frequent auditory hallucinations), disorganised¹¹²⁹ (disorganised speech and behaviour, flat or inappropriate affect), catatonic (motor immobility, excess motor activity, extreme negativism, peculiarities of voluntary movement, echolalia, echopraxia), undifferentiated (not meeting criteria for foregoing subtypes – commonest type in clinical practice), and residual (no prominent symptoms or signs, but has attenuated features, e.g. odd beliefs, unusual perceptual experiences). Detailed guidelines are given for describing the course of chronic illness.
- *Schizophreniform disorder*. Similar to above but lasting 1 to 6 months. The term schizophreniform psychosis was used in DSM-III-R to prevent the premature diagnosis of schizophrenia, although first episode schizophreniform cases may be as cognitively dysfunctional as are cases of chronic schizophrenia. (Heff ea, 1992) Schizophreniform disorder is heterogenous, some cases developing schizophrenia, schizoaffective disorder, a mood disorder, or other psychiatric disorder. (Ho ea, 2003, p. 397) Some cases are acute and brief with a relatively good outcome. (Marneros & Pillman, 2007, p. 100)
- *Schizoaffective disorder*. A mood episode plus active phase schizophrenic symptoms occur together and are preceded or followed by at least 2 weeks of delusions or hallucinations without prominent mood symptoms.
- *Delusional disorder*. At least 1 month of non-bizarre delusions without other active phase schizophrenic symptoms. Seven subtypes, depending on the prominent delusional theme: erotomanic, grandiose (megalomania, delusions of personal greatness), jealous (infidelity of sexual partner), persecutory (persecution of self or of others emotionally close to self), somatic (false belief one has physical defect or general medical condition; monosymptomatic hypochondriacal psychosis: parasitophobia, insects in skin, dysmorphophobia or body dysmorphic disorder, body odours¹¹³⁰, and non-functioning body parts), mixtures of foregoing, and unspecified because delusions do not fit into any specified category.
- *Brief psychotic disorder*. Psychosis lasting more than a day and less than a month.
- *Shared psychotic disorder*. Cf. folie à deux.
- *Psychotic disorder due to a general medical illness or induced by chemicals*. A period of observation may be required before attributing psychosis to a drug.

The existence of simple schizophrenia¹¹³¹ remains controversial. Kendler ea (1994) found simple schizophrenia to be rare, debilitating, similar to 'typical' schizophrenia in presentation and course except for the absence of positive symptoms, and, from a family perspective, it appeared to be related to 'typical' schizophrenia.

Males with schizophrenia appear to be more prone to suffer from a defect state than do schizophrenic women, although this is not an absolute.

¹¹²⁸ Do not diagnose paranoid subtype in the presence of disorganised speech or behaviour, flat or inappropriate affect, or catatonia.

¹¹²⁹ **Disorganised** is synonymous with **hebephrenic**: early onset, poor social/occupational functioning, more severe illness, and poorer longterm prognosis than the paranoid subtype. The patient may be deluded and hallucinated but these phenomena are not as prominent as in the paranoid subtype. Do not use this diagnosis if criteria for catatonic subtype are met.

¹¹³⁰ More often seen by dermatologists and may respond to antipsychotics, including pimozide.

¹¹³¹ **'Simple schizophrenia'**, simple deteriorative disorder in DSM-IV, is attributed to Diem who described it in 1903. However, Clouston, Pick and Sommer and others described a similar state before him).

An interesting phenomenon found in chronic schizophrenics is temporal disorientation¹¹³². Elvevåg ea (2003) found that schizophrenics are relatively inaccurate at estimating brief time periods (< 1 s). Thought disorder might be due to dysfunction of the cortico-subcortical loops that project into the prefrontal cortex.

Medication can impair attention. Therefore drug-naïve patients are ideal subjects for neuropsychological testing.

Executive processes include a broad range of operations involved in initiating and maintaining controlled information processing and co-ordinated mental activity. Included are goal or context representation and maintenance, attention allocation and stimulus-response mapping, and performance monitoring.¹¹³³

According to Goldberg ea (2003, p. 171), impaired executive function in schizophrenia is a core deficit that is independent of IQ. However, Dikken ea (2009), who found (in a meta-analysis) that negative symptoms and disorganisation are associated with partially dissociable patterns of executive impairment¹¹³⁴, believe that co-existing intellectual impairment (low IQ) has been a confounding factor in research. Also, studies of executive function should control for substance use. (Rodriguez-Jimenez ea, 2010) Barnett ea (2005) argue that impaired executive function (as tested by attention-shifting) is a stable, trait-like at onset of psychosis. The neural network involved in executive function includes the DLPFC and the anterior cingulate cortex. Besides disturbances in these areas, functional imaging studies in schizophrenia have reported disturbances in tempero-limbic regions, including the hippocampus, superior temporal gyrus, striatum and cerebellum. In a meta-analysis, Bora ea (2009) found no categorical differences in terms of cognitive functioning between schizophrenia, schizoaffective disorder and affective psychosis, except that a subgroup of schizophrenia sufferers with particularly severe negative symptoms may be more cognitively impaired than those in the other groups.

Gross cognitive impairment in schizophrenia was found by Buhrich ea (1988) to be related to the disease and not premorbid intellectual impairment or past physical treatment. However, according to Meshulam-Gately ea (2009), who conducted a meta-analysis of 47 studies of first episode schizophrenia, cognitive impairment is present by the time of the first episode and does not differ substantially from established illness, and IQ is lower at first episode than in the premorbid state and remains stable thereafter. Stahl (2003) suggests that antipsychotic drugs may improve working memory by releasing DA and NA in the dorsolateral prefrontal cortex (DLPFC). Hyde ea (1994) found that intellectual function did not decline markedly during the course of schizophrenia, suggesting to the authors that schizophrenia was more likely to be a static encephalopathy than a dementing disorder. Most schizophrenic patients perform poorly on IQ tests. Such deficits have been found to predate onset of disorder and to be lifelong. (Russell ea, 1997) Both general intellectual impairment and thought disorder are naturally associated with poor performance on language tests. Walder ea (2006) found that language was more impaired in males than in females with schizophrenia, but that phonology was, relative to controls, more affected in the female patients. Verbal memory (see Leeson ea, 2009) is defective from the beginning of a schizophrenic illness, and the extent of this deficiency may be greater the earlier the age at onset of the illness. (Tuulio-Henriksson ea, 2004) Episodic memory dysfunction, which may be due to reduced parahippocampal connectivity, (Talamini ea, 2005) may point toward a poor outlook. In fact, schizophrenics may even confabulate¹¹³⁵ with answers that

¹¹³² Classically out by about five years in their determination of how long they are in hospital. Patients have difficulty in giving their ages correctly (*age disorientation* – usually the patient says they are much younger than their chronological age) or telling the time. These are probably not delusions and probably reflect cognitive difficulties.

¹¹³³ Put simply, the generation and implementing of plans depend on intact executive processing. Schizophrenic patients have difficulty solving a problem when the solution is not obvious or when they must use the knowledge they already possess in a novel way. They find it difficult to keep information ‘in the forefront of their minds’ (on-line). When testing different races for cognitive function it is essential to control for confounding variables such as education and motivation. (Joyce & Huddy, 2004) Findings in first-episode schizophrenia include poor ability to plan, poor ability to recall a story and learn unrelated word pairs, but intact ability to shift attention from one set to another; and inability to predict the wishes and intentions of others (deficits in ‘theory of mind’), made worse by a low premorbid IQ.

¹¹³⁴ E.g. clinically stable patients showed significantly higher correlations with executive impairment than did those with unstable illness, and negative symptoms as well as disorganisation were related to current IQ.

¹¹³⁵ So-called ‘*delusional confabulation*’ (‘*confabulatory paranoia*’) is manifested by the patient apparently making up fantastic delusional memories as needed. These ‘recollections’ are subject to change and elaboration during an interview. (McKenna, 2007, p.4) Mullen (2008, p. 27) writes that whilst the listener may be tempted to dismiss this phenomenon as malingering (because of the tendency of the patient to respond to suggestions or scepticism on the part of the listener) a prolonged encounter will convince the examiner that it is abnormal.

reveal a poor understanding of the gist or moral of a story they are asked to recall. (Lorente-Rovira *et al.*, 2007) Cutting and Murphy (1988) found that 75% of schizophrenics were markedly deficient, relative to neurotic patients, in their knowledge of everyday social issues. Elderly schizophrenics have been reported to demonstrate greater cognitive deterioration than can be accounted for by necropsy evidence of a dementing process. (Purohit *et al.*, 1998) Wood *et al.* (2002) found that recognition memory deficits were common to early and established schizophrenia, whereas impaired associative learning was confined to the established cases. According to González-Blanch *et al.* (2008) cognitive impairment is common in first-episode psychosis regardless of good prognostic features such as short illness duration, being female or having a later illness onset, and negative family history of psychosis. Researchers (Brewer *et al.*, 2005; Barnett *et al.*, 2005; Tiihonen *et al.*, 2005) have reported visuospatial processing impairment and some memory deficits prior to full development of psychosis. Cannon *et al.*, (2002) in their prospective New Zealand study from childhood to adulthood, found that later DSM-IV schizophreniform disorder (at age 26 years) was associated with significant impairments in neuro-motor, receptive language, and cognitive development in childhood, and that developmental impairments also predicted self-reported psychotic symptoms at age 11 years. Reichenberg *et al.* (2010) examined a cohort of males and females born 1972-3 in Dunedin, New Zealand, when they were aged 3-32 years: children who went on to develop schizophrenia in adults entered primary school with major problems of verbal reasoning and they lagged behind other children in working memory, attention, and processing speed as they aged. Schubert and McNeil (2005) looked prospectively at offspring (mean age 22.3 years) of mothers with a history of psychotic disorders and found (compared with normal risk offspring) significant impairment of verbal memory, selective attention, and grammatical reasoning. Such impairment identified more cases at risk for schizophrenia-spectrum psychosis than for affective-spectrum psychosis.

The left hemisphere is superior in its use of syntactic or semantic information, the right hemisphere being better for contextual information. It has been suggested that thought disorder relates to poor organisation of semantic memory. Schizophrenic patients are better able to recall concrete facts about social situations but seem impaired when attempting abstract deductions, *e.g.* they can remember the words used by an actor but are less able to describe his affect or goals. There may be no problem in recalling that an event happened, but there may be difficulty remembering when it occurred, a so-called context memory deficit. Not surprisingly, patients with schizophrenia may tend not to recall past achievements but rather recall hospitalisation and the stigmatisation of illness. (Raffard *et al.*, 2009) Schizophrenic patients find it difficult to fill in deliberately deleted words from a narrative or to interpret a partial narrative. Elderly chronic schizophrenics may perform particularly poorly on tests of naming and constructional praxis. Both poverty of speech and incoherence of speech could be due to difficulties retrieving words from an internal lexicon, the former reflecting premature cessation of searching for words and the latter being related to incorrect word selection. The unaffected close relatives of schizophrenic patients have an excess of impaired information processing and deficits in working memory. Neuropsychological testing supports a relationship between temporal lobe dysfunction and reality distortion. (O'Shea, 1997)

Deficits in theory of mind ('mentalising ability' – ability to determine others' attitudes, beliefs and intentions) have been reported in children who later developed schizophrenia¹¹³⁶ (Schiffman *et al.*, 2004) and in adult schizophrenics (*e.g.* difficulty in distinguishing between sarcasm and sincerity: Leitman *et al.*, 2006; Horan *et al.*, 2009), but results have not always been consistent. (Kern *et al.*, 2009) Mizrahi *et al.* (2007) felt deficits may be less pronounced in schizophrenia, where they tend to be associated with negative symptoms, than in autism.¹¹³⁷ However, a meta-analysis (Sprong *et al.*, 2007) found that all symptom subgroups (especially disorganised) and patients in remission had deficits in theory of mind. Patients with schizophrenia have problems integrating what they see (articulatory motions like lip movement and facial expression) with what they hear; an fMRI study (Szycik *et al.*, 2009) that this problem stems from dysfunction of the speech motor system¹¹³⁸ in the right hemisphere and, possibly, reduced lateralisation of language functions to the

¹¹³⁶ Deficits in this area are also found in bipolar affective disorder of various ages and mood state. (*e.g.* Schenkel *et al.*, 2008) There have been many reports (*e.g.* Lysaker *et al.*, 2009) suggesting that individuals with schizophrenia have difficulty recognising the emotions of other people.

¹¹³⁷ Couture *et al.* (2010) used a battery of tests that examined social cognition and found that people with high-functioning autism resembled schizophrenia patients with negative symptoms more than schizophrenia patients with paranoid symptoms.

¹¹³⁸ Pars opercularis, middle frontal sulcus, and superior temporal gyrus.

left hemisphere. Bach et al (2009) suggest that people with schizophrenia have a general difficulty in identifying high-clarity emotional cues.

Other reports in schizophrenic patients are listed in the box.

Cognition and schizophrenia (roughly in order of time when published; scz = schizophrenia/schizophrenic; FES = first-episode scz; PFC = prefrontal cortex)

Difficulties on verbal short-term memory tasks due to limited 'representational capacity' and maintenance of information over delays

In elderly scz cognitive impairment predicted overall outcome and specific adaptive deficits, whereas positive symptom severity correlated more with specific adaptive deficits than with overall adaptive outcome

Significant cognitive decline in scz is not explained by age, whereas slow, gradual decline can be so explained

Impairment of mnemonic strategies despite preservation of IQ

Women with scz may be less vulnerable to certain cognitive deficits, especially those involving verbal processing, than are males with the disorder

Some cases have selective a deficit in verbal memory despite normal motivation, attention and general perceptual function, whereas others have multiple cognitive deficits

Greatest reduction in brain potentials associated with cognitive processing over the left temporal lobe

Problems in the attribution of desires and attentions to others as demonstrated using theory of mind comic strips

Scz unable to link separate aspects of events into a cohesive, memorable, and distinctive whole (*autonoetic* awareness - type of awareness involved in mentally reliving events from the personal past - is defective)

Scz patients have considerable cognitive dysfunction in the first 4 to 5 years of illness that remains stable at 1 to 2 standard deviations below that of comparison subjects, with little evidence of cognitive deterioration during that time except for verbal memory

Only negative symptoms associated with poor cognitive outcome

Performance and full scale IQ improved over first 5 years of illness, but verbal IQ remained stable

Abnormalities in eye movements, frontal release signs and short-term memory problems were associated with poor neuropsychological test results

Infant offspring of scz mothers may have impaired cognitive development (such results are confounded by birth weight and social status)

Healthy people have no difficulty with the Wechsler Digit Span Test (forward test measures general attention, backward test measures verbal working memory), relatives of patients have problems with the backward test, and patients have problems with both parts of the test suggesting a generalised verbal memory deficit

Scz usually have impaired explicit but preserved implicit function.

Most severely disabled scz have the most marked executive and attentional problems (despite stabilisation of psychosis)

Schizotypal personality disorder associated with impairment in working memory (but not perhaps in discrimination of form and trajectory)

Relatives of scz have poor attention as measured by Continuous Performance test (CPT) – MRI and CPT on drug-naïve FES suggests working memory deficit due to impairment in context processing due to deficits in DLPFC activation

Prompts and cues help scz patients to tackle chores sequentially

Cross-sectional study of elderly scz suggests scz have stable cognitive impairment

51% of scz patients showed cognitive decline; executive function and attention deficits may be core features of scz and independent of IQ variations

In a catchment-based study cognitive dysfunction was found to be pervasive in scz, the main affected area being memory

Duration of untreated symptoms does not explain widespread cognitive deficits, ventricular enlargement, and some loss of cortical mass in FES

Scz patients fail to form and use transient memory traces to guide behaviour (event-related potential study)

Poor outcome in scz associated with sensory processing dysfunction (tone-matching threshold study)

Neuropsychological impairment in ambulatory scz remains stable over time (did not include 'back ward' patients)

Tryptophan depletion in scz impaired executive function only, leaving, for example, mood uninfluenced

In test of object recognition, scz is associated with impaired perceptual closure that is improved to non-patient level with prior exposure to the objects (pictures) and the giving of valid word prompts; performance declines with increase in severity of negative symptoms

Study of sustained attention from Edinburgh (high-risk participants, controls, and FES) found that deficits were not associated with a genetic vulnerability to scz or with occurrence of psychiatric symptoms

Smaller anterior (but not posterior) hippocampal volumes on MRI in FES males (but not females) with poorer executive and motor function

Working memory tested by introducing a delay element: authors suggest that there is dysfunction in scz of posterior brain areas mediating visual perception processes and of prefrontal areas involved in active maintenance of information

In a controlled EEG/high-resolution event-related potential study, scz showed lower amplitude of mismatch negativity for across-phoneme changes than for change in duration of tone or vowel; for across phoneme change, scz had lower bilateral amplitude of mismatch negativity; scz also had significantly weaker L temporal combination of current sink (perpendicular sinking into scalp) and current source (arising out of scalp) and significantly weaker R frontal/temporal current sink than comparison subjects

Continuous Performance Test (measures sustained attention) is a stable vulnerability indicator for scz, is particularly abnormal in bipolar patients if psychotic, and is state-dependent in major depression

Patients with deficit scz had poorer adjustment in childhood/early adolescence and more impaired complex motor act sequencing (suggests fronto-parietal dysfunction) than non-deficit scz

Scz patients in remission performed worse on an irony task but not on other theory of mind tasks: interpreted as suggesting a trait deficit

Working memory components (perceptual competency and holding stimuli on-line – measured with a visual delayed match-to-sample task) all affected in FES, even if unmedicated

When people with scz try to think about beliefs/intentions of others they use analogical reasoning

Impaired working memory deficit in stable chronic male schizophrenics tested with neuropsychological test battery: appears to be a core component of the disorder

Chronic scz may have difficulty comprehending written material, although thought disorder (e.g. tangentiality) may play some role

Global intellectual impairment present at illness onset but does not decline over time (cross-sectional study favouring neurodevelopmental hypothesis)

N-back working memory task plus fMRI suggest that scz whose performance resembles healthy controls use greater prefrontal resources but achieve lower accuracy, and that other scz fail to sustain prefrontal network that processes the information and achieve even lower accuracy as a result

Chronic scz in encounters with mental health professionals recognised that others did not share their delusions and attempted to reconcile others' beliefs with their own; while recognising that they did not convince professionals they did not make their claims understandable; and the ensuing disagreement did not lead them to modify their beliefs: psychotic beliefs are not changed just because it is realised that they are not shared

First-episode unipolar psychotic depressives had similar (but less severe) neuropsychological dysfunction as did neuroleptic-naïve scz; non-psychotic unipolar depressives had mild attentional dysfunction

Marked deficits in ability of scz subjects in ability to interpret social cues from faces; those with positive symptoms were impaired in recognising even basic facial cues

Mismatch negativity deficits in scz is associated with poor everyday functioning

Schizophrenic patients have a specific deficit in context processing

Intellectual deficits relate to genetic liability to scz

Visual processing dysfunction exists early in schz and may be due to decreased non-linear signal amplification, consistent with glutamatergic theories; dysfunction occurs within low-level visual pathways involving thalamo-cortical radiations

Modafinil may enhance short-term memory in scz (inconsistent findings); it may elicit early gene expression in anterior hypothalamus and anterior cingulate cortex in animals; it increases activation in anterior cingulate cortex in humans (on fMRI) undertaking working memory task

Scz and schizophreniform subjects have a deficit in the initial process required to maintain information, e.g. ability to form an internal representation of complex objects

Presumed obligate carriers for psychosis (close relatives with psychosis) had impaired verbal memory and visuospatial manipulation

Mismatch negativity deficits and their relationship to poor functional status are stable over time in chronic scz

Poor ability to perceive and discriminate emotional expressions present at onset of scz and show minimal response to effective antipsychotic treatment

Emotion recognition deficits in scz are trait features that worsen with length of illness

Intellectual asymmetry with relative superiority of verbal skills to spatial skills represents a possible endophenotype of schizophrenia

Faulty inhibitory mechanisms for negative information may not be general in scz but may be selective for depressed cases

Origins of thought disorder may be closely linked to deficient executive functioning and semantic processing

Deficits in early stages of face perception in scz, and these deficits are associated with small fusiform gyrus volume

Decreased activation in whole thalamus, anterior nuclei, and medial dorsal nucleus in scz whilst performing memory tasks, e.g. N-back task for working memory

Scz is associated with a specific deficit of relational memory (ability to learn associations between individual items); this is associated with impaired function (fMRI) of parietal cortex and hippocampus

Psychotic (espc. positive symptoms) people use externalising bias when explaining negative social events, and this attribution style is not part of vulnerability to psychosis

Visuospatial dysfunction may be an association between brain-derived neurotrophic factor Met ($BDNF_{Met}$) variant and poor temporal lobe-related memory performance in scz

fMRI results suggest unstable cortical signal processing underlies classic abnormal cortical activation patterns as well as psychosis in scz

Working memory and executive cognition may be affected by abnormal hierarchical organisation of PFC in scz, the latter resulting in loss of functional specialisation and integration at dorsal PFC and compensatory activation from ventral PFC

33 year follow-up of scz; baseline impairment in verbal and non-verbal intelligence; significant decline over time in non-verbal intelligence only

Impaired attention/sequencing highly predict communication failures related to language structure in scz

Medicated chronic scz, especially with positive thought disorder, have inappropriate increases in activity in inferior prefrontal and temporal cortices in response to semantic associations on fMRI

Lorazepam impaired working memory and flumazenil enhanced working memory in chronic scz more than in healthy volunteers

Donepezil tried in 20 chronic scz with severe cognitive impairment: no improvement in cognition or negative symptoms

Neurocognitive measures are associated with scz, differentiate unaffected relatives from comparison subjects, and may have significant presumed heritability

Frontal release signs scores inversely correlate with IQ in scz

Scz and healthy siblings showed impaired emotion recognition but normal gender recognition – did not improve in scz despite clinical improvement (therefore phenotypic of scz)

Deficits in facial recognition may pre-date overt psychosis

Event-related brain potential study (N400 following sight of prime and target words of different relatedness levels) in scz suggests lack of direct and indirect semantic priming¹¹³⁹

Meta-analysis provided qualified support for semantic priming underlying schizophrenic thought disorder – but it might simply be a reflection of generalised slowed reactions

Meta-analysis showed improvement in most cognitive tasks in scz over time; practice may account for more improvement than did cognitive remediation; semantic verbal fluency is likely to be a cognitive endophenotype of scz

Patients with scz, and to a lesser extent their well siblings, are inclined to see trustworthiness in faces deemed untrustworthy by healthy controls

When testing facial emotional recognition the use of faces from races other than the patient's can lead to spurious results

Patients with scz have reduced ability to detect humour but have unimpaired appreciation of humour

Patients with scz who have hallucinations and delusions are more likely to misattribute source of negative (relative to neutral) words to others than to the self compared to scz in remission

Scz is associated with an increased tendency to accept as trustworthy (liberal acceptance) material that a non-scz would tag as untrustworthy

Neuropsychological impairment in scz resembles that seen with brain damage in terms of severity and stability; poor test results translate into real-life cognitive failures

Global measures employed may not be appropriate when attempting to find specific relationships between symptoms and executive functions; the interactions are complex

Women's superior ability (vs men) in identifying affective prosody and emotional content of the spoken message is better preserved in scz and the male advantage (vs women) in visuospatial processing is compromised in scz

Similar scores on several dimensions of neurocognitive function and psychopathology among DSM-IV scz and schizoaffective/bipolar affective disorder with psychotic features (versus community control group); relationship between neurocognitive function and psychopathology similar in both patient groups – suggests neurobiological continuum

151 cases of first-episode psychosis: lower performance on verbal and working memory associated with poor outcome at 6 months of treatment

Relative to controls, greater signal strength is needed for visual and cognitive processing of facial information in scz

Relative to controls, scz out-patients are impaired in their ability to recognise that they were the source of an earlier mental event

Cell membrane essential fatty acid composition and dynamics are associated with semantic memory and language in scz

Total eye scanning length and responsive search score, being parameters of exploratory eye movement, discriminate schizophrenia (sensitivity 73.3%, specificity 79.2%) from patients with mood disorders or neurotic disorders and from normal controls

First-episode scz is associated with reduced behavioural and neural (fMRI) sensitivity to bizarre facial expressions; this may be due to disturbed control of emotion-related face processing in the fusiform gyrus by the amygdala and prefrontal cortex

On fMRI scz had deficit in amygdala reactivity to negative face stimuli and an alteration (correlated with antipsychotic drug dosage) in functional coupling between amygdala and subgenual cingulate; well siblings were similar to controls; this suggests that this problem is not a heritable phenotype but rather an effect of treatment

Using fMRI and a continuous performance task authors found significant impairment in functional connectivity between dorsolateral PFC and task-relevant brain regions

In the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) both psychotic symptoms and neurocognitive deficits appeared to contribute independently to decreased quality of life in scz

Scz were more impaired on memory indices than were bipolar cases and the latter were mildly impaired compared to healthy controls; scz had smaller total cerebral volume and bigger ventricles; left amygdala volume was predictive of memory performance in both patient groups

Loss of effective associative learning in scz can be assessed by eye-blink conditioning processes and eye-blink conditioning improved at 2 and 24 hours following secretin¹¹⁴⁰ but not placebo, suggesting a possible role for secretin in the modulation of cerebellar-mediated classically conditioned learning

Mistakenly seeing anger in other people's expression is related to high suspiciousness and low self-esteem in scz

There may be a specific impairment of voluntary response inhibition in scz (stop-signal reaction time) – patients demonstrated intact involuntary response inhibition (masked priming task)

In a 15-year Chicago follow-up study, external locus of control was not specific to schizophrenia but was significantly associated with less recovery periods, to both depressed mood and psychosis, and, most importantly, to personality

People at high genetic risk for scz (N = 97) performed poorly on tests of spatial memory capacity and planning processing speed compared to controls (N = 25) even after controlling for IQ

Scz patients performed lexical decisions on target words that were semantically related and unrelated unconsciously perceived masked prime words: increased unconscious activation of several related concepts may interfere with conscious goal-directed thinking in those patients with formal thought disorder

Youth-onset scz is associated with severe cognitive deficits whereas late-onset scz is associated with specific deficits (e.g. attention, fluency, IQ, and visuospatial construction) that are not simply due to ageing

Compared with intellectually matched controls, first-episode scz/schizoaffective disorder is associated with multiple deficits in executive function, processing speed, and verbal memory

Scz patients who over learn verbal material bring compensatory brain areas in to action to make up for cortical inefficiency

Motivation is important in neurocognition, social cognition and functional outcome in scz

Whilst scz is associated with positive affect evaluation (pleasure) there is a problem translating this experience into motivation

¹¹³⁹ Maher's (1983) theory that associative processes are overdeveloped in schizophrenia, e.g. 'bees make honey' becomes 'bees make sweet'. (McKenna, 2007, p. 202)

¹¹⁴⁰ Secretin, which enjoyed a brief vogue in autism, is a hormonal agonist for the prototype group B G-protein-coupled receptors. (see Bolbecker et al., 2009)

Used Temperament and Character Inventory in Northern Finns born in 1966 who developed a psychotic disorder: reward dependence and persistence were significantly correlated with PANSS negative symptoms; higher P scores predicted higher social and occupational functioning, and higher harm avoidance predicted higher likelihood of being on disability pension

Regarding first episode psychosis, scz have severe, widespread neuropsychological impairments compared to other diagnostic groups

African Americans with schizophrenia or schizoaffective disorder were slower and more inaccurate when performing neurocognitive tests than their biological relatives, the latter doing less well than community comparison subjects; there were significant heritabilities for most neurocognitive domains (especially abstraction/flexibility, verbal memory, face memory, spatial processing, and attention speed)

Premorbid adjustment before first psychotic episode influences severity, but not form, of cognitive dysfunction

When effects of general impairment of intellect are reduced (by using scz patients who were relatively free of this problem) there was no deficit in identifying facial emotions but there may be difficulty to the intensity of such emotions; difficulty in recognising familial faces (not found on *Benton Facial Recognition Test*) may be a semantic memory problem

Scz had reduced working memory capacity but were similar to controls in precision of working memory representations

In a longitudinal study with 2.5-year follow-up, global neuropsychological functioning (NF) was equally impaired in individuals at high risk for schizophrenia or other psychoses (CHR) and family high-risk groups compared to controls; NF in CHR group was much lower in people who progressed to psychosis than in those who did not and was worst in the subgroup with a family history of psychosis; tests of processing speed and verbal and learning best discriminated CHR from controls; and worse verbal memory predicted more rapid conversion to psychosis

A meta-analysis of 70 studies (Aleman ea, 1999) showed that there is a stable but significant impairment of memory in schizophrenia that is unaffected by age, medication, illness duration, patient status, symptom severity, or positive symptoms, with negative symptoms having a small but significant effect. Another meta-analysis of 187 studies (Forbes ea, 2009) found working memory deficits in schizophrenia patients and that these could not be simply explained by any current IQ differences between patients and controls. Barrett ea (2009) found that first-episode bipolar disorder and schizophrenia subjects, relative to healthy controls, were most impaired in terms of memory, executive function and language but bipolar patients performed much better on tests of response inhibition, verbal fluency and callosal function; and the differences could be explained by the greater likelihood of schizophrenia cases to be globally impaired and to have negative symptoms.

Negative symptoms (subtractions from behaviour and emotion) may be a primary feature of schizophrenia (e.g. social withdrawal, blunted affect, and avolition) or be secondary to positive symptoms like depression or paranoid delusions. The idea that they are confined to 'burned out' cases has been abandoned; anyway, evidence for 'burn out' is weak at least. Nevertheless, there is some support for the idea that negative symptoms are less prominent in late-onset schizophrenia and more prominent in early-onset cases that have grown old. Schizophrenic patients tend to be less concerned by their negative symptoms than are depressives. Negative symptoms might result from (or made worse by) environmental deprivation, although this is disputed, (Phillips ea, 1991; Curson ea, 1992) or EPS. Negative symptoms may be less common in Nigerian schizophrenics. The relatives of patients with mainly negative symptoms may be at less risk for schizophrenia than is the case in other circumstances. (Baron ea, 1992) However, other work (Malaspina ea, 2000) has suggested that schizophrenia in association with a positive family history is associated with particularly treatment-resistant negative symptoms but not especially with deficit syndrome (DS: described below), although the familiarity of DS is supported elsewhere. (Ross ea, 2000) The *clinical poverty syndrome*, which is not specific to schizophrenia, consists of withdrawal, social isolation, flattening of affect, poverty of speech and ideation, and lack of drive or motivation. Johnstone and Frith (1996) divided schizophrenia into three dimensions ('poverty', 'hallucinations and delusions', 'disorganisation') based on principal component analysis. Mayerhoff ea (1994) reported their findings in first episode cases in remission from positive schizophrenic symptoms. Four percent had the full *deficit syndrome* (DS; *restricted affect, reduced emotional range, diminished speech, curbing of interests, reduced sense of purpose, and decreased social drives*), 19% had some deficit symptoms, and 77% had no deficit symptoms. Those patients in the last group had better premorbid functioning and a better global outcome than did patients with deficit symptoms. The '*neuroleptic-induced deficit syndrome*' (NIDS) is said to resemble the negative symptoms of schizophrenia but clears when medication is stopped, whereas primary schizophrenic DS tends to remain stable. It is said that atypical antipsychotic drugs (olanzapine, clozapine, risperidone, sertindole, quetiapine, and ziprasidone) are less prone to induce NIDS. A patient's negative symptoms may

be exacerbated by D2 blockade, possibly by downregulation of prefrontal D1 receptors¹¹⁴¹. There is still some debate as to whether atypicals like clozapine are effective against primary as distinct from negative symptoms¹¹⁴². (Miyamoto *et al.*, 2003, p. 461; Cunningham Owens, 2004, p. 269; Harvey *et al.*, 2005) The same can be said for using anticholinergic drugs, which also have known detrimental effects on cognitive function.

A number of authors, including Frith and Done (1988), attributed positive symptoms (e.g. alien control) to a defect in the internal monitoring of action, (Johns *et al.*, 2006) and negative symptoms to a defect in the initiation of action by the brain. There might be a DA deficiency in the prefrontal cortex, excess blockade of 5-HT_{2A} receptors by serotonin, or excitotoxicity from excess glutamate.

In pseudoneurotic schizophrenia, described by Hoch and Polatin in 1949, a diagnosis that is basically redundant, the presentation consists of neurotic symptoms, the patient being mistaken initially as having a 'neurosis'. Close scrutiny may reveal evidence of schizophrenia. The patient is very anxious but the normal therapies for this are disappointing. Some authors would hold that Hoch and Polatin were actually describing borderline personality disorder.

The presence of excess 'soft' (*minor*¹¹⁴³) *neurological signs* (SNS) unrelated to medication (Dazzan & Murray, 2002) in schizophrenia has attracted much attention, as has suggestions that they may be mainly left-sided. Examples of SNS include poor motor sequencing/co-ordination, right-left discrimination, and sensory integration difficulties. Hard signs, on the other hand, are localisable to specific brain regions and typically involve motor or perceptual systems. The borderland between soft and hard signs is difficult to follow in the literature, e.g. early-onset schizophrenia has been found to be accompanied by an excess of choreiform movements and corticospinal tract signs that persist over time. Are these soft or hard?

Polydactyly may be over-represented in patients with familial schizophrenia. In comparison with normals and psychiatric controls, left- and mixed- handedness are significantly more common in schizophrenia. Mixed handedness may be associated with more neurological impairment¹¹⁴⁴, and a history of poor scholastic attainment and poor premorbid adjustment. Dragovic *et al.* (2005) found that leftward reversal (shift to left in behavioural lateralisation) rather than reduced lateralisation was associated with clinical severity and neurocognitive deficits in schizophrenic patients. The head circumference of long-stay schizophrenic patients and at birth in those later to develop the illness has been found to be pathologically small by some but not all researchers. There have been reports of facial anomalies in schizophrenia in the form of an overall narrowing and elongation of the mid- and lower face. (Lane *et al.*, 1997; contrast these findings with McGrath *et al.*, 2002, e.g. smaller glabella to subnasal height) Minor hand and mouth anomalies, together with anomalies of the face, may be commoner in schizophrenics and their siblings than in the general population, (Egan *et al.*, 2001) but the members of the same family do not necessarily have the same anomalies. (Ismail *et al.*, 1998) Male schizophrenics may have shorter stature than healthy comparators. (Nopoulos *et al.*, 1998) Kinney *et al.* (1986) reported that the prevalence of neurological abnormalities in the relatives of schizophrenics was significantly greater than in controls, but similar to that among the schizophrenics. Relatives and controls differed even more markedly on signs involving motor system abnormalities of localising significance. Similar findings have been recorded by others workers. (see O'Shea, 1997) Schubert and McNeil (2004) found more soft signs, involuntary movements, and cranial nerve abnormalities among the offspring of women with schizophrenia, whereas the offspring of women with affective psychosis had no such excess. There are many methodological flaws in research into SNS. They are found in other psychiatric disorders (e.g. mood disorders – see Goswami *et al.*, 2007; Lloyd *et al.*, 2008¹¹⁴⁵), their relationship to aetiology is unclear, and the literature in conflicting regarding findings. Lawrie *et al.* (2001) consider soft signs and minor physical anomalies to be non-genetic, non-specific markers of developmental deviance. Leask *et al.* (2002) could not link soft signs to infectious illnesses. Whitty *et al.* (2003) concluded that motor and cortical signs were state-dependent whereas 'harder' signs were more static. Bachmann *et al.* (2005) found that the level of soft signs varies with illness course in first-episode

¹¹⁴¹ Hirvonen *et al.* (2006) looked at twins discordant for schizophrenia and found that high D1 receptor density in medial prefrontal cortex, superior temporal gyrus, and angular gyrus was associated with increasing genetic risk for schizophrenia and that D1 receptor binding showed widespread reduction in medicated schizophrenic patients.

¹¹⁴² Kumra *et al.* (2008) found that children with early-onset schizophrenia who were resistant or intolerant to at least two antipsychotics responded better (including negative symptoms) to clozapine than to olanzapine (up to 30 mg/day) in a randomised, comparative trial.

¹¹⁴³ Do not localise to tract or nuclear lesion. Both groups developed significant metabolic problems.

¹¹⁴⁴ Mixed handedness is increased in combined schizophrenia and intellectual disability. (Hemmings & Bouras, 2007, p. 205)

¹¹⁴⁵ Lloyd *et al.* (2008) suggest that these anomalies occur during the first trimester.

schizophrenia but that the level remains steady in comparison subjects. Also, predictors of soft sign scores at follow-up were soft sign levels at remission and compliance with treatment. It should be noted that minor physical anomalies are very common in the normal population.(Lane ea, 1997) A total physical anomalies score on the *Lane Scale* (Lane ea, 1997) in first-episode psychosis was associated with grey matter reduction in prefrontal cortex and precuneus and grey matter excess in basal ganglia, thalamus and lingual gyrus.(Dean ea, 2006) MRI in 70 adolescents aged less than 18 years who had positive psychotic symptoms for under 6 months revealed that increased severity of sensory integration SNS had smaller thalami bilaterally whereas those with more severe sequencing of complex motor acts SNS had a smaller right caudate nucleus.(Janssen ea, 2009) Dazzan ea (2008), in a controlled study, suggested that SNS were specific to psychosis. However, the comparison was between psychoses and ‘normals’ (general population), so other diagnoses were not tested.

Biswas ea (2007) looked at SNS in outpatients with schizophrenia diagnosed according to WHO diagnostic research criteria in India. Some findings are shown in the table. The earlier the onset of psychosis the more frequent and severe were the SNS and the more severe was the psychopathology; there was no relationship between SNS and dose or type of antipsychotic medication; and there was no correlation between duration of illness and SNS. There was a positive association between lower educational status and lower IQ (especially in the two younger onset groups) and more SNS, suggesting to the researchers that neurodevelopmental abnormalities predate overt psychosis onset.

Ruiz-Veguilla ea (2008) examined 92 cases of first episode ‘functional’ psychosis (87% non-affective) and found SNS had a significant independent association with not having been a heavy cannabis user¹¹⁴⁶, having a family history of psychosis, male sex, lower score in verbal fluency and higher score in negative symptoms.

Thomann ea (2009) looked at brain changes underlying SNS in schizophrenia and in healthy controls. MRI showed reduced grey or white matter densities in pre- and post-central gyrus, pre-motor area, middle and inferior frontal gyri, cerebellum, caudate nucleus, and thalamus in subjects with schizophrenia. The only association with SNS in the controls was reduced densities in frontal gyri. These findings supported the notion of cognitive dysmetria¹¹⁴⁷ with disruption of the cortico-cerebellar-thalamo-cortical circuit in schizophrenia.

Neurological soft signs (SNS) in India

Biswas ea (2007)

Numbers: 15 with onset < 14 years of age: childhood-onset, 20 with onset > 14 and < 18 years: adolescent onset, 20 with onset > 18 years (adult onset)

SNS frequency: 100% in childhood onset cases, 90% in adolescence onset cases, 55% in adult onset cases

Goswami ea (2007)

Used modified Kolakowska battery (maximum score = 42) for SNS on 53 euthymic bipolar affective disorder (BAD) patients and controls: SNS increased slowly and significantly with age in controls (average score = 2.8) but BAD cases had high scores (average score = 8, i.e. lower than reported in schizophrenia) throughout age range that were not age related (do not get worse)

Spontaneous dyskinesias unrelated to medication have been known to occur in schizophrenia since the time of Kraepelin. There is some evidence that Parkinsonism, not attributable to medication, may be part of the schizophrenia spectrum, e.g. a greater tendency to right over left sided signs could be interpreted as indicating left striatal hypodopaminergia.(Caligiuri ea, 1993; McCreadie ea, 2002b) In fact, Parkinsonism had been described by Kraepelin in dementia praecox in 1919. Rosso ea (2000) followed up Philadelphia children during their first 7 years of life and found that at ages 4 and 7 years tremor, tics, spasms, or athetosis were significant overrepresented in those later diagnosed with DSM-IV schizophrenia. Walker ea (1994) compared childhood home movies of DSM-III-R schizophrenics, their siblings, and normal controls and found an excess of motor abnormalities in the patient group (choreoathetosis, abnormal posture [e.g. of the hand], and a tendency to move a body part when the contralateral part was called into action).

¹¹⁴⁶ Does this mean that cannabis protects against SNS or that cannabis causes psychosis without SNS?

¹¹⁴⁷ Abnormal connectivity may underlie psychopathology.

Different mechanisms may underlie brain dysfunction in familial and sporadic cases of schizophrenia, with an excess of 'primary' problems (e.g. cranial nerve signs, frontal release signs) in sporadic cases and 'integrative' (depending on integration within and between motor and sensory systems) problems (e.g. astereognosis) in familial cases.(Griffiths ea, 1998)

Three syndromes of schizophrenia (Liddle & Barnes, 1990)

Psychomotor poverty - poverty of speech, flat affect

Disorganisation - formal¹¹⁴⁸ thought disorder, inappropriate affect

Reality distortion - delusions and hallucinations

The *psychomotor poverty syndrome* (PPS) consists of reduced spontaneous movement, poverty of speech, flat affect, reduced cerebral perfusion in the left prefrontal cortex, and impaired neuropsychological testing of frontal lobe function, perhaps with low levels of the DA metabolite homovanillic acid in the CSF.

A wide range of psychotic disorders are associated with impaired ability to distinguish between fragrances, even when the psychosis is brought under control.(Brewer ea, 2001; Good ea, 2006) Such *olfactory* identification deficits are found in both treated and neuroleptic-naïve schizophrenics as well as, in some but not all studies (Compton & Chien, 2008), in their well relatives.(e.g. Kopala ea, 2001; Turetsky ea, 2008; Turetsky & Moberg, 2009) Malaspina and Coleman(2003) found that olfactory identification deficits in schizophrenia were related to negative symptoms and the deficit syndrome and that both relationships could be explained by an association of olfactory identification deficits with diminished social drive. Male patients may have impaired assignment of pleasantness to amyl acetate, an effect that seems to independent of smoking status.(Moberg ea, 2003) People at very high risk for developing schizophrenia because of attenuated or brief psychotic symptoms or loaded family histories may have impaired olfactory identification ability.(Brewer ea, 2003) A finding of smaller posterior nasal volumes in schizophrenia has been interpreted as indicating a specific developmental cranio-facial abnormality.(Moberg ea, 2004) Olfactory structures develop in conjunction with the palate and ventral forebrain. Using MRI, Turetsky ea (2009) found shallow olfactory sulci in schizophrenic subjects compared with normal controls (N = 36 and 28 respectively). The authors suggested that this finding may be a marker of early disruption of embryonic development.

Self-blinding¹¹⁴⁹

Many causes, e.g. schizophrenia, TLE, drug misuse (e.g. LSD), encephalitis, diabetes

May represent a failed suicide act

Autoenucleation is usually carried out with the fingers

Patient may be left with a temporal hemianopia in the surviving eye (traction on optic chiasma)

Children with severe, early onset bilateral retinal disease (e.g. CMV retinitis) may poke the eye in order to produce visual sparks or *phosphenes* - this activity has been misinterpreted as either badness or autism

Autocastration

Reported in paranoid schizophrenia and in personality disordered chronic transsexuals with a history of self-mutilation

Psychotic denial of pregnancy (O'Shea, 2000c)

Rare

Associated with schizophrenia, history of loss of custody of children, fear of loss of future custody - carries risks of poor prenatal care, violence to the foetus or newborn,¹¹⁵⁰ and unassisted delivery

Depression in schizophrenia: Affective symptoms are common in schizophrenia and depression is a common reason for attempted suicide in these patients. This must not be confused with neuroleptic-induced Parkinsonism. However, when drug-induced Parkinsonism is misdiagnosed as depression and treated with tricyclic antidepressants (TCAs) the patient often improves because these drugs are anticholinergic! Also,

¹¹⁴⁸ I.e. structure, organisation, and coherence of thinking.

¹¹⁴⁹ The mythology of self-inflicted eye injuries goes back to Odin, a Norse god, and Oedipus. Self-blinding is recommended by St Matthew (chapter 5, v. 29) for sinful thoughts.

¹¹⁵⁰ Including poor nutrition and self-induction of labour.

dysphoria is commonly associated with akathisia. The notion of post-psychotic depression is an old one.¹¹⁵¹ Psychosocial factors might be important here but studies have failed to support an increase in depression following recovery.(e.g. Koreen ea, 1993) Indeed, depression is common early in the course of schizophrenia, and has been shown to correlate with positive symptoms. Also, Simms and Mulholland (2008) failed to link depression in schizophrenia to perceived lack of social support. Many schizophrenic patients who are taking their medication complain of being 'trapped' or of feeling vaguely unwell. Many researchers believe that that depression is an integral part of schizophrenia. It may be that dysphoric symptoms precede, coincide with (during which they may be masked), and follow the more florid illness. Whether this is due to a functional link between the two symptomatologies or due to a common physiological disturbance is still disputed. Treatments for these depressive symptoms include cognitive therapy, antidepressant drugs¹¹⁵², neuroleptics and, if necessary, electroconvulsive therapy (ECT). The term 'revealed' depression simply infers that the depression was revealed by treating the florid symptoms. Some authors hold that verbal memory impairment in schizophrenia is explained by depression and that it is not an integral part of the disorder.(Brébion ea, 2001)

Manic symptoms in schizophrenia: Experienced clinicians know of a few patients with long histories of undoubted schizophrenia that have episodes of superimposed manic and hypomanic symptoms. Depending on how one defines such symptoms, 3-10% of cases may experience such episodes at some stage.(Häfner & an der Heiden, 2003, p. 122) The rare patient appears chronically elated. How to fit them into the nosology is difficult to say. Even when one considers bipolar disorder, schizoaffective disorder, drug-induced disorder¹¹⁵³, and somatic disorders (e.g. neoplasia) one is left with the above residuum.

Schizophrenia in patients with intellectual disability (ID): Schizophrenia may be more common in this patient group than in the general population.(Reid, 1993) It may not be possible in individual cases to refine diagnosis beyond 'psychosis not otherwise specified'. Brief psychotic episodes may follow stress¹¹⁵⁴. When one is dealing with cases with mild ID and relatively good verbal ability then there is little difference from people in the normal range of IQ in terms of clinical features apart from simple, concrete reporting of delusions. Questions must be understood, e.g. asking someone with a low IQ about 'hearing or seeing things' may be interpreted as 'can you hear and see?' Relatives may be able to distinguish change from the usual poor verbalisation to delusions. With lower IQ levels observation becomes more important for diagnosis than verbal interaction.

Diet and schizophrenia: Schizophrenic patients smoke heavily, are often overweight¹¹⁵⁵ or obese, eat too much saturated fat, have a low intake of antioxidants, and eat too little fruit and vegetable.(McCreadie, 2003) Their diet is low in Vitamin E relative to cholesterol.(McCreadie ea, 1998; Scottish Schizophrenia Research Group, 2000) According to Peet,(2004) a higher national intake of refined sugar and dairy products predicted a worse two-year outcome of schizophrenia. This may be aetiologically relevant or an example of ecological fallacy.(McIntosh & Lawrie, 2004) Correlation does not necessarily equal causation and interventions need to be sustained.(McCreadie ea, 2005)

Substance misuse in schizophrenia:

- Up to 65% of patients with schizophrenia have lifetime diagnoses of substance use disorders (Mueser ea, 1990)
- 15% -60% of patients with schizophrenia in America abuse psychoactive drugs (Dixon ea, 1991)

¹¹⁵¹ And not uncommonly reported in treated delusional disorder.(Munro, 1999) Indeed, it was recognised as early as 1920, long before the advent of antipsychotic drugs.(Goff & Shader, 2003, p. 574)

¹¹⁵² Which often fail to work (Johnson, 1981) and which can potentially exacerbate psychosis.(APA, 2002, p. 425) However, Siris & Bench (2003, p. 151) wonder if the treatment of depressive symptoms during psychotic decompensation has led to an erroneous attribution of psychotogenicity to antidepressant drugs.

¹¹⁵³ In DSM-IV terms, by determining that the mental disorder came before the substance use disorder or lasted for 4 or more weeks following cessation of substance use.

¹¹⁵⁴ Stress here refers to what someone with ID finds stressful, which may not be so for people with greater intellectual ability.

¹¹⁵⁵ Whilst early weight increase is typically associated with atypical antipsychotic drugs typical agents may be associated with similar increases in the longer term.(Perez-Iglesias ea, 2008) Not all (particularly abdominal) **obesity** in schizophrenia appears to be related to antipsychotic drugs, education, diet or smoking.(Saarni ea, 2009) Patients with affective psychosis do not appear to share this problem.(Saarni ea, 2009)

- The combination of drug misuse and schizophrenia is associated with male sex, homelessness, excess psychotic symptoms, non-adherence to treatment, poor prognosis, violence and aggression (Soyka, 2000)
- Young and male patients are the main users in central London (Duke ea, 2001)
- First-episode schizophrenia patients in West London who persistently use substances have worse positive and depressive symptoms but not negative symptoms (Harrison ea, 2008)
- First-episode schizophrenia patients are less likely to adhere to medication or to stay in treatment if they use cannabis (Miller ea, 2009)
- First-episode psychosis cases in Northern Ireland who persist with substance misuse have more severe depression, more positive symptoms, poorer functional outcome, and a greater relapse rate at one year compared to patients who stop such misuse after presentation and those with no history of misuse, with no difference in outcome between patients who stop such misuse and those with no history of misuse (Turkington ea, 2009)

Drug abusing patients are more likely to be hostile, commit offences, and commit suicide. Duke ea (2001) found high use of cannabis, psychostimulants, LSD, opiates, and anticholinergics in central London. Veen ea (2004) reported a strong association between use of cannabis¹¹⁵⁶ and earlier age at first psychotic episode in males with schizophrenia. This research receives support from Barnes ea (2006) and Di Forti ea.(2009) Wade ea (2006), in a follow-up study of first-episode psychosis, found substance misuse increased risk of inpatient admission, relapse of positive symptoms¹¹⁵⁷ and shorter time to relapse of positive symptoms. Henquet ea (2005), in a prospective and population-based (Munich) sample, found that cannabis use in people aged 14 to 24 years moderately increased the risk for psychotic symptoms but had a much stronger effect in those with evidence of predisposition for psychosis. An increase in psychotic symptoms predicted relapse to cannabis abuse and medication adherence reduced cannabis relapse risk in a prospective post-discharge study of psychotic patients.(Hides ea, 2006) Arendt ea (2005), using the Danish Psychiatric Central Register, found an increased risk for later development of schizophrenia spectrum disorders in patients who had been treated for cannabis-induced psychosis; male gender and young age were associated with increased risk; and schizophrenia tended to commence at a relatively young age. Further work conducted by Arendt ea (2008) was suggestive of cannabis-induced psychosis being an early manifestation of schizophrenia rather than a distinct disorder. Barnett ea (2007) reported increased substance use in people with first-episode psychosis, age at first use of cannabis, cocaine, ecstasy and amphetamine being significantly associated with age at first psychotic symptoms. Moore ea (2007) performed a systematic review and concluded that cannabis increases risk of psychotic outcomes independent of confounding and transient psychotic effects. Miettunen ea (2008) found cannabis use to be associated with prodromal symptoms of psychosis in adolescence and Mata ea (2008) found that cannabis abuse was associated with impaired decision-making before onset of psychosis but could not determine direction of causality¹¹⁵⁸. Rais ea (2008), in a Dutch MRI study, found that first episode schizophrenia patients who use cannabis have a greater brain volume reduction over a five-year follow-up than do patients with schizophrenia who do not use cannabis.

Veling ea (2008b) conducted a study among non-Western immigrants to The Hague with first-episode schizophrenia. Cases used cannabis more often than their siblings or general hospital controls. Cannabis use predicted schizophrenia but genetic predisposition did not predict schizophrenia. Barkus and Lewis (2008) looked at repetitive users of cannabis and suggested that their results indicate that cannabis reveals

¹¹⁵⁶ Independent of cannabis use, levels of the endogenous cannabinoid **anandamide** were found to be elevated in the blood and CSF of patients with schizophrenia.(e.g. Giuffrida ea, 2004) However, Koethe ea al (2009) found that lower levels of anandamide in CSF were associated with greater likelihood of transition to psychosis from the prodromal state, making them suggest that the endocannabinoid system might protect against schizophrenia. Weiser and Noy (2005) suggest that, rather than cannabis causing schizophrenia, an abnormal endogenous cannabinoid system might be common to both schizophrenia and the tendency to use cannabis. Eggan ea (2008) reported reduced cortical cannabinoid 1 receptor (CNR1) mRNA and protein expression in schizophrenia at autopsy – this might be secondary to reduced GABA neurotransmission in the dorsolateral prefrontal cortex. However, it should be borne in mind that CNR1 variants have been implicated in cannabis use and nicotine dependence.

¹¹⁵⁷ See also Malla ea.(2008)

¹¹⁵⁸ I.e. does cannabis cause impairment or does the impairment make a patient abuse cannabis?

an underlying vulnerability to psychosis in people with high schizotypal traits. Acute cannabis use induced psychotomimetic symptoms in people prone to psychosis in a study conducted by Mason ea.(2009)

Hospitalised first-episode psychosis patients (N = 109; Compton ea, 2009)

Cross-sectional retrospective design

Classifying by maximum frequency of cannabis or tobacco use (zero, ever, weekly, daily) before onset – no significant effect on risk of onset

Progression to daily use of cannabis or tobacco – increased risk of onset (F > M)

Key: N = number off individuals; M = male; F = male

Nordentoft and Hjorthøj (2007) suggest that about 800 cases of schizophrenia could be prevented annually in the UK if cannabis consumption ceased. Netski ea (2003, p. 168) are sceptical of theories of self-medication¹¹⁵⁹ by substances in schizophrenia and the findings of Aguilar ea (2005) in relation to nicotine dependence in schizophrenia did not offer support for a self-medication hypothesis. Henquet ea (2010) found that patients had an acute enhancement of mood and subacute hallucinations from cannabis and, again, they found no direct connection between cannabis use and attempts at self-medication.

Diagnostic criteria for schizophrenia

Schneider's First Rank Symptoms (FRS)¹¹⁶⁰ have high reliability in diagnosis, are poor predictors of outcome, and are of low specificity¹¹⁶¹. The heritability of FRS remains controversial.(Cardno ea, 2002) Mellor (1982) stated that third person hallucinations were the least discriminating of the FRS. Feighner's criteria pick up poor prognosis cases. Spitzer derived his *Research Diagnostic Criteria* from Feighner's criteria. The RDC require only a two-week history. A structured interview known as the SADS (Schedule of Affective Disorders and Schizophrenia) has been developed for use with the RDC.

Type I and Type II: TJ Crow, in 1981, divided schizophrenia into 2 types, I and II. One version reads as follows: the overlap between the two types conforms to the hebephrenic illness of the old classification; type I corresponds to 'paranoid', 'reactive' and 'good-prognosis' schizophrenia or to 'schizophreniform' psychosis, whereas type II cases conform to 'simple' schizophrenia or to the 'defect' state; type I can change into type II.; and type II can enter the overlap zone with hebephrenic features but it cannot become a true type I illness. From the most to the least common the order seems to be a mixture of the two types, type I, and type 2. The usefulness of this dichotomy has been questioned.

International diagnostic differences: In 1972 Cooper and his colleagues published the results of the US-UK Diagnostic Project. The concept of schizophrenia was shown to be very wide in New York. Under the same nosological rubric was subsumed the occasional manic, depressive, or personality disorder. In the UK, on the other hand, persons given the diagnosis of schizophrenia were more obviously suffering from the same syndrome. A year later, the WHO published the International Pilot Study of Schizophrenia in which they examined the diagnosis of schizophrenia in nine countries. Broad criteria were found in use in both the US and the USSR. However, if standard diagnostic methods were employed then one could still demonstrate a core of patients in all centres with similar symptomatology.¹¹⁶²

¹¹⁵⁹ The **cannabidiol** (CB1 antagonist) in cannabis may have antipsychotic properties, reduce dysphoria and quell anxiety but it is present in only small amounts in high-THC cannabis.(Atakan, 2008)

¹¹⁶⁰ FRS were published by Kurt Schneider.(1959: lived 1887-1967) although the individual symptoms were described long before that.(e.g. Haslam, 1810)

¹¹⁶¹ E.g. they may occur in as few as 20% of schizophrenic patients.(Ho ea, 2003, p. 388) They also occur in mania and depression. FRS can occur in organic mental disorders, especially if consciousness is not impaired, and particularly in post-ictal epileptic psychosis or alcoholic hallucinosis. The frequency of FRSs in schizophrenia ranges from 28 - 72%. This variation may be due to the diagnostic criteria used and the methods employed in eliciting FRS. However, FRSs occur much more commonly in schizophrenia than in other psychiatric disorders.

¹¹⁶² It should be borne in mind that there are wide intra-national differences also, e.g. Washington v New York and Leningrad v Moscow. In like manner there are some individuals who hold extreme views, e.g. Szasz holds that mental illness is a 'myth' and that schizophrenia is the 'sacred symbol of psychiatry'. At the Serbsky Institute in Moscow, Snezhnevsky offered a broad concept of schizophrenia - many eccentrics and personality-disordered individuals were included in his idea of schizophrenia. Snezhnevsky took more cognisance of the course of the illness than of the manifestations. He divided the disorder into the following: (a) 'continuous', (b) 'periodic', (c) a mixture of (a) and (b) 'shift-like'. The Russian concept of 'sluggish' schizophrenia has been attacked as being a political abuse of psychiatry. 'You'd want to be mad to be a dissident'.

Prognosis in schizophrenia

'The symptom patterns conventionally diagnosed as schizophrenia and regarded as reliable produce a rather heterogeneous spectrum of illness courses'. (Häfner & an der Heiden, 2003, p. 113)

'Schizophrenic illness remains heterogeneous with regard to illness course and outcome even when narrowly diagnosed with the help of modern operationalized diagnostic criteria'. (Modestin ea, 2003) 'When workers are in short supply, the burden of illness expands to include the lost labour potential; in hard times, concern is more focused on the cost of care'. (Warner, 2003)

'There is a marked heterogeneity in the outcomes of schizophrenia, depending on the domain considered'. (Ruggeri ea, 2004)

There are about 150,000 cases of schizophrenia at any one time in the UK. Hegarty ea (1994) reported that only 40% of subjects could be considered to have improved after follow up averaging 5.6 years during the century spanning 1895-1992. Outcome was better with broad or undefined criteria, but poorer (27%) with narrow criteria. Outcome varied for different reasons (treatment, criteria changes) at different times. In the closing years of the 19th century Kraepelin viewed schizophrenia as a disorder which always carried a poor prognosis. In the 1960s Brown and others found that after five years 56% of discharged schizophrenics made a social recovery, 35% were socially damaged but lived outside hospital, and only 11% had spent all their time in hospital. Bland and Orn (1978) found that after fourteen years about half were coping well with minimal disability, one-quarter had moderate to marked disability and a further quarter were disabled psychiatrically, socially and occupationally. Manfred Bleuler (in 1974, lived 1903-94) followed up 208 patients for over twenty years and found that there was usually no further deterioration after five years; in fact, some even improved. The WHO found that Third World schizophrenics had a relatively good outcome - one wonders if these cases were not different illnesses with an acute onset, (McCabe, 1976; Häfner & an der Heiden, 2003, p. 130) whether they had a more accepting society, or whether the pace of life had an ameliorating effect on them. Also, there have been reports of a relatively good outcome for schizophrenia in some industrialised societies (Prague, Nottingham) and of a poor outcome in Cali. Singh ea (2004) found that 19% of first episode psychosis identified in Nottingham between 1992 and 1994 received an intake diagnosis of acute and transient psychotic disorder (ATPD: ICD-10 F23). They concluded that ATPD identifies a heterogeneous group of disorders in which diagnostic stability was confined to females. Three-year outcomes were similar to that of affective psychosis and significantly superior to that of schizophrenia. Also, in non-affective psychotic disorders, being a woman and having good premorbid function, but not acute onset or early remission, predicts favourable outcome at three years. Pillman and Marneros, (2005) in a study that consisted of 76% females, found a much better prognosis for ATPD than for 'positive' schizophrenia: 31% v 0% respectively were functioning well without medication at the end of the follow up period. Sikanerty and Eaton (1984) reported a lower prevalence for schizophrenia in the Third World. However, Stevens (1987) was sceptical about what diagnosis one was dealing with. There are also reports from developing countries of symptomatic, severely disabled chronic, untreated patients living with extended families. (Padmavathi ea, 1998) Interestingly, African Americans are at risk of misdiagnosis for schizophrenia in the presence of affective or organic¹¹⁶³ brain disorders. (APA, p. 428)

Prognosis in first episode acute schizophrenia¹¹⁶⁴

Average duration of acute episode = 8 to 12 weeks (but undetected for 2 to 3 years)

25% achieve full, permanent recovery

50% relapse without progression to chronicity

25% experience recurrent relapses with deterioration of personality deterioration, and impaired social function and behaviour

Therefore, 75% (at least) are at risk of relapse

Prognosis in first episode non-affective psychosis (Crumlish ea, 2009)

118 consecutive referrals¹¹⁶⁵ prospectively followed up

Negative and disorganised symptoms improved between 4 and 8 years

DUP¹¹⁶⁶ predicted remission, positive symptoms and social function at 8 years

¹¹⁶³ One rarely sees a patient who, on recovering from delirium, persists in believing that his hallucinatory experiences were based in reality. (David, 2009, p. 11)

¹¹⁶⁴ Figures vary greatly depending on study quoted, time study was conducted, and criteria used, e.g. DSM-IV-TR criteria for schizophrenia define a narrow disorder with perhaps 10% having only a single episode with full recovery. Early improvement on the PANSS total score (30% or more at week 2) appears to be associated with response/remission in first-episode cases. (Schnenach-Wolff ea, 2010)

¹¹⁶⁵ St John of God service, South Dublin.

DUI predicted continuing functional recovery between 4 and 8 years
Suggests that there is an early critical period of deterioration

Brockington ea (1978) used ten different occupational definitions of schizophrenia and compared them to determine their efficacy in predicting the long-term outcome. The RDC was found to be best at identifying the poor prognostic group. Even the best studies fail to predict more than one-quarter of the variation in subsequent course.

Wing and Brown (1970) looked at the long-stay schizophrenic patients of three different hospitals. The hospitals with the most barren, understimulating wards had the most withdrawn, silent and affectively blunted cases.

Prognosis

Although readers of the literature will be well aware that not all research finding agree it can be argued that, in general, a:

Good prognosis is associated with

Living in a developing country¹¹⁶⁷

Female sex

Married status

Good social and occupational adjustment

Adverse life events

Substance-induced

Affective symptoms¹¹⁶⁸

Acute onset

Low familial loading seems to be associated with later onset and better outcome

Poor prognosis is associated with:

Male sex

Low social class

Living in a developed country

Low IQ, cognitive dysfunction

Childhood problems e.g. difficulties in learning

Poor medication response¹¹⁶⁹ or compliance

Insidious onset

Long duration of untreated psychosis (DUP) or untreated prodrome (Fusar-Poli ea, 2009)

Negative symptoms

Poor preservation of affect

Lack of depression

Excited state

Family history of schizophrenia¹¹⁷⁰

Poor insight

Poor premorbid adjustment¹¹⁷¹ (non-socialising, no relationships, poor work record)

High levels of EE (expressed emotion) in the family

Large cerebral ventricles

Abnormal MRI or EEG

Early onset

¹¹⁶⁶ **DUP** = duration of untreated psychosis; **DUI** = duration of untreated illness = duration of **prodrome** (start of prodromal symptoms to start of psychosis) + DUP.

¹¹⁶⁷ But not all studies agree, e.g. Mojtabai ea(2001) and Ran ea.(2001)

¹¹⁶⁸ In self or family.

¹¹⁶⁹ A naturalistic sample of inpatients (N = 247) with ICD-10 schizophrenia (Jäger ea, 2009) found that 27% and 54% were in remission (defined as at least a 40% reduction in total PANNS score from admission to discharge) at week 2 and on discharge respectively; a 20% reduction in total PANNS score within 2 weeks predicted remission and a 30% reduction predicted response.

¹¹⁷⁰ A few researchers found the opposite.

¹¹⁷¹ Rabinowitz ea(2006) found good premorbid functioning in first episode psychosis to be associated with better treatment response and less extrapyramidal symptoms.

Cognitive dysfunction is a major determinant of outlook.(Stahl, 2003) Milev *et al.* (2005) found verbal memory predicted impairment in recreational activities, negative symptoms and memory predicted relationship impairment, and attention and negative symptoms predicted work performance, findings broadly similar to those of Kopelowicz *et al.* (2005) Brodaty *et al.* (2003) in a small study with methodological shortcomings¹¹⁷², suggested that late-onset schizophrenia might be a prodrome of Alzheimer's disease. While this was not borne out by a cross-sectional study conducted by Eyler Zorrilla *et al.* (2000) it received support from a study showing an increased risk of developing dementia compared to patients with osteoarthritis and to the general population.(Kørner *et al.*, 2008) Ciompi (1980) performed an average 37-year follow-up of 1,642 patients with a diagnosis of schizophrenia from the start of the century to 1962. One-third had a good to fair social outcome. The symptoms often became less severe in later life. However, more recent studies suggest that elderly schizophrenics remain symptomatic and impaired.(Eyler Zorrilla *et al.*, 2000; Jeste *et al.*, 2003) Early onset may be associated with neuroleptic-resistance.(Meltzer *et al.*, 1997) Symptom dimensions may tell us more about prognosis than can diagnostic categories. In a London WHO study (Prudo & Blum, 1987), after a five-year follow-up of 100 schizophrenics, 49% had a good symptomatic outcome, and 42% had a good social outcome. Poor social functioning at the start of the study predicted a poor symptomatic outcome. Mason *et al.* (1995) performed a 13-year follow-up of Nottingham first episode ICD-9 schizophrenia cases. Four were lost to follow up and 5 had died. Fifty-two percent had no psychiatric symptoms in the previous two years, 52% had no negative symptoms, 55% had good to fair social functioning, and only 17% were fully well, symptomless, and off treatment. The same authors later reported that the course may be stormiest at the start but tends to plateau later, with no progression or alleviation in the long run. Finnerty *et al.* (2002) were able to follow up only 37 of 67 (55%) first episode schizophrenic patients over 15 years: 43% (of the 55%) were more or less continuously psychotic, a similar percentage suffered recurrent episodes of their disorder, two out of three had moderate to severe symptoms for most of the time, over four-fifths were unemployed, and there had been eight deaths (6 male and 2 female; 5 suicides or 11% of the 55%; 3 from natural causes), the excess mortality being due to male deaths. According to Casey and Hansen, (2003, p. 18) the suicide rate in schizophrenia may have increased as a result of the move from chronic institutional life to 'less intensive treatment emphasising outpatient care'. While Healy *et al.* (2006) reported a rise in the suicide rate associated with schizophrenia, Danish workers reported a fall.(Nordentoft *et al.*, 2004) Finnish workers (Joukamaa *et al.*, 2006) found an association between mortality and the neuroleptics used at baseline: is this an indictment of polypharmacy¹¹⁷³ or some other aspect of care or of illness severity?(see Healy, 2006) However, Tiihonen *et al.* (2006) in Finland found that excess mortality was highest in patients not taking antipsychotic drugs¹¹⁷⁴.

Women have a better prognosis than do men in schizophrenia. This might be due to dopamine blockade by oestrogens; and higher blood oestrogen levels in schizophrenic women are associated with better cognitive ability.(Hoff *et al.*, 2001) Women respond better to medication, family interventions, and are more compliant with treatment than are men; women may experience exacerbation of schizophrenia before or after menses are postpartum; and schizophrenia has a delayed onset in women. (Late-onset cases are more likely of paranoid subtype, never married and with a better work record.) Whilst results with exogenous oestrogens or anovulants have been mixed, there is some evidence that adjunctive oestrogens reduce psychotic symptoms.(Kulkarni *et al.*, 2008)

There is some evidence that patients diagnosed before the advent of antipsychotic drugs ended up with greater deficits than those who diagnosed during the phenothiazine era.(McCreadie *et al.*, 1991) Some authors have speculated that the illness has become milder over the years. Over 50% of schizophrenic patients will relapse during the first 9 months after stopping medication (compared to 16% in those remaining on medication), the great majority will have done so after 2 years¹¹⁷⁵.

¹¹⁷² Attrition of cases, poor cognitive performance at baseline, and no necropsy.

¹¹⁷³ The practice of polypharmacy (e.g. more than one second generation antipsychotic drug) and high dose regimens are persistent.(Tungaraza *et al.*, 2010) Whilst such approaches may make some sense in individual cases it is important that the rationale for such decisions are documented in the clinical file.

¹¹⁷⁴ The same follow-up study of first admissions found hospitalisation and discontinuation were reduced by perphenazine depot, clozapine and olanzapine compared to haloperidol.

¹¹⁷⁵ Different authors give slightly different figures and follow up periods, e.g. fivefold increase in risk of relapse after stopping medication, with earlier relapse in those with poorer premorbid adaptation to school and social withdrawal.

Readmission rates are increased in those with more prior admissions and brief periods outside hospital between admissions and by shorter periods in hospital.(O'Shea, 1997) Such rates are also increased by non-adherence to antipsychotic drug therapy.(Knapp ea, 2004)

Allebeck and Wistedt (1986), in Sweden, performed a mortality study on 1,190 patients with a discharge diagnosis of schizophrenia during 1971. They identified all deaths through 1981. The schizophrenics had about twice the overall mortality of the general population. The excess mortality was found in all causes of death, but it was particularly high in 'unnatural death'. The suicide mortality was about ten times higher among male patients and eighteen times higher among female patients than in the general population.

Females with schizophrenia may be more suicide-prone if single and living alone, or if depressed. Some authors report equal suicide mortality for both sexes. Other work from Sweden and England has confirmed the increased mortality in schizophrenia from all causes, including suicide, cardiovascular disease, digestive disorders, endocrine conditions, nervous and respiratory diseases, undetermined causes and violence. Heavy smoking, poor diet, lack of exercise and obesity must be important in these cases.

Suicide in schizophrenia can occur at any stage of the illness. Most schizophrenic suicides have made prior suicide attempts. A recent systematic review (Hawton ea, 2005) found that risk of suicide in people with schizophrenia is strongly associated with depression, previous suicide attempts, substance misuse, agitation/motor restlessness, fear of mental disintegration, poor treatment adherence, and recent loss, and less so with active psychotic features. Methods are often violent, e.g. throwing oneself under a train.

Prediction is very difficult and prevention is best approached generally.(Kelleher ea, 1998; O'Shea ea, 2000) Many methodological factors interfere with the extraction of predictive factors from published studies, e.g. publication bias, different researchers looking at different risk factors, robustness of cohort design, and confounding factors.

Suicide in schizophrenia: risk factors

Male sex
 Young age
 Early onset of illness
 Early stages of illness
 Severe illness
 Recurrent relapses
 Command hallucinations
 Bizarre delusions
 Akathisia
 Anorexia or weight loss
 Excess alcohol intake or substance abuse
 Co-existent depression
 Hopelessness
 Social isolation
 Loss of job or being unemployed
 Fear of deterioration (higher IQ, current failure despite earlier academic success)
 Other negative life events, stress (? high EE)
 Return of insight
 Less than 3 months since discharge from hospital
 Spending a relatively short period in hospital
 Being on leave from hospital
 Communicating feelings of loneliness

Estimates of attempted suicide rates among schizophrenic patients vary from 18%-55%.(Siris & Bench, 2003, p. 152) Schizophrenics who attempt suicide tend to use lethal methods, to have high suicidal intent, and are often depressed. Suicide and accidents, together with other causes of death, account for an increased mortality rate in schizophrenia. Although suicide is an important cause of death in schizophrenia, the main source of excess mortality derives from natural causes,(Casey & Hansen, 2003, p. 21) especially cardiovascular, respiratory, and endocrine (espc. diabetes mellitus) diseases. According to Meyer,(2003, p. 63) the prevalence of diabetes in schizophrenia is about double that in the general population, a problem

compounded by low potency typical and certain typical antipsychotic drugs. However, the retrospective nature of most research suggests that diabetes may be intrinsic to schizophrenia and unravelling the differential role of different antipsychotic drugs requires prospective research. (Dinan, 2004) Drug-naïve first-episode schizophrenic patients in Dublin have greater visceral obesity and impaired fasting glucose levels relative to healthy controls. (Thakore et al, 2002; Ryan et al, 2003) Unidentified risk factors for cardiovascular disease and type II diabetes are common in Dublin patients with schizophrenia or schizoaffective disorder. (Behan et al, 2008) A Canadian comparison of schizophrenia subjects and appendicitis controls (Callaghan et al, 2009) reported a significantly increased risk in the former group of being admitted for a cardiac event during 4-year follow-up. Saarni et al (2009), in a Finnish study, found that people with schizophrenia had an excess of abdominal obesity, high fat percentage, and low muscle mass. These were not completely explained by medication, education, diet and smoking. Venkatasubramanian et al (2007) found raised mean plasma insulin and mean insulin resistance score as well as low plasma insulin-like growth factor-1 (IGF-1) in antipsychotic-naïve schizophrenia in India relative to healthy controls. Fernandez-Egea et al (2009) looked at the metabolic profile of antipsychotic-naïve individuals with non-affective psychosis and found significant increases in 2-hour glucose (oral GTT) and IL-6 concentrations.

Spanish¹¹⁷⁶ study of patients with schizophrenia (Bernardo et al, 2009)

National, cross-sectional of patients on second-generation antipsychotics in short-stay units

733 consecutive admissions

Smokers – 71%

Hypercholesterolemia – 66%

Raised triglycerides – 26%

Hypertension – 18%

Diabetes – 5%

Metabolic syndrome – 19-24% depending on definition used

Patients were at increased risk of fatal cardiovascular events

Deduction: cardiovascular risk factors are underdiagnosed and therefore insufficiently treated

It is not yet possible to be definite about the differential risk for different forms of cancer in schizophrenia.

Other conditions

Brief psychotic disorder (DSM-IV; acute and transient psychotic disorder in ICD-10). Considered to be uncommon¹¹⁷⁷, similar patients have been diagnosed as having reactive (brief reactive psychosis in DSM-IV-TR), acute transient polymorphic¹¹⁷⁸, hysterical, psychogenic, or stress-related psychosis, or *bouffée délirante*¹¹⁷⁹ (see below). Jaspers' writings about reactive psychosis describe massive stressors¹¹⁸⁰, a relationship in time between stress and psychosis, a benign course, content of psychosis often reflecting the nature of traumatic experience, and the possibility that psychosis acts as an escape route. DSM-IV stresses a return to premorbid functional level (although recurrences occur in some cases). Stressors may be positive (e.g. promotion) or negative (e.g. being fired), and onset may be postpartum. Good prognosis is associated with high premorbid functioning, few premorbid schizoid traits, severe precipitating stressors, sudden onset, affective symptoms, confusion and perplexity, little affective blunting, short duration, and no schizophrenic relatives.

¹¹⁷⁶ This was conducted in an area with a low cardiovascular disease risk.

¹¹⁷⁷ However, certain groups may be particularly vulnerable, e.g. refugees, military recruits, immigrants, and people exposed to environmental disasters.

¹¹⁷⁸ Research findings conducted using these various labels are difficult to integrate into the general corpus of knowledge, e.g. the possibility of low plasma serine levels in acute transient polymorphic psychosis. (Marneros & Pillman, 2007, p. 108) The reader is referred to Linden et al (2010) who demonstrated a rise in admissions for brief polymorphic psychoses in North Wales during a religious revival (and its attendant intense religious experience) in the first decade of the 20th century.

¹¹⁷⁹ Marneros and Pillman (2007, p. 98) also list cycloid (associated with Kleist, Leonhard, and Perris), atypical (Mitsuda), and non-affective acute remitting (Susser) psychoses. Cycloid psychosis appears as acute polymorphic psychotic disorder in ICD-10, but is not included in DSM-IV.

¹¹⁸⁰ Most cases of brief and acute psychosis do not in fact experience significant life events. (Marneros and Pillman, 2007, p. 110) *Bouffée délirante* is reported from Haiti and West Africa. Sudden onset of agitation, aggression, excitement, and confusion characterise his condition. Some sufferers experience hallucinations and paranoid ideas.

Differential diagnosis includes transient psychosis in personality disordered individuals (particularly, but not confined to, borderline personalities¹¹⁸¹ – especially following stress, often interpersonal), psychosis due to substance use/withdrawal, and psychosis secondary to a medical disorder. Management usually involves admission to hospital since patients are usually floridly psychotic. Response to antipsychotics is often rapid. Continued treatment may be needed in recurrent cases (or in those cases that persist beyond this diagnostic compartment). Patients need psychotherapeutic help to make sense of their experience.

Acute delusional psychosis (*Bouffée délirante*)

Historically associated with Magnan and Ey

Elements of trance or dream state

Acute onset and sudden recovery

Relapse is common

Clouding of consciousness may be present

Intense but fleeting delusions and disturbance of affect

IV sodium amytal makes it worse

Some cases appear to be precipitated by tiredness, infection or other stress

Closely resembles DSM brief psychotic disorder or schizophreniform disorder

Many, perhaps 40%, develop schizophrenia later (?)

Psychiatrists see a large number of acute undifferentiated psychoses resembling everything and fitting nothing - this classification problem is highlighted in our interactions with Third World psychiatrists

Reactive (hysterical, psychogenic) psychosis

Popular in Scandinavia

Person under stress becomes psychotic

Obvious precipitant - onset closely related in time to precipitant

Content reflects precipitant

Clears up with removal of precipitant

Lasts several hours to one month

Patient perplexed and emotional labile

No other cause found

Resembles DSM's brief psychotic disorder or schizophreniform disorder and ICD's and transient psychotic disorders

Paraphrenia: These cases came on later than schizophrenia, showed less destruction of the personality, and often hallucinated. Many psychiatrists would now view paraphrenia as simply schizophrenia of later onset. Indeed, Brodaty et al (1999) failed to distinguish early v late (> 50 years) schizophrenia on any grounds. It is difficult to interpret MRI reports of hyperintensities in such cases. (see Zanetti et al, 2008) ICD-10 divides what was termed '**late paraphrenia**' (Frank Fish called this 'senile schizophrenia' in 1960) between schizophrenia and delusional disorder. This is a controversial diagnosis, (Munro, 1999) being diagnosed if onset is over 60 years of age. Late paraphrenia is associated with a wide range of delusions, usually persecutory or referential, hallucinations (usually auditory), and with no catatonia or inappropriate affect, and very rarely is there any formal thought disorder, all of which might suggest that its inclusion under other diagnoses is unwarranted. (Cf. O'Shea, 1997) It is particularly associated with socially isolated, deaf females who show an excess of soft neurological signs. Some authors see late paraphrenia as a heterogeneous disorder. Others regard it as being genetically related to depressive disorders.

In general, paranoid symptoms in the elderly are associated with cognitive impairment and social isolation. Almeida (1998) does not accept that late paraphrenia should have 'disappeared' the way it did and does not believe that the excess of females is simply due to late-onset schizophrenia in women. Almeida sees aetiology in this case as an interaction involving age, female sex, social isolation, hearing (mainly conductive) impairment, subtle brain lesions and cognitive decline. Almeida divides late paraphrenia into functional (many psychiatric symptoms including first rank one, and cognitive deficits confined to the executive sphere) and organic (generalised cognitive decline and an excess of neurological signs) types.

¹¹⁸¹ If such episodes are extremely brief (< 1 day) DSM-IV TR categorises them as 'psychiatric disorder not otherwise classified'. However, if they last for > 1 day but < 1 month they are diagnosed as brief psychotic disorder + (whatever) personality disorder.

Frégoli's 'illusion' or delusion, described by Courbon and Fail in 1927 and called after an actor (Léopoldo Frégoli) who was a master of disguise, is different from the Capgras phenomenon (the latter is also called *illusion de sosies* or illusion of doubles). The patient sees a single persecutor, who usually 'follows' the patient about the place, as having many disguises, i.e. he believes a number of people are in fact the one person. The imagined persecutor changes faces or disguises to avoid detection. Both the Capgras and Frégoli phenomena are actually delusions and not illusions, the latter term being misused in this case.

Zombi phenomenon: A Zombi is a person who is raised in a comatose trance from the grave and forced to toil as a slave. Alternative explanations have included the use of potions by the Haitian voodoo priests (tetrodotoxins - potent neurotoxins from certain species of puffer fish) and neurosyphilis.

Dysmorphophobia (body dysmorphic disorder) is discussed elsewhere. However, it should be noted that it can be very difficult to decide if a patient is actually deluded in such cases, the intensity of belief varying between patients and in the same patient. Patients are sure that other people react in a negative way to their appearance and often have ideas or delusions of reference. Extreme cases become housebound because of social avoidance behaviour. Even 'delusional' cases may respond to SSRIs. Both body dysmorphic disorder and OCD may be aggravated by m-chlorophenylpiperazine, a partial 5-HT agonist.

Black Patch Psychosis

Occurs when perceptual deprivation is severe e.g. patient with bilateral corneal transplants forced to lie on his back for a long period of time

Visual and auditory hallucinations may occur

Uncommon postoperative delirium

Possession states¹¹⁸²

Belief that one is possessed by spirit or ghost

Normal in people with strong cultural beliefs

Delusions of possession are known to occur in depression, schizophrenia, and substance-induced psychoses

Malingering and 'hysteria' are other possible causes

Delusions of bromosis

Belief that one emits an offensive odour

Mainly in young men

Frequent washing and change of clothes frequently

Use strong perfumes and deodorants

May be associated with depression, schizophrenia or TLE, or may conform to the definition of delusional disorder

Ganser's syndrome (Tyndel, 1956)¹¹⁸³

Common in prisoners?

Acute onset

Resolves suddenly

Amnesia for the episode

Must be distinguished from both aphasia and acalculia

Individual symptoms common in other disorders

May follow head injury

Ganser believed it to be a hysterical pseudodementia

Approximate answers¹¹⁸⁴ (*vorbeireden* – Question: 'How many legs has a cow?' Answer: 'Five' or 'three')

Approximate answers have been recorded in association with organic brain disease, intellectual disability and malingering), somatic conversion symptoms (e.g. paresis), visual and/or auditory hallucinations, and clouding of consciousness

¹¹⁸² The author had a patient with borderline personality disorder who believes she is possessed by a demon. Her belief was refractory to medication but abated when ignored.

¹¹⁸³ The German psychiatrist Sigbert Josef Maria Ganser (1853-1931) described this exceedingly rare (Dwyer & Reid, 2004) and controversial (Bass et al, 2000) syndrome in 1898.

¹¹⁸⁴ The term **paralogia** (talking past the point) has been used as a synonym for approximate answers. However it also has a wider meaning of illogicality.

Schizoaffective disorder¹¹⁸⁵: DSM-IV-TR requires a continuous period during which active phase schizophrenia symptoms plus depressive, manic, or mixed mood symptoms occur (*said to exclude schizophrenia*) and during the same episode that delusions or hallucinations are present for at least 2 weeks without being accompanied by prominent mood symptoms (*said to exclude psychotic affective state*). In reality, patients differ in the timing, sequence, degree of overlap, and stability of symptomatology. However, *the occasional episode of mixed 'schizophrenic' and affective symptoms in a person with well-established bipolar affective disorder or recurrent unipolar depression should not necessitate a change in overall diagnosis*. Based on morbidity risks for schizophrenia and affective disorders in relatives, schizoaffective patients seem to some to have an independent disorder, whereas others believe that some cases are truly affective, others really schizophrenic. (O'Shea, 1997; Liddle, 2001, p. 201; Laursen et al., 2005) Diagnostic stability over time has been shown to be relatively poor. (Forrester et al., 2001) Prognosis appears to be better than for schizophrenia but worse than for affective disorders. Poor prognosis is associated with mainly psychotic (particularly negative) symptoms, a family history of schizophrenia, poor premorbid functioning, early or insidious onset, a continuous course, and lack of precipitants. First rank symptoms are not related to outcome. At least 10% commit suicide. Comparatively, prognosis disimproves as we progress along the line of major depression, bipolar disorder, and schizoaffective disorder, to schizophrenia. Schizoaffective disorder has tended to be lumped together with schizophrenia or bipolar disorder in research work. (Abrams & Arciniegas, 2007, p. 86) Some genetic studies suggest that certain genes may confer susceptibility across the functional psychosis spectrum, e.g. the DISC 1 gene¹¹⁸⁶ on 1q42 (Hamshere et al., 2005) and Shao and Vawter (2008), looking for shared gene expression alterations in schizophrenia and bipolar disorder found some examples¹¹⁸⁷ of overlap. Schizoaffective disorder patients, but not those with schizophrenia, may be more likely than healthy controls to carry two copies of the most common BDNF haplotype¹¹⁸⁸. (Lencz et al., 2009) ECT and neuroleptics may relieve 'schizodepressive' episodes, whereas neuroleptics or mood stabilisers (e.g. lithium – not all findings agree) may relieve 'schizomaniac' episodes. **Delusional disorder** (DSM-IV): This is the modern name for paranoia/paranoid psychosis or state. F22 in ICD-10 includes delusional disorder, other persistent delusional disorder (insufficient symptoms to diagnose schizophrenia or presence of persistent hallucinations) and persistent delusional disorder, unspecified.

Delusional disorder

Relatively rare (US prevalence = 0.025 to 0.03%; annual incidence of 1 to 3/100,000 population)
 Hallucinations uncommon - tactile and olfactory hallucinations allowed if related to delusional theme
 Can appear normal except when engaged in a topic related to fixed, circumscribed, systematised delusions
 DSM-IV allows non-bizarre¹¹⁸⁹ delusions with content possible in ordinary life, such as being followed or loved from afar
 May be one delusion or a set of related delusions that are usually persistent, if not lifelong; they must be present for at least 3 months
 Delusional content may reflect life experiences
 May act on delusions
 Other symptoms must be a minor or transient finding
 Abnormal eye tracking has been described
 Sex incidence equal or slight female excess
 Usual time of onset is middle age, but earlier onsets are possible (mean = 40 years, range 18 to >90)
 Depressive episodes may occur

Some authors are sceptical about the existence of delusional disorder/paranoia as a separate entity, suggesting that sufficiently lengthy follow up will reveal that many cases will develop schizophrenia. (Sturgeon, 1990) From most to least common, themes of paranoia according to Winokur

¹¹⁸⁵ Such cases resemble Leonhard's 'cycloid psychosis' of the 1950s.

¹¹⁸⁶ Disrupted in schizophrenia 1.

¹¹⁸⁷ 5 dysregulated genes were shared by both disorders and 3 genes (AGXT2L1, SCL1A2, and TU3A) were highly enriched in brain expression; the differential distribution of AGXT2L1 expression in both disorders vs controls was highly significant ($p < 10^{-6}$).

¹¹⁸⁸ That is the one containing the valine allele of the Val66Met polymorphism.

¹¹⁸⁹ Some delusions are difficult to classify as being bizarre or non-bizarre. (Combs & Mueser, 2007, p. 251)

(1977) include jealous (see Othello syndrome), persecutory, litigious/legal, (Lester et al., 2004) sexual (see erotomania), and scientific (having special knowledge).

Shelton (2008, p. 296) states that two-thirds of cases recover or improve significantly and that one-fifth are chronic and resistant to treatment. However, it is difficult to prognosticate about a disorder that often fails to reach medical attention.

Capgras' syndrome¹¹⁹⁰ (*illusion des sosies*¹¹⁹¹) is present when the patient's spouse, family, friends, pets, furniture or indeed any other possession is believed to have been removed and replaced by an exact double. The double of a loved one may be human, a robot¹¹⁹², or an alien. The fact that one patient believed that her toothbrush was replaced by an identical other is against Sims' (2003, p. 135) contention that replaced objects are emotionally important. Capgras' syndrome may have an organic basis even when it occurs in a setting of a 'functional' disorder (O'Shea, et al., 1989). It has been described in AIDS patients who became confused during an opportunistic infection with an associated right parietal lesion on the CT scan. (Crichton & Lewis, 1990) It has also been described in association with lithium intoxication. The patient may believe that he himself has been replaced by a double (or that a separate double of himself exists), may attack others, develop the syndrome as a child in the setting of shared delusions, or believe that his letters or town has been replaced. It may rarely form part of a transient organic psychosyndrome following ECT. (Hay, 1986) Neuroimaging and neuropsychological research (impaired facial processing) suggest right hemispheric malfunction. (Pull et al., 2003, p. 59) Delusional misidentification syndromes are further discussed in the box. Delusional misidentification was present in 25% of 56 cases of postmortem-verified Alzheimer's disease. (Forstl et al., 1994) Draaisma (2009, p. 283) suggests that Capgras represents a loss of the ability to identify rather than a problem of recognition. He also suggests that there are two face recognition pathways (Draaisma, 2009, p. 295): the conscious (damage leads to *prosopagnosia*: defective face recognition due to occipital damage) and the unconscious/emotional (damage leads to Capgras). However, blind people may develop Capgras delusions and people may believe that loved ones who have emigrated (and therefore cannot be seen) have been replaced! (Draaisma, 2009, p. 297)

Delusional misidentification syndromes (DMSs)

According to Cutting (1991), DMSs involve disturbance in the judgement of identity or uniqueness and the common neuropsychological substrate is right hemisphere dysfunction.

Distortion errors in the perception of others can be divided into (e.g. Ellis, 1997):

- parapsoprosia – apparent transformation of a face, usually into a frightening appearance, especially in childhood schizophrenia but also in adults
- intermetamorphosis – appearance of a person's face changes to that of another person
- Frégoli delusion – Q.V.
- Capgras delusion – Q.V.
- subjective doubles – other people have same physical appearance as the patient

Morbid jealousy ('Othello' syndrome¹¹⁹³, 'conjugal paranoia') may be associated with paranoid personality disorder, alcoholism (some cases only reveal themselves when inebriated), cocaine, depression, schizophrenia, brain damage (e.g. pugilists), or early senile dementia. The mechanism probably varies with the underlying cause. Homosexuality does not appear to be of aetiological significance. What is accepted as normal jealousy varies between cultures (e.g. cultures vary in the equality given to female partners) and at different times. Examples of behaviours suggesting morbid jealousy include cross-questioning of partner, using the telephone to ascertain partner's whereabouts, turning up unexpectedly, searching belongings, opening partner's mail, following partner, and examining clothes for evidence of illicit sexual contact. (Mullen & Martin, 1994) Morbid jealousy occurs in both sexes but has been reported more often in men. It may possibly be precipitated or made worse by premenstrual tension. (Mullen & Martin, 1994) Murder of the sexual partner has occurred. Some wives of jealous husbands are housebound because of fear

¹¹⁹⁰ Described by Kahlbaum in 1866, by Clifford Beers (in himself) in 1908, and by the French psychiatrist Jean Marie Joseph Capgras in 1923.

¹¹⁹¹ *Sosies*, a double.

¹¹⁹² One American lady beheaded her stepfather to look for the batteries that she believed would be within! (Blount, 1986)

¹¹⁹³ Although, as pointed out by Munro, (1999) Othello was set up by Iago rather than truly deluded about Desdemona.

of retaliation if they are not always within reach. Affected men are more likely to have symptoms of anxiety and depression, to live alone, to have married very young, and to attempt to ignore perceived threats to their relationship in the hope that it will go away. Affected women are more likely to be jealous if they partake of excess alcohol, to have low self-esteem, to be less than 30 years of age, and to challenge a partner and show overt distress. (Mullen & Martin, 1994) In some cases the jealousy is the chief component of a monosymptomatic delusional state, in which case drugs such as pimozide (Orap) may produce improvement. Crowe (1995) puts forward various approaches that may be useful in managing morbid jealousy. (see box)

Management approaches for morbid jealousy (after Crowe, 1995)

- *Couple therapy* – reciprocity negotiations, communication training, timetables (e.g. discuss problem ideas at set times only), paradoxical injunctions ('I can't cure you. You need jealousy to keep your relationship stable'), reversed role-play (to get other person's perspective across), and sculpting (non-verbal; put each person in positions representing current state of relationship).
- *Individual psychotherapy* – dynamic, cognitive, eclectic.
- *Physical* – antidepressants (SSRIs), antipsychotics.
- *Others* – reduce alcohol intake, separation.
- *Added by Kingham & Gordon (2004)* – treat substance abuse, child protection, hospital admission

Delusions of jealousy are believed, not resisted and are egosyntonic; jealous overvalued ideas are egosyntonic, open to reason, and not resisted; and jealous obsessions are egodystonic, seen as senseless, and usually resisted. (Kingham & Gordon, 2004)

Prognosis depends on underlying phenomenology, comorbidity, and treatment response. Second homicides have been recorded. Careful monitoring over a protracted period is warranted.

Folie à deux¹¹⁹⁴ is a delusion transmitted from one person to another, the couple being emotionally very close. The recipient of the false belief is usually the passive partner and often recovers over a period of months if the two are separated. If three people are involved it is called *folie à trois*, and so on. If the whole family is involved it is styled *folie à famille*. Diagnostic criteria include evidence that the partners have been intimately associated; identical or near identical delusional themes; and acceptance, support and sharing of each other's delusions. The syndrome has been described in 81-year old twin sisters without any evidence of organic brain damage. If one person gets the delusion first and 'infects' another it is called *folie communiquée*. If both develop it together it is called *folie simultanée*. (see box) Separation should be accompanied by help to detach from a dependent relationship. Reuniting such cases (the usual outcome) must be accompanied by regular contact with services. Probably only a minority of these cases resolve on separation only, most cases needing antipsychotic drugs.

Subtypes of 'induced psychosis'

- (a) *Folie imposée*. Induced psychosis. The commonest form (64%). Psychotic, dominant individual induces pseudo-psychosis in recipient, the latter being submissive and suggestible. Recipient does not elaborate on the delusions. Separation may cause the recipient to abandon the delusions.
- (b) *Folie simultanée*. Six percent of cases. Delusions form simultaneously and independently in two people predisposed to develop a true psychosis. Separation does not cause either individual to shed psychopathology.
- (c) *Folie communiquée*. Twenty-five percent of cases. Both individuals are truly psychotic, but onset in one precedes that in the other. The other may take up delusional ideas arising in one of them.
- (d) *Folie induite*. Five percent of cases. A psychotic person may adopt the delusion of another patient and make it his own.

Doppelganger syndrome consists of the delusion of being followed by an exact duplicate of oneself.

¹¹⁹⁴ Described first by Baillarger as *folie à communiquée* in 1860, and then as *folie à deux* by Ernest Charles Lasègue and Jules Falret in 1877.

Erotomania (O'Shea, 2003)¹¹⁹⁵ may be neurotic or psychotic. A female (or less often a male) believes that an unavailable male secretly loves her but is unable to declare this fact. She persecutes him with letters, requests meetings, and so on. Eventually she may turn on him because he does not return her love. It is one cause of stalking. (Mullen et al, 1999) Hayes and O'Shea (1985) have described a case of a woman with Type I schizophrenia who looked after a husband with multiple sclerosis and who developed delusions of this type for a priest. Erotomania can occur in a homosexual setting. The underlying disorder may be depressive or schizophrenic. It can occur in association with organic illness, including AIDS. The object of the delusion may change. The delusion may last for many years, wax and wane, or come in episodes. Some experts believe that it can occur in pure form.

The term 'borderline erotomania' (pathological infatuation) refers to a group whose pursuit of others is pathological but who do not claim to be loved in turn. It may be based on a delusion, an overvalued idea, or an obsession. It may be part of a spectrum that merges with the normal.

The 'incubus syndrome' may be a variant of erotomania. It consists of delusions of imposed sexual approaches or sexual intercourse at night by an unseen lover, the 'incubus'.

Delusional parasitosis,¹¹⁹⁶ a monosymptomatic hypochondriacal psychosis, is one of at least three syndromes associated with the Swedish physician K A Ekblom.¹¹⁹⁷ A person falsely believes that they are infested with insects or worms¹¹⁹⁸. This may be dangerous if the patient burns or floods property. Sufferers may complain of feeling insects stinging, biting or crawling. The patient may wash affected parts excessively, use insecticides or caustics (with secondary dermatitis), use needles to extract 'insects', or burn clothes. Skin may be excoriated, broken or scarred. The *matchbox sign* occurs when a person presents with dust in a box that he believes to be 'bugs'. The latter may be collected on adhesive tape. *Folie à deux* is common in such cases. Freyne and Wrigley (1994) described 6 elderly cases and underlying diagnoses: dementia, drug-induced (Sinemet), primary depression, monosymptomatic hypochondriacal psychosis, and hypochondriasis. There may be an associated organic state¹¹⁹⁹. Many different treatments have been reported as effective¹²⁰⁰. Remission rates are probably the same for typical and atypical antipsychotic drugs. (Lepping et al, 2007)

Delusional parasitosis by proxy may occur in children or pets. (Nel et al, 2001)

Diagnosis

Schizophrenia is a diagnosis that entails clear consciousness and the absence of other (drugs, alcohol, dementia etc) possible causes. Psychiatrists are more likely to tell a patient that he has schizophrenia if it is recurrent than if it is a first episode, a stance that most likely refers to an awareness of initial diagnostic instability rather than any conspiracy of silence. (Wild & Petit, 2002)

Differential diagnosis of schizophrenia

Extreme eccentricity/social isolation/sensory deprivation
 Drug-induced disorders: LSD, cannabis, amphetamines, cocaine, and alcohol (including alcoholic hallucinosis)
 Organic cerebral disorders: temporal lobe epilepsy (TLE), infections, Huntington's disease, etc
 Narcolepsy (hallucinations: Haba-Rubio, 2005)
 Paranoid states - delusional disorder (paranoia) and 'paraphrenia'
 Morbid jealousy
Folie à deux
 Affective and schizoaffective disorders
 Obsessive disorder¹²⁰¹

¹¹⁹⁵ Old Maid's Psychosis, de Clerambault's syndrome, *délires passionnels*, or fantasy lover syndrome.

¹¹⁹⁶ Parasitophobia, delusional infestation, Ekblom's syndrome, acaraphobia.

¹¹⁹⁷ Ekblom published his account in 1937, but Thirbierge and Perrin had described the syndrome independently during the 1890s.

¹¹⁹⁸ The present author had a deluded African patient who complained of infestation with the Guinea worm.

¹¹⁹⁹ Alzheimer's disease, Huntington's disease, cerebral infarct, syphilis, cocaine- or amphetamine-induced psychosis.

¹²⁰⁰ Antipsychotics, antidepressants, antipellagrous treatment, B12, iron, leucotomy.

¹²⁰¹ Nechmad et al (2003) found that of 50 adolescents with DSM-IV schizophrenia, 13 (26%) met the DSM-IV criteria for OCD. Obsessive-compulsive symptoms were found to be overrepresented in prodromal (for psychosis: 'ultra-high risk') adolescents by Niendam et al. (2008) Comorbid schizophrenia and OCD ('schizo-OCD') may be associated with particularly severe set-shifting difficulties and there may be an excess of tics. (Patel et al, 2010)

Schizoid or schizotypal personality disorder

Foreign cultures and sub-cultures

Adolescent adjustment difficulties

Gaslight phenomenon: spouse or other caretaker stresses partner/charge in order to induce psychosis-like change in order to have then admitted to hospital

Treatment strategies

'(Before phenothiazines) schizophrenic patients hallucinated openly, talking animatedly to non-existent companions, cowering from imagined attack, or preparing to fight imaginary enemies. Delusions were common'. (Jones, 1991)

The treatment of schizophrenia is not confined to a prescription. A package of care should be designed to meet individual requirements. The optimal agent and dose of a treatment can vary over time. (Tandon & Nasrallah, 2006)

According to many authors (Falloon ea, 1998; Drake ea, 2000; Verdoux & Cougnard, 2004; Iyer ea, 2008; Jeppesen ea, 2008; White ea, 2009; McGorry ea, 2010; Saravanan ea, 2010¹²⁰²) duration of untreated psychosis (DUP¹²⁰³) is associated with poor premorbid adjustment, severe negative symptoms, poor insight, social isolation and poor coping skills and shorter DUP correlates with improved prognosis. Possible reasons for delayed access to care in rural Egypt include belief in spirit causes, preference for traditional healers, and being female. (El-Adl ea, 2008) Patients in less well off economies tend to have longer DUPs. (Large ea, 2008) Clarke ea (2007) found that 171 patients in Dublin had an average DUP of 18 months (shorter in mania than in schizophrenia). DUP was not associated with age of onset of psychosis but longer DUP was associated with increased social withdrawal. Less negative symptoms, more years spent in education, and shorter DUP predicted better outcome at 4 years in an Irish study of first-episode schizophrenia. (Whitty ea, 2008) Self-harm was common (11.3%) in first episode psychosis between psychosis onset and presentation to services in an English survey. (Harvey ea, 2008) Independent correlates of self-harm were male sex, social class I/II, depression, and a prolonged DUP. Increased insight was also associated with self-harm. Reducing DUP in first-episode schizophrenia ameliorated negative symptoms in a two-year study. (Melle ea, 2008) Dodgson ea (2008) looked at two groups of psychosis patients, one attending a service in Northumberland before the setting up of an early intervention service and the other following initiation of such a service: the latter had less hospital admissions, less total bed days, and better engagement with the service; also, the authors suggested that an early intervention service saves money in the longer term. A Melbourne study (Henry ea, 2010) followed up first-episode psychosis patients who had presented to the Early Psychosis Prevention and Intervention Centre (EPPIC). Median follow-up was 7 years after index admission. There were 723 cases but follow-up information was available for 651 cases. In the last 2 years, 57% of schizophrenia/schizophreniform cases, 54% of schizoaffective cases, 62% of affective psychosis cases, and 68% of patients with other psychosis reported some paid employment. 37-59% of the cohort achieved remission of their symptoms, 31% were in social/vocational recovery, and around one-quarter of cases were in symptomatic remission and in social/vocational recovery. A major problem with this very positive study was the lack of a control group.

Black people in the UK do not appear to have longer treatment delays than White British patients. (Morgan ea, 2006a) It is strongly suggested that early institution of treatment reduces future relapse rates and prevents or limits deterioration (e.g. Loebel ea, 1992; Scully ea, 1997; Drake, 2000; Harrigan ea, 2003; Keshavan ea, 2003; Melle ea, 2004; Addington ea, 2004; Marshall ea, 2005; Perkins ea, 2005; Garety ea, 2006; Clarke ea, 2006) but some studies disagree that DUP has an influence on treatment response. (e.g. Robinson ea, 1999; Ho ea, 2000) An association between DUP and neurocognitive function at baseline has been found by some (Keshavan ea, 2003) but not all researchers. (Rund ea, 2004; Lawoyin ea, 2007) Larsen ea (2004) reported that patients with a stable social course compared with a deteriorating course had a shorter DUP, but Marshall ea, (2005) in a systematic review, found that premorbid adjustment did not

¹²⁰² This study from India found a relatively good 1-year outcome and changes in psychopathology and insight during the first 6 months and DUP predicted outcome.

¹²⁰³ Due to funding restrictions, the Dublin East Treatment and Early Care Team (DETECT)/Wicklow (DELTA) project was launched in 2005/6 as a pilot project. Basically, patients with early symptoms (e.g. ideas of reference or interference with thinking) and signs (e.g. marked social isolation or impaired scholastic functioning) of (any) psychosis (and their families) receive a battery of tests (e.g. SANS) and, where appropriate, CBT and family psychoeducation are offered. (McWilliams, 2006; Foley, 2006)

explain the observed relationship between DUP and outcome. Perkins *et al* (2004) found that earlier antipsychotic treatment improves outcome in first episode schizophrenia, but so did good premorbid functioning. Barnes *et al* (2008) assesses 98 cases of first episode schizophrenia at presentation and after a year had lapsed: longer DUP predicted more severe positive and negative symptoms and poorer social function at one year, and DUP was not significantly associated with cognition. Norman *et al* (2005) concluded that DUP is probably important for predicting remission of positive symptoms over the first year of treatment, but that the evidence concerning neurotoxicity of DUP is inconsistent. The evidence available is entirely correlational and new approaches to research may provide firmer evidence. An association of longer duration of symptoms with poorer outcome is not unique to psychosis in psychiatry. (Kisely *et al*, 2006) Most cases of first-episode schizophrenia (FES) do not receive treatment until months or even years have passed since the first symptoms developed, which may be toxic to the brain. (Waddington *et al*, 1995) Psychosis may take considerable time to become obviously such and needs to be distinguished from normal adolescence. Morgan *et al* (2006b) found that insidious onset and unemployment increased DUP, the opposite applying to having a family who sought help. A high index of suspicion and a readiness to refer early are suggested. Funding of early intervention teams is controversial in a resource-strapped era, (David, 2004) some authors suggesting that monies are diverted thereby from the care of patients with severe and enduring disorders. (See Pelosi & Birchwood, 2003 for debate) Greater involvement at primary care level is needed to make early intervention work and people need to be helped within the community to seek help. (Shiers & Lester, 2004)

Not all authors agree that there is adequate evidence for early intervention in psychotic disorders. Bosanac *et al* (2010) suggest that there may be no beneficial effects in the long term and that rates of transition to psychosis are too low to justify intervention outside of research settings. Cunningham Owens *et al* (2010) looked at the Northwick Park Study of First Episodes data from the DUP viewpoint: bizarre behaviour at admission made the single biggest contribution to outcome and the authors suggest that DUP may reflect characteristics of psychosis rather than any effect of treatment delay. Gafoor *et al* (2010) reported that early intervention in non-affective psychosis gives superior results to those achieved by generic mental health services but that gains achieved tend to be lost when patients are handed back to the generic team, suggesting that improved generic teams might be as good as early intervention teams.

Non-compliance with treatment in schizophrenia

Major problem

Up to 50% of outpatients do not comply with prescribed treatment

Some patients are cognitively compromised, challenging the idea of informed consent

Reasons given by patients for non-compliance: thinking more clearly (subjectively) when psychotic, side effects (acute dystonia and Parkinsonism common in first-episode cases), feeling better, dissatisfaction with treatment, forgetfulness, lack of transport, financial reasons, failure to improve, employment, confusion over medication, and being out of town

Syrup and depot preparations, and possibly¹²⁰⁴ atypical drugs, (Lieberman *et al*, 2003; Haddad, 2008) increase compliance

Patients prescribed depots tend to have less insight than do those on atypical drugs (Mahadun & Marshall, 2008)

Sophisticated testing suggests very few acute voluntarily admitted patients understand need for antipsychotic drugs (Paul & Oyebode, 1999)

Patients outside hospital have only limited knowledge about their depot medications (Goldbeck *et al*, 1999)

Adherence therapy may not be effective, at least in ordinary clinical settings (Gray *et al*, 2006)

Beta-blockers in high dosage were suggested but have not become popular, results being contradictory. (Wahlbeck *et al*, 2000) They interfere with phenothiazine catabolism, which may account for at least some of their alleged therapeutic activity. Classical (typical) neuroleptics are said to be less effective for negative symptoms (e.g. social withdrawal) than are the newer, atypical agents, although excessive

¹²⁰⁴ Valenstein *et al* (2004) examined compliance by checking on the filling of prescriptions among 63,000 people with schizophrenia in the US Veterans Affairs medical system and found widespread non-compliance for both conventional and atypical antipsychotics.

dosing with the earlier drugs may have been partly responsible.¹²⁰⁵ Antipsychotic medication should be continued for at least 6 months in acute cases. Megadosing with neuroleptics was fashionable but more time on more conservative doses may have the desired effect. There is a potential danger of sudden death when excessive doses are employed. Similarly, caution has replaced rapid neuroleptisation because of the potential risks of neurological and cardiac adverse effects; anyway, the efficacy of rapid escalation of doses in order to speed up response has not found support from research. Cigarette smoking stimulates hepatic enzymes, thereby enhancing drug metabolism. Patients who smoke may need higher doses of antipsychotic drug than do non-smokers. Nicotine reduces Parkinsonian side effects, possibly because of nicotine-dependent activation of dopaminergic neurones. One theory states that there may be a primary defect in the CNS nicotinic system in schizophrenia leading to abnormal sensory gating.

There is insufficient evidence to guide clinicians about when or in whom to stop maintenance drug therapy for schizophrenia. (APA, 2002, p. 433) If a trial off drugs seems warranted dosage should be tapered slowly as this approach is associated with lower relapse rates than is abrupt cessation of medication. McEvoy *et al.* (2006) found clozapine superior to other atypicals in chronic schizophrenic patients who did not respond to one atypical and the same group (Stroup *et al.*, 2006) found that in chronic schizophrenic patients who just stopped taking an atypical that risperidone and olanzapine were more effective than quetiapine and ziprasidone. Use of medication only when symptoms emerge is associated with an increased risk of relapse and admission to hospital. (Schooler *et al.*, 1997) Anyway, so-called early warning signs have only a predictive value of 43%, no better than by chance. (Gaebel, 1999) Benzodiazepines (BZDs) may sometimes prevent progression if given early in the course of a relapse. There is a tendency for schizophrenic patients to receive long term BZDs in conjunction with antipsychotic drugs. The addition of the selective cyclooxygenase-2 (COX-2) inhibitor celecoxib to risperidone improved symptomatology in schizophrenia in a prospective, double-blind study. (Müller *et al.*, 2002) Whether this resulted from an immune action or an NMDA receptor effect was unknown.

In the Robinson *et al.* (1999) study, poor response to antipsychotic medication in first episode schizophrenia or schizoaffective disorder was associated with being male, having a history of OCs, severe hallucinations or delusions, poorer baseline attention, and Parkinsonism during treatment. Whilst Irish GPs usually refer first episode cases of schizophrenia they may avoid prescribing antipsychotic drugs themselves and may advise such patients to continue medication for less than a year. (Gavin *et al.*, 2006)

Sikich *et al.* (2008), using a double-blind methodology, treated paediatric cases of schizophrenia or schizoaffective disorder for 8 weeks with one of three antipsychotic drugs: molindone¹²⁰⁶ showed a 50% response rate plus an excess of akathisia; olanzapine showed a 34% response rate plus an excess of weight increase and metabolic problems; and risperidone showed a 46% response rate plus an excess of weight increase and was associated with weight gain, albeit less than with olanzapine. Aripiprazole was superior to placebo in the acute treatment of 13-17 year-olds with schizophrenia (Findling *et al.*, 2008), the main adverse effects being EPS, somnolence, and tremor.

Strous *et al.* (2003) augmented the antipsychotic therapy of DSM-IV schizophrenics with oral dehydroepiandrosterone (DHEA)¹²⁰⁷ in a double-blind study and found an improvement in negative, depressive, and anxiety symptoms.

Silver *et al.* (2003) and Bodkin *et al.* (2005) found fluvoxamine and selegiline (MAO-B inhibitor) to improve negative symptoms respectively.

Electroconvulsive therapy is still a useful treatment for some cases of schizophrenia. (Chanpattana & Andrade, 2006) Transcranial magnetic stimulation (TMS) applied to the left temporo-parietal region may have beneficial effects on auditory hallucinations. (e.g. Hoffman *et al.*, 1998) However, despite observed improvement in negative symptoms and a trend toward improvement in depression with high-frequency rTMS, Hajak *et al.* (2004) reported a trend for worsening positive symptoms in schizophrenic subjects. Holi *et al.* (2004)¹²⁰⁸ found no therapeutic benefit from rTMS in a group of chronic and severely ill schizophrenia

¹²⁰⁵ **Efficacy v side-effects:** Ganguli and Strassnig (2006) hold that efficacy differences between older and newer drugs (excepting clozapine) are small, that side-effect differences come down to a trade-off (neurological v metabolic), and that the older ones are a cheaper option (especially when treatment is for the long term). The meta-analysis of Crossley *et al.* (2010) found that typical and atypical drugs were of similar efficacy but the side-effect profile was different.

¹²⁰⁶ Patients received bentiropine with this first-generation of antipsychotic.

¹²⁰⁷ Starting with 25 mg/day and titrating up to 100 mg in divided doses during 6 weeks.

¹²⁰⁸ Sham v real rTMS.

patients. Loo et al (2010) found no reduction in auditory hallucinations in subjects with schizophrenia given rTMS during the initial (double-blind, sham-controlled, left and right temporal lobe rTMS) phase of their study but there was a modest improvement during the continuation (open label) phase of treatment. There is a suggestion of abnormal corpus callosum function from TMS research as suggested by a delay in transcortical inhibition. The work of Daskalakis et al (2002) with TMS suggests that schizophrenia is associated with deficits in cortical inhibition and that antipsychotic drugs may increase cortical inhibition.

Management of clozapine-resistance (Williams et al, 2002; Kerwin and Bolonna, 2005)

Consider a longer trial of clozapine¹²⁰⁹

Consider measuring clozapine levels

Adding (or switching to) sulpiride (Shiloh et al, 1997), risperidone (Josiassen et al, 2005¹²¹⁰), aripiprazole (Henderson et al, 2006), pimozide, olanzapine, quetiapine, or lamotrigine

Effect of ECT may not be sustained - continuation/maintenance ECT may be an option (see Hustig & Onilov, 2009)

Psychosocial issues may require attention, e.g. EE, family therapy, compliance therapy, and psychotherapy for hopelessness

Obsessive-compulsive symptoms, common in schizophrenia, may respond to the addition of clomipramine or SSRIs, and fluoxetine may reduce a tendency towards violence, participation in programmes and socialisation in some cases.

Obsessive-compulsive symptoms (OCS) in schizophrenia (Tiryaki & Özkorumak, 2010)

N = 62 patients and 35.5% of these had OCS

Those with OCS had more severe psychotic symptoms and worse quality of life but neurocognitive function was the same whether OCS was present or absent

Positive correlation found between obsessions and delusions and between compulsions and total Scale for the Assessment of Positive Symptoms score and bizarre behaviour subscore

Psychotherapeutic interventions¹²¹¹, practical advice and help with environmental problems, and stress management training (for patients and carers) are helpful. Psychoanalytic treatments are rarely indicated.¹²¹² Psychotic transference phenomena may complicate such approaches, e.g. the patient believes the therapist to be a hostile father and cannot distinguish an as-if feeling from reality. However, psychoanalytic theory may provide useful insights into the meaning of psychotic behaviour and thinking that, when used judiciously, may be helpful.

Cognitive behaviour therapy: In the setting of a non-confrontational, trusting relationship, patients are asked to review symptoms and associated reasoning, to monitor them, to change the focus of attention and to relax, and to modify behaviour.

Cognitive behaviour therapy (CBT)¹²¹³

Not always available (Kingdon, 2006)

Normally an adjunct to medication (Scott, 2007)

Pharmacological stabilisation is a prerequisite before using CBT¹²¹⁴ (Friedman et al, 2008, p. 1935)

¹²⁰⁹ 30% of treatment-resistant patients responded to clozapine and 4% responded to a conventional neuroleptic but when trials lasted at least six months 60% of patients responded to clozapine. (Kane et al, 2001)

¹²¹⁰ But Honer et al (2006) found no advantage with this combination.

¹²¹¹ Most often supportive.

¹²¹² But see Cullberg (2006): whilst one would not employ full psychoanalysis, some cases benefit from limited-goal psychoanalytic-informed help.

¹²¹³ Holloway (2001, p. 173) points out that prioritisation of clinical activities is essential: '...it is futile to demand' **CBT for psychosis** 'if these skills are not available locally'. Various CBT techniques are employed. (see Turkington et al, 2006) The therapist may need to appear neutral regarding delusional beliefs. A strong therapeutic alliance is important. 'Peripheral questioning' is a way of getting the patient to go into details about delusions. 'Inference chaining' involves discovery of the meaning for the patient and the trail of thinking underlying such beliefs. 'Graded reality testing' is the process whereby the patient is brought to question delusions and to consider other possible explanations.

¹²¹⁴ This applies to a number of disorders, e.g. schizophrenia, psychotic depression, and bipolar disorder.

May help patients cope with delusions¹²¹⁵

Startup ea (2004, 2005) reported sustained symptomatic and social functioning benefits in consecutive admissions with acute schizophrenia spectrum disorders who received CBT (v treatment as usual)

Lewis ea (2002) found only transient positive effects for acute symptoms in early schizophrenia

Morrison ea (2004) evaluated efficacy of CBT (given for 6 months) over 12 months in 58 people at very high risk for developing psychosis and found that a reduced likelihood of developing psychosis

Tarrier and Wykes (2004) found no study that showed clear and significant overall differences between CBT and non-specific control groups

Jackson ea (2005) found no advantage for cognitively-orientated psychotherapy over and above routine care for early psychosis

Wykes ea (2005) found that group CBT significantly ameliorated hallucinations only if led by skilled therapists

Jackson ea (2008) found that CBT (up to 20 sessions in 14 weeks) was better than befriending¹²¹⁶ in promoting better early recovery in first-episode psychosis, although the sample was relatively small

In an open trial design (n = 20 adults) 11-weeks of exposure-based CBT reduced PTSD symptoms in patients with PTSD and schizophrenia or schizoaffective disorder and this effect was maintained at 3-month follow-up (Frueh ea, 2009)

CBT may be useful for patients in the early stages of psychosis with problems in the area of social recovery (Fowler ea, 2009)

Meta-analysis: CBT is no better than non-specific control interventions in the treatment of schizophrenia and does not reduce relapse rates (Lynch ea, 2010)

Schizophrenia is over represented among the homeless, many of whom will have no or only erratic contact with mental health services.(O'Shea, 1998) Patients need help to become more active and less withdrawn. Redevelopment of skills can be aided by industrial and occupational therapy, social therapies, living-skills courses, day care programmes, rehabilitation schemes, community care schemes, and sheltered accommodation that provides support and supervision. Halfway houses and hostels may ease transition from hospital to community. Employment at some level, often below their previous level, is essential, be this open or sheltered. The aim of rehabilitation is to promote optimal functioning. Too much or too little pressure should be avoided. Even with optimal rehabilitation, many patients will require continuing attention and care. Schizophrenic patients may improve in an area specifically chosen for treatment, such as one aspect of memory, without benefit generalising to other aspects of the same function. Improvement in verbal memory may correlate with increased task-related activation of the left inferior frontal cortex during fMRI. However, one meta-analysis of cognitive remediation and social skills training in schizophrenia found them to have no benefit (Pilling ea, 2002b) and another meta-analysis (McGurk ea, 2007) found moderate improvement in cognitive performance with cognitive remediation. Krabbendam and Jolles (2002) conclude that the jury is still out on cognitive remediation whereas Szöke ea (2008) suggest that practice produces better results than cognitive remediation. Dickinson ea (2010) found that measures of cognitive function improved with computer-assisted cognitive remediation but that such improvement was not reflected in broader neuropsychological or functional outcome measures. However, Hogarty ea (2004) report positive findings for cognitive enhancement therapy (CET) for stable schizophrenic subjects in a 2-year randomised trial and the positive effects are durable at 1-year follow-up in early schizophrenia.(Eack ea, 2010) Also, there is evidence that cognitive enhancement therapy¹²¹⁷ may increase serum BDNF levels.(Vinogradov ea, 2009a) Cognitive enhancement therapy may also help to preserve grey matter in early schizophrenia.(Eack ea, 2010) Attention shaping, a reward-based learning procedure, may improve attentiveness and promote skill acquisition in people with chronic schizophrenia.(Silverstein ea, 2009) The family and self-help groups need support.(O'Shea, 1994)

Some notes on rehabilitation in schizophrenia

¹²¹⁵ Some of the research evidence for the efficacy suffers from small numbers,(Valmaggia ea, 2005) from non-blindness, and from lack of supervision of drug therapy.

¹²¹⁶ Befriending consists of talking about non-upsetting subjects or engaging in activities such as board games or walking.

¹²¹⁷ Clinically stable, chronic schizophrenia patients received either 50 hours over 10 weeks of computerised auditory and verbal processing training or (with no effect on BDNF levels) computer games.

No medication corrects years of psychosocial damage
 New emphasis on teaching and training with focus on behaviour and functioning – focus less on unfocused industrial-type work and more on specific problem areas
 Treatment planning should be individualised: needs and capacities
 Greater involvement of client in setting goals and planning treatment (may take a long time)
 Impaired information processing is a major obstacle
 Multiple domains involved: attention, abstract reasoning, verbal and working memory, processing speed, sensorimotor integration – determine extra mural performance and ability to stay in social skills program
 Verbal learning is an important predictor of change in performance of daily living skills (Kurtz ea, 2008)
 Difficulty generalising skills from training to real life
Social skills training: small groups; break down behaviours into components; instruct how to master each part; rehearse in simulated social situations – combined with assertive outreach such skills may survive into real life (Lieberman ea, 2001)
Cognitive rehabilitation – e.g. cognitive remediation therapy (Wykes ea, 1999, 2007): one patient to one therapist; graduated focus on executive functioning/problem-solving
Cognitive adaptation training: Environment structured to reduce demands on client, e.g. organising appropriate clothing, reminders re medication, notes on mirrors (Velligan ea, 2000)
Vocational rehabilitation: Case manager finds patient a real job and supports him/her in that position (Drake ea, 1999)

Counselling, help and practical guidance are the main ingredients of such intervention.(see box) A number of families need to be treated to produce a measurable affect on relapse or hospitalisation rates. Treatment needs to be intense and prolonged.(Birchwood & Spencer, 1999) A number of authors have speculated that the main effect of family interventions may be improved medication adherence although Girón ea (2010) found family intervention effects to be independent of compliance and prognostic factors. Others have suggested that when the high dropout rate from family interventions is taken into account (intention to treat analysis) there is a significant reduction in benefit in terms of relapse prevention. Still others have commented on the lack of effect of behavioural interventions on intrafamilial communications. Priority families for intervention include those with a treatment-compliant schizophrenic relative living with them but who relapses frequently, those in whom disagreements erupt into violence, families who resort to the police, and those making heavy demands on staff.

Assertive community treatment (ACT) programmes involve outreach¹²¹⁸, high staffing levels, heavy involvement of nurses and counsellors, frequent visits, direct compliance monitoring, co-ordination of social services by treatment team and careful following of patient through the system, and the use of patient and family satisfaction as outcome measures. The Danish OPUS Trial (Bertelsen ea, 2008) found that such intensive treatment¹²¹⁹ (versus community mental health centres) of first episode psychosis patients improved clinical outcomes at two years but that that the effects were not sustained at five years¹²²⁰.

Family intervention strategies (Kane and McGlashan, 1995)

- *Psychoeducation* – didactic information about the illness; information about vulnerability to relapse/role of stress; understand need for treatment to control symptoms*
- *Stress management* – enhanced communication (listening skills, clarifying wants/needs, providing positive/negative feedback), problem solving (managing daily problems and discrete but significant stressors, general problem solving skills)
- *Crisis intervention* – recognising prodromal signs/symptoms, plans to deal with threatened compliance, active intervention during prodrome or relapse during treatment, and more structured psychosocial programmes

*Burns (1999) stated that that psychoeducation adds little where general services are well developed. Haley (2009), who employed telemedicine in Donegal to link up to a program already provided by St John of God services in Dublin, discussed carer education (not well provided for even in US and UK) the main aims of which are improved empathy, provision of knowledge, non-pathologising

¹²¹⁸ The team goes to the patient.

¹²¹⁹ ACT, psychoeducation, and social skills treatment.

¹²²⁰ However ACT patients fared better in terms of numbers in supported housing and days in hospital.

approach with emphasis on improved coping, communication skills (clear instructions and balance between support and expectations), and better problem solving. Carer education can be provided by a range of health professionals.

Prevention of schizophrenia

There are good reasons why primary prevention is currently impossible. (Murray & Castle, 2000) If all cases with a first degree relative could be prevented, it would remove only about one in ten of all cases. Most babies exposed to severe OCs do not develop schizophrenia (although special care is indicated to avoid hypoxia in the birth of a schizophrenic patient's offspring). Early precursors of schizophrenia in childhood are too non-specific and many children who later develop schizophrenia are perfectly normal as children.

Olanzapine reduces the positive symptoms of prodromal psychotic states but induces weight gain. (McGlashan et al, 2006) There is some evidence that antidepressants or CBT given during the prodrome may help to prevent overt psychosis (Fusar-Poli et al, 2007), although methodological issues (e.g. small numbers and bias in prescribing) abound.

Delusions

As for hallucinations, delusions of influence might simply derive from a real difficulty in attributing one's own actions to the self. (Synofzik et al, 2009) Some patients derive meaning and importance from their delusions, recovery being too much to bear. A schizophrenic patient may believe that he is the president of his country whilst residing in gaol for petty theft: this profound lack of awareness of a fundamental contradiction is called *double orientation*.¹²²¹ Psychoanalysts have interpreted delusions as providing a defence against low self-esteem, although it is difficult to see how a delusion of persecution could fulfil this role (unless persecution is equated with self-importance¹²²²). Delusions tend to keep pace with the times, e.g. being spied upon by satellite dishes during the late twentieth century.

Somatic delusions relate to the body. McGilchrist and Cutting (1995) found that male schizophrenics located abnormal phenomena principally on the left with depressives locating them on the opposite side, results that might relate to localisation of brain dysfunction in psychosis. The schizophrenic patients typically had delusions of a 'peculiar' sensation, or, more specifically, of rotation and paraesthesiae. Depressives more often had delusions of blockage, pressure, weight, fullness, liquidity, pain or weakness.

Hallucinations

Perhaps half of psychiatric patients who have auditory vocal hallucinations experience welcome as well as unwelcome voices, and up to half of them wish to keep them. (Jenner et al, 2008) Deaf people can have auditory hallucinations and people blinded by cataracts can experience visual hallucinations. Hallucinations are often said to be experienced as originating in the outside world or within one's own body, but not, according to time-honoured dogma, within the mind as through imagination¹²²³. Third person auditory hallucinations heard in clear consciousness are not unique to schizophrenia, being found also in alcoholic hallucinosis. Auditory hallucinations are common in mania. It is suggested that people that feel marginalised or subordinate in society may hear voices of people they believe to be their superiors. It has been known for many years that direct stimulation of superior temporal gyrus structures can provoke complex hallucinations. Altered preconscious planning of discourse has been suggested as a cause of auditory hallucinations in schizophrenia. Defective feedback so that self-generated subvocal speech is not recognised as such constitutes another such hypothesis. (Stephane et al, 2010) The problem may be in disrupted speech perception and verbal working memory rather than in non-language cognitive or attentional deficits. Imagining sentences spoken in another person's voice necessitates monitoring of inner speech. Using this technique and PET it has been shown that hallucinating schizophrenics deactivate the *left* middle temporal gyrus and the rostral supplementary motor area, these parts of the brain being strongly activated by normals and non-hallucinating schizophrenics. However, an fMRI study (Shergill et al, 2003) found that getting the schizophrenic subject to increase the rate of inner speech was associated with a relatively attenuated response in the *right* temporal, parietal, parahippocampal and cerebellar cortex. Also, Diederen et al (2010), also using fMRI, found that patients with a psychotic disorder deactivated the

¹²²¹ In the past, this same phenomenon was well described in sufferers from general paresis (e.g. Al Capone).

¹²²² However, one sometimes sees a patient with so-called '*delusions of assistance*' wherein persons/deity/forces/powers/organisations try to help him/her improve themselves or overcome some problem. (McKenna, 2007, p. 3)

¹²²³ However, many patients admit that voices are heard inside the head. (Mayer-Gross et al, 1969; Lawrie & Johnstone, 2004, p. 394; McKenna, 2007, p. 197)

parahippocampal gyrus *before* reporting auditory verbal hallucinations. Hoffman *et al.* (2008) performed fMRI on six right-handed (dextral) patients with either DSM-IV schizophrenia or schizo-affective disorder in order to map changes before onset of auditory hallucinations. Patients activated left anterior insula and right middle temporal gyrus and deactivated anterior cingulate and parahippocampal gyri. In another study, when hallucinators imagined speech they differed from other groups by their reduction in activity of the parietal operculum. (McGuire *et al.*, 1996) However, some authors have found no evidence that schizophrenic people are unable to distinguish an inner voice from external speech. Others have found an inability of patients with a wide range of psychoses who had auditory hallucinations or passivity phenomena to distinguish between self-stimulation and external stimulation (tap own palm *v* experimenter doing so). Maruff *et al.* (2005), using MRI, found a connection between reduced volumes of parietal and frontal association areas and motor passivity delusions. Fu *et al.* (2001) got healthy volunteers and schizophrenic patients to read adjectives aloud, their voice then been audible in a distorted or undistorted manner. Controls hearing their own distorted voice activated hippocampus, cingulate and cerebellum. Acutely psychotic patients failed to engage these areas of the brain and tended to attribute their own distorted voice to other people. Remitted patients showed activation patterns intermediate between the controls and the acute psychotics.

Unilateral auditory hallucinations have been reported in association with a contralateral left superior temporal gyrus lesion and ipsilateral conductive deafness; the hallucinations stopped on wearing a hearing aid. MRI studies suggest that schizophrenics with auditory hallucinations have a smaller superior temporal gyrus. (O'Shea, 1997) PET studies in hallucinating schizophrenic patients suggest low metabolism in the right hemisphere homologue of Broca's area; severity of hallucinations are related to relative metabolism in striatal and anterior cingulate areas; and antipsychotic drugs increase striatal metabolism. (Cleghorn *et al.*, 1992) SPECT studies reveal increased blood flow in Broca's area under the same circumstances. (McGuire *et al.*, 1993) In the Shergill *et al.* (2000) study, fMRI revealed evidence for attenuated activation when schizophrenic patients with auditory hallucinations were processing inner speech in areas implicated in verbal self-monitoring (posterior cerebellar cortex, hippocampi, superior temporal cortex, and nucleus accumbens). Other fMRI work suggests involvement of somewhat different areas. Probably, auditory hallucinations involve a number of cortical and subcortical areas.

Visual hallucinations are probably much more common in chronic schizophrenia than we generally think. According to Dubovsky and Thomas (1992) visual and auditory hallucinations are equally common in psychotic depression. Visual hallucinations¹²²⁴ are common in Lewy body dementia and have been reported in a minority of dissociative (hysterical) cases. Hallucinations as conversion symptoms ('pseudohallucinations') have a long history and *may* differ in a number of ways from those seen in the psychoses, e.g. childish content (e.g. a giant pink panda), personal meaning (e.g. wish fulfilment), a subjective sense that the hallucinations are not true, multiple-modality involvement, and absence of other manifestations of psychosis. DSM-IV-TR mandates that dissociative identity disorder and PTSD be outruled before diagnosing hallucinations as conversion symptoms. Hallucinations associated with bereavement should also be kept in mind.

The *Charles Bonnet syndrome* consists of poor sight and visual hallucinations.

Autoscopic hallucinations are visual hallucinations of all or part of the self. The vision is usually transparent and colourless and imitates the patient's movements. Onset is usually sudden, unheralded, as with a phantom. Most cases do not progress or incapacitate, the person being able to remain emotionally detached from the experience. An underlying brain lesion should be considered. Autoscopic hallucinations are rare in the functional psychoses, including schizophrenia.

Heautoscopy, an extension of autoscopia, refers to the projection of sensation as well as visual aspects of the self – the patient is able to see and feel his double outside the self. This is different from two phenomena that may occur together in some organic disorders: a *feeling of presence* (feeling that an invisible other being is close by) and from *out of body experience* (feeling that one is separated from one's body).

¹²²⁴ Some people with Parkinson's disease experience visual hallucinations that might reflect dopamine disturbance in the visual system or REM sleep breakthrough whilst napping.

Various non-drug therapies of variable efficacy have been advocated for auditory hallucinations, such as unilateral earplugs (rarely effective), subvocal counting or singing, and listening to music through headphones.

Synaesthesia (stimulation of one sensory modality is experienced as an hallucination in another modality, e.g. 'seeing music') is classically associated with LSD₂₅, although they can occur in people with normal mental states as when a cold feeling in the back follows scraping of a finger nail on a blackboard.

Splitting of perception, a rare experience found in schizophrenia or organic disorders, involves a failure to make the normal link between two or more perceptions, as when a patient watching a movie experiences the visual and sound elements to arise from unconnected sources¹²²⁵.

Musical hallucinations

The composer Schumann believed that deceased composers were dictating melodies that he could hear. Risk factors include acquired deafness, being female or old, cerebral pathology, and being isolated from other people. They have been reported in a number of disorders (e.g. schizophrenia, depression, dementia, salicylates, benzodiazepines, propranolol, clomipramine, ECT, and chronic alcoholism) but may be an isolated non-psychotic phenomenon. The superior temporal lobe may be involved as shown by neuroimaging studies; neurological lesions (tumour, CVA, epileptic focus) may be more common on the right than the left; there may be a history of tinnitus.(see Stewart *et al*, 2006) Bilateral musical hallucinations were described in a syphilitic woman in Wakefield asylum with brain damage associated with focal epilepsy following surgery during the 1890s. Her mental state is said to have improved despite these complications!(Goodall, 1893) Musical hallucinations were elicited at surgery during the 1950s by stimulating the temporal cortex. They may occur in association with vascular lesions of the left temporal/parietal lobes. Some musical hallucinations may respond to anticonvulsants and be refractory to antipsychotic drugs.

In *phantom radio* the patient hears repetitive instrumental or vocal music, often familiar to the patient.(Warner & Aziz, 2005)

Command hallucinations (e.g. 'Assault her!') should alert carers to the possibility of violence to the self or others.

People who value their hallucinations before receiving treatment are more likely than others to be hallucinating despite being treated. Chronic hallucinations may be viewed as 'companions' or as 'persecutors'. The number of reported 'voices' may increase, dialogue may become extended, and the degree of intimacy with the subject may also increase.(Nayani & David, 1996) Even if treatment does not rid the patient of hallucinations they may become less frequent or intense and less likely to determine overt behaviour.(Miller, 1996)

Catatonia

Once commonly reported,(Kahlbaum, 1874, O'Shea, 2001; Bräunig & Krüger, 2004; Rajagopal, 2007; Fink & Taylor, 2009) catatonia has become apparently 'rare' (or missed) and non-specific,(Caroff *et al*, 2004) especially in developed countries, at least in its classical form.(Chalasani *et al*, 2005) Catatonia has been reported to be more common in affective disorders (Dabholkar, 1988; Taylor & Fink, 2003) than in schizophrenia. Hysterical cases are rare. Other causes include brain disease, metabolic disturbances, alcohol and drugs.

¹²²⁵ Badly dubbed movies excluded.

Karl Ludwig Kahlbaum (1828-1899)

*Organic causes of catatonia*¹²²⁶

Infection¹²²⁷
 Head injury
 Cerebral tumours
 Vascular¹²²⁸
 Wernicke's encephalopathy
 Multiple sclerosis
 Lesions of third ventricle, brain stem, or basal ganglia
 Metabolic¹²²⁹
 Drugs¹²³⁰
 Benzodiazepine withdrawal
 Epileptic¹²³¹
 Childhood affectations – learning disability, autism, Prader-Willi syndrome

The EEG is generally normal in catatonia.

Catatonia seems to be a disorder of the appropriate termination of movement rather than of initiation as in Parkinson's disease.

Suggested mechanisms underlying catatonia

Neuroimaging studies suggest a mainly *cortical disorder* in catatonia, whereas NMS is a basal ganglia disorder with secondary involvement of cortical motor structures (Northoff, 2004)
 Catatonic withdrawal represents *primitive avoidance-separation behaviour* (Fricchione, 2004)
GABA deficiency (BZDs are used in treatment)
Sudden and massive blockade of DA (antipsychotics may precipitate/exacerbate the disorder)
Cholinergic and serotonergic rebound (as in clozapine-withdrawal catatonia)

Apart from catatonic schizophrenia itself, other schizophrenic subtypes may manifest transient and single catatonic symptoms. Whether it is a subtype of the neuroleptic malignant syndrome (NMS) is debatable (*cf. infra*). According to Carroll, (2001) 10% of catatonic patients may develop NMS. Although more than forty motor signs of catatonia are known, Taylor and Fink (2003) would make the diagnosis if two prominent features were present for at least 24 hours. Using the Taylor and Fink definition, catatonia occurs in about one in ten acute psychiatric inpatients. Studies in rats found that endorphin injected into the cerebral ventricles lead to catatonia. Therefore, it was suggested that intravenous naloxone would reverse catatonia in man. However, there is little evidence to support this contention, including the present author's clinical

¹²²⁶ Organic catatonic disorder in ICD-10, catatonic disorder due to a general medical condition in DSM-IV.

¹²²⁷ E.g. anti-NMDAR encephalitis (a paraneoplastic syndrome with anti-NMDA receptor antibodies), encephalitis lethargica, herpes simplex.

¹²²⁸ Basilar thrombosis.

¹²²⁹ Hyperthyroidism, porphyria, hypercalcaemia, diabetic ketoacidosis, carcinoid syndrome, hepatic encephalopathy, homocystinuria, carbon monoxide, NMS.

¹²³⁰ Alcohol, disulfiram, neuroleptics, lithium, amphetamines, phencyclidine, corticosteroids.

¹²³¹ Non-convulsive epileptic status.

experience. Complex dysfunctions of DA, GABA-A and GABA-B, and NMDA receptors may be involved in catatonia.

ICD-10 criteria for catatonic schizophrenia (F20.2)

Prominent psychomotor disturbances

May alternate between hyperkinesia and stupor, or automatic obedience and negativism

Constrained attitudes and postures may be held for prolonged periods

There may be episodes of violent excitement

Catatonic phenomena may be combined with an oneiroid (dream-like imagery) state¹²³² with vivid scenic hallucinations

Chronic schizophrenic patients may have command automatisms (automatic compliance with instructions) and perseveration of words and phrases.

General features of catatonia

Psychomotor disturbances predominate: can change from stupor to hyperactivity

Waxy flexibility (flexibilitas cerea): found in catatonic schizophrenia (stuporose type) - resistance to passive limb movement resembling that found on bending the candles of yesteryear; *blocking/freezing* refers to the sudden stopping of a purposive movement midway in its enactment, followed by fixation in that position or gradual return to the resting position; waxy flexibility may also occur in hepatic encephalopathy

Maintenance of imposed postures – a limb left in any position will remain there, despite gravity¹²³³

Stereotypy, posturing, catalepsy, echolalia and echopraxia; automatic obedience - unquestioningly does what is requested

Obstruction: intermittent difficulty/inability to carry out an action; may not complete intended actions - may resist compliance until examiner appears to stop requesting an action (despite repeated requests to be seated nothing happens until examiner goes to leave)

Opposition: opposition to attempted passive movement

Negativism:¹²³⁴ apparently motiveless resistance to suggestion or interference (refuses to carry out requests or follow instructions)

'Command negativism': patient reflexly does the opposite of what is asked of him (if asked to approach, he retreats; if asked to keep seated, he stands)

Mutism - no verbal communication¹²³⁵; found with severe depression or catatonic schizophrenia

Mood may be depressive or hypomanic

Psychological pillow: patient may lie in bed with his head just off the pillow, requiring sustained sternocleidomastoid muscle contraction. This may last for hours!¹²³⁶ It is also found in dementia.

Catatonic symptoms are not always easy to distinguish from extrapyramidal side effects of drugs, with which they may be related neuro-anatomically. Amobarbital given intravenously may assist in the interview of a catatonic mute, the response being better in one randomised blind trial (compared with saline) if the patient was older and female.

In psychiatric stupor¹²³⁷, the patient is mute, immobile, and conscious; if the eyes are open the patient may follow external movement; there is resistance to passive eye-opening; and the patient is aware of what is being said. The causes of (psychiatric) stupor include psychogenic (rare), depression, mania, catatonic schizophrenia, and akinetic (organic), e.g. Rathke's pouch tumour, cysts of third ventricle.

Medical complications of chronic catatonia

¹²³² The person is awake. Prolonged oneiroid states are sometimes called twilight states.

¹²³³ *Mitmachen* refers to an extreme form of obedience: therapist able to place patient's body part in any position without being resisted, the part slowly returning to its resting position.

¹²³⁴ Somewhat the same is '*ambitendency*': series of hesitant, incomplete movements when expected to perform a voluntary action, e.g. keeps extending and withdrawing his hand when examiner offers his in greeting.

¹²³⁵ A few mute patients may say something as the psychiatrist takes his/her leave: *reaction of the last moment*. This is different from patients who only reveal the crux of the problem at the end of an interview.

¹²³⁶ Maintenance of an uncomfortable position for a few seconds has been called *Haltungsverharren*.

¹²³⁷ Neurologists use the term to infer a reduced level of consciousness.

Dehydration, malnutrition, constipation/ileus
 Dental caries/gum disease/fungal oral (and vaginal) disease from antibiotics, aspiration leading to pneumonia and/or pneumonia
 Venous stasis/thrombosis/pulmonary embolism
 Decubitus ulceration
 Urinary retention due to bladder distension, urinary incontinence, urinary tract infection (e.g. indwelling catheter)
 Complications of nasogastric/feeding tube usage¹²³⁸
 Pressure nerve palsies, flexion contractures, vaginal infections (poor hygiene), and colonisation by fleas¹²³⁹
 Rhabdomyolysis (due to prolonged immobility) has been reported in acute lethal catatonia, severe neuroleptic-induced dystonia, and NMS (Levenson & Pandurangi, 2004)

Catatonia responds to benzodiazepines (BZDs) and/or electroconvulsive therapy (ECT). If BZDs fail and ECT is subsequently used treatment parameters may need adjustment due to a raised seizure threshold. BZDs may be less effective in catatonic schizophrenia. (Rosebush & Mazurek, 2004) Bromocriptine may ameliorate both NMS and catatonic stupor. In one study, patients with high Abnormal Involuntary Movement Scale (AIMS) scores and low levels of Parkinsonism had high creatine phosphokinase (CPK) levels and a tendency to respond to lorazepam (Ativan); those with low CPK levels, low AIMS scores and high levels of Parkinsonism tended to be lorazepam-resistant. Lorazepam has demonstrated efficacy in prospective studies whereas neuroleptics have low efficacy. (APA, 2002, p. 567) Amantadine (100 mgs. b.i.d. for several weeks) has been suggested for neuroleptic-induced catatonia. Acute catatonia has also been treated with IV amantadine. IM and IV anticholinergic agents have been used effectively in some cases. Sodium amobarbital can also be effective. (Rosebush & Mazurek, 2004) ECT is the first choice in treatment for lethal (malignant) catatonia. (Petrides et al, 2004)
 Comorbid medical disorders should be stabilised. Seizure-induced cases may respond to lorazepam and anticonvulsant drugs. Dehydration, nutritional disorders, infection (e.g. pneumonia), bedsores, and deep vein thrombosis with pulmonary embolism (from immobility) should be prevented. (Carroll & Goforth, 2004)

Gjessing's syndrome (periodic catatonia)

Rare disorder of cyclical nitrogen retention (Gjessing, 1938)¹²⁴⁰
 Nitrogen retention causes psychosis
 May not constitute one disorder¹²⁴¹
 Attempts at replicating Gjessing's findings have not been uniformly successful (Minde, 1966)
 Reported as autosomal dominant disorder with disease locus mapping to chromosomes 15q15 and 22q13¹²⁴² in different families (Beld et al, 2004)
 According to Beld et al, (2004) most cases are misdiagnosed and partially treated
 Was managed by giving thyroid hormones or low nitrogen diet to deplete body nitrogen storage – this may have helped some cases - modern pharmacotherapy largely replaced such approaches

Stauder's acute lethal (malignant, pernicious) catatonia: This rare condition¹²⁴³ could cause sudden death in psychiatric patients and was well known before the neuroleptic era.

¹²³⁸ Oesophagitis, pneumothorax, empyema, bronchopleural fistula, diarrhoea, dependent oedema, bacterial contamination of stomach contents, hypoglycaemia, hypercapnia, electrolyte imbalances.

¹²³⁹ One case had moving circular colonies in the finger web spaces.

¹²⁴⁰ Named for Rolf (or Rolv) Gjessing (1889-1959), a Norwegian psychiatrist.

¹²⁴¹ According to McKenna (2007, p. 368) a schizophrenic outcome was 'evident' in Gjessing's cases. Also, these patients do not seem to have been mentally recovered between attacks (apathy, dullness, insightless).

¹²⁴² The affected gene at 22q13 is WKL1. This gene carries the code for a cation channel protein found in dorsal striatum and the limbic system.

¹²⁴³ Stauder published details of 27 cases of 'lethal catatonia' in 1934, although Calmeil, Bell ('Bell's mania'), and Schüle (Schüle's *delirium acutum*) had described the same syndrome in 1832, 1849, and 1867 respectively. (Bräunig & Krüger, 2004; Mann et al, 2004)

Clinical picture

Personality change

Mood disorder

Hyperactivity

Hallucinations

Delusions

Confusion

Catatonia

Often begins with extreme psychotic excitement, which, if persistent, can lead to fever, exhaustion, and death from respiratory arrest or cardiovascular collapse*

*NMS starts with severe extrapyramidal muscle rigidity (less so when atypical drugs, including clozapine, are involved¹²⁴⁴) and necessitates immediate cessation of neuroleptics, which are ineffective in lethal catatonia. It is therefore important to differentiate between them, but catatonia may precede NMS and may be a risk factor for NMS.

There may be a prodrome lasting weeks to months with behavioural and personality changes or frank schizophrenic symptoms. Alternatively, there may be an acute onset without prodrome. Excitement follows, with intense anxiety and restlessness lasting a few days. There may be self-destructive or assaultive behaviour. Sometimes there are fever, tachycardia, and acrocyanosis. The complete syndrome may include choreiform movements, mutism, rigidity, and/or stupor alternating with excitement. There may be an increasing and fluctuating fever, rapid and weak pulse, profuse and clammy perspiration, and hypotension. Towards the end there are cachexia, convulsions, delirium, coma, and exhaustion. Sudden death may terminate the episode.

The relationship between lethal catatonia and NMS is controversial and both disorders may be clinically identical, or, more controversially, possibly both conditions are the same entity. Lethal catatonia may have become even rarer after the 1950s, when neuroleptics became available.

Antipsychotic drugs should be withheld. ECT may be the most effective treatment (Petrides *et al.*, 2004), especially if given before the onset of coma. (Sackeim, 2003, p. 535) If benzodiazepines (BZDs) have failed, they should not be withdrawn rapidly (withdrawal may provoke or worsen catatonia). Petrides *et al.* (2004) suggest continuing BZDs during ECT. Some patients may need to their BZDs continued for some time after ECT.

There is no laboratory test to help differentiate lethal (malignant) catatonia from NMS. Whilst low serum iron is extremely common in both NMS (96%) and lethal catatonia (100%), it is only found in 34-35% of cases of simple catatonia. (Lee, 2004) Low serum iron is found in many disorders (inflammatory, infectious, tissue destruction, strenuous exercise, and stress). Why iron levels should be depressed in catatonia and NMS is unknown but iron is important for D2 receptor structure and function, perhaps leading to reduced D2 receptor numbers in the basal ganglia. Nevertheless, central and peripheral iron levels are poorly correlated with one another. (Sachdev, 1993) Whilst CPK and leucocyte levels are raised in most cases of NMS and lethal catatonia, leucocytosis is uncommon in simple catatonia and CPK levels are raised in a majority of simple catatonic cases. (Lee, 2004) According to Insel *et al.* (2008) low maternal haemoglobin concentration may be a risk factor for 'schizophrenia spectrum disorders' in their offspring¹²⁴⁵.

In conclusion, catatonic features nowadays are most common in affective disorder, especially mania. They are also seen in organic states and, but not pathognomonic, in schizophrenia. Catatonia is best viewed as a syndrome rather than a final diagnosis. Subtle forms are often missed or ignored. Classically, for acute or prophylactic management, ECT may be the most effective therapy in most cases, although benzodiazepines (BZDs) are gaining favour. ECT may be combined with BZDs in such cases, and the combination may act synergistically, probably because both approaches increase the seizure threshold.

¹²⁴⁴ CPK levels may be normal in NMS secondary to atypical drugs. (Fricchione *et al.*, 2008, p. 767) Also, CPK is often raised in catatonia.

¹²⁴⁵ Does this mean that iron deficiency (iron is important for brain development and function) predisposes to schizophrenia or that mothers carrying children predisposed to schizophrenia are relatively undernourished any way?

Affective (mood) disorders and suicidology

Brian O'Shea

'We need a paradigm shift to recognise that depression is a life course disorder'. (Scott, 2006)

Affective disorders include conditions characterised by excessive depression (L. *de*, down, *premere*, to press) or elation of mood. Depression may mean an appropriate mood state, a symptom, or an illness.

Cost

Mood disorders represent about 21% of the cost of mental illness in America.

Economics of mood disorders¹²⁴⁶

Global

In 2006 WHO says depression is leading cause of years lost because of disability¹²⁴⁷

Republic of Ireland

Total cost of depression for 1993 = c. £99 million¹²⁴⁸

Economic productivity loss of 280 young adult suicides 1981-94 = c. IR£75,600,000¹²⁴⁹

Europe

Working day loss in previous 30 days due to depression, cardiac disease, and diabetes respectively = 9%, 7%, and 2%¹²⁵⁰

USA

Annual cost of depression 1993 = c. \$43.7 billion¹²⁵¹

Cost of affective disorders 1985 = c. \$20.8 bn, 1990 = c. \$30.4 bn

Annual cost of depression the late 1990s = c. \$15 bn

Canada

Premature mortality and reduced productivity due to depression costs C\$2.53bn¹²⁵² which represents 58% of overall economic cost of depression

UK

Annual cost of depression (UK) late 1990s = £2 bn

Total cost of adult depression in the England during 2000 at £9 bn¹²⁵³

Annual cost (UK) of bipolar disorder = c. £2 bn (1999/2000 prices)¹²⁵⁴

¹²⁴⁶ €1 = IR£0.79 at introduction of euro.

¹²⁴⁷ Reifler (2006)

¹²⁴⁸ Keogh and Walsh (1995)

¹²⁴⁹ National Task Force on Suicide (1998). The National Task Force on Suicide, estab. 1995.

¹²⁵⁰ Wittchen and Jacobi (2005)

¹²⁵¹ 28% direct costs, 17% mortality costs, and 55% derived from morbidity cost categories, i.e. absenteeism and reduced productivity.

¹²⁵² (Lam & Mok, 2008, p. 7)

¹²⁵³ Thomas and Morris (2003): £370,000,000 direct treatment costs; 109.7 million working days lost; 2,615 deaths.

¹²⁵⁴ Gupta and Guest(2002): 86% = indirect costs.

As a generalisation, indirect costs (e.g. productivity loss) are about seven times direct (e.g. medication) costs. Direct costs of treating major depressive disorder (MDD) with antidepressants among US employees increased if there was a comorbid anxiety disorder.(Birnbaum *et al*, 2009)

TCAs are cheaper as far as direct costs are concerned than SSRIs as first-line treatments, although complex calculations have been published arguing that SSRIs may be cheaper in the long run when total costs (including side effect burden and ICU care after overdose) is included. One argument against the finding that SSRIs are ultimately cheaper than TCAs is that if economic outcome studies were long enough (> 1 year) TCAs would come out cheaper.(Woods & Baker, 1999) Baker *et al* (2003) conclude that 'pharmacoeconomic studies of antidepressants reveal clear associations of study sponsorship with quantitative outcome'! Many authors reserve TCAs for depression (especially 'melancholia') resistant to other drugs.(Howland & Thase, 2002) Chisholm *et al* (2004) state that older antidepressants are more cost-effective than the newer drugs, particularly in poorer parts of the world.

*Epidemiology*¹²⁵⁵

'With the exception of hypertension depression is likely to be the commonest condition seen in primary care'.(Tylee & Walters, 2002)

In the early 1970s, between 3-4% of the general population were found to be depressed at any one time (point prevalence). One in five sought medical advice from a GP or specialist, one in fifty were hospitalised, and one in two hundred committed suicide. About one in twenty had a future manic episode. Most would have a further attack of depression. Major depression has a point prevalence of about 5% in the general population. Depressive illness, like suicide, is most common in spring and autumn (Postolache *et al*, 2009), although the reasons for this remain unknown. Whilst women present more often than men with depression, there is some evidence that this gap between the sexes may not be as wide as heretofore because of changing social roles. Scott (1988) reviewed the subject of chronic depression and, when defined as persistent symptoms of depression for two or more years, gave it a prevalence of 2-15%. It has been suggested that most cases of depression treated in general practice satisfied criteria (e.g. PSE or RDC) for psychiatric disorder but tended to be relatively mild and borderline in quality. They were said to be much less severely ill than outpatients, have less depressive symptoms and a shorter illness, and less primary and less endogenous depression. However, while severe, suicidal and psychotic depression can be expected to cluster in in-patient settings, major depression may not differ much between GP and psychiatric OPD settings.(Vuorilehto *et al*, 2007) Barrett *et al* (1988) estimated an 11-36% frequency of diagnosable psychiatric disorders in general practice (GP).

McGuffin and Katz (1986)

Morbid risk of bipolar illness (BP) in first degree relatives of BP probands = 8% and of unipolar illness (UP) = 11%

Morbid risk is for UP illness only among relatives of UP probands (9%)

Reich *et al* (1982)

Lifetime risk in general population for BP and UP disorder = <1% (figures vary: 0.5-15%) and 3% respectively

Andreasen *et al* (1987)

1.1% of relatives of BP II probands have BP I illness

8.2% of relatives of BP II probands have BP II illness

Kennedy *et al* (2005)

35-year epidemiological study of BP

74% of 246 first episode mania cases experienced psychotic symptoms

A BP parent is more likely to have a UP than a BP offspring, but is most likely to have a child who will develop neither.(Kay & Tasman, 2006, p. 557) Other examples of published statistics are given in the table.

Summarised epidemiology of affective disorders¹²⁵⁶

¹²⁵⁵ See Parker and Hickie (2007) for a debate on whether depression is over- or under-diagnosed. Tyrer and Silk (2008, p. 13) suggest that as the number of people receiving antidepressant drugs increase the threshold for prescribing such drugs has been lowered.

381

<i>Year</i>	<i>Findings</i>	<i>Comments</i>
1939 & 1956	BP found throughout cities	Schizophrenia in city centres
1988	Major depression LP = 5%	USA
1988	Dysthymia LP = 3%	ECA (F>M) ¹²⁵⁷
1992	Prevalence of Depression in GH = 5.2%	Standardised interview (UK)
1992	Major depression LP = 16%	Zurich
1994	Major depression LP = 17%	USA
1995	Autumn preponderance of depression and no specific seasonality for mania	London and Dunedin, NZ
1995	90% of cases of mania have BP relapse	
1995	Psychosis in MDD increases likelihood of BP Type I disorder diagnosis	
1997	Suicide prevalence 9-10/100,000	UK; especially young M, middle-aged F; mostly overdose, violent in 30%; highest in April-June
1999	7.9% of years lived with disability from depression in Australia	Dementia was next (5.6%), then asthma (4.8%)
2000	9.4% of years lived with disability from depression worldwide	Adult deafness was next (5.5%), then cataracts (5.2%)
2000	Failed to find seasonality for suicide	UK
2002	Study of 15 primary care centres: 15-fold variation in prevalence of current major depression: high prevalence associated with lower impairment	14 countries; raises question of definition
2002	17% and 10% of Irish psychiatric inpatients had diagnoses of depression and mania respectively	On census day 2001
2003	Rates of admission in Ireland for depression = 235.9 and 325.9 for men and women	2001 rates/100,000; 31% of total admissions = depression
2003	33% of admissions in Ireland = depressive disorders in 2002	2002 admission rate (all diagnoses) = 781.7
2003	59 children admitted in 2002 in Ireland	31% neurotic, 24% conduct disorder, 19% depressive
2004	Global Burden of Disease	Depression is fourth leading cause of disease burden, accounting for 4.4% of total DALYs in 2000; causes largest non-fatal burden (12% of of all total years lived with disability worldwide)
2004	Lifetime prevalence of psychotic symptoms in BP = 40%	Grandiose delusions typify mania; doom/death in depression
2004	29% of admissions in Ireland for depression	12% were for mania
2005	30% of admissions in Ireland for depression	Admission rate for depression = 215.8/100,000 (mania = 89.7)
	4% of people have BP I or II disorder	Replication of NCS
2007	Depressive disorder accounted for 55%, anxiety disorders 30% and alcohol dependence for 15% of QALY loss on the population level	Finnish population study of those at least 30 years of age
2007	1-year prevalence for ICD-10 depression alone = 3.2% ¹²⁵⁸	Episodes of depression, 60 countries
2008	Childhood/adolescent BP onset twice as common in US as in Germany or Netherlands	This US study also found excess of childhood abuse and genetic/familial risk for affective disorders in the US patients (requires replication)
	24.1% of mood disorder cases used alcohol/drugs to relieve symptoms (BP = 41%)	US community study (N=43,093 aged 18 years or more)
		Excess comorbid anxiety and personality disorders associated with such self-medication
2009	The gap between men and women for MDD may be narrowing	WHO world study: this is related to changing female gender roles
2010	Median duration of BP I episodes = 13 weeks	219 subjects with this diagnosis
	BP I and II: depression and anxiety comorbid cross-sectionally and longitudinally; substance use disorders moderately associated with manic symptoms, and eating disorders with depressive mood	DSM-IV diagnoses; prospective latent analyses
	Major depression and GAD are 2 distinct conditions that frequently co-occur due to shared underlying trait	Australian study did not support artificial comorbidity produced by current diagnostic system (used NESARC data)

¹²⁵⁶ Disparate results in prevalence are at least partly explained by the absence of a clear cut-off point between normal low spirits and depressive disorder.

¹²⁵⁷ Reported lifetime prevalence of dysthymia varies from 1% to 12% with M:F ratios of 1.5-2.5.

¹²⁵⁸ Compare with angina (4.5%), arthritis (4.1%), asthma (3.3%), and diabetes (2%).(Moussavi et al, 2007)

BP, bipolar affective disorder. GH, general hospital. LP, lifetime prevalence. DALYs, disability adjusted life years. QALY, quality-adjusted life year. MDD, major depressive disorder. NESARC, National Epidemiologic Survey on Alcohol and Related Conditions. NCS, National Comorbidity Study in USA. WHO, World Health Organisation.
Irish rates are per 100,000 pop. 16 years and over.

Major depression is no longer considered to be rare in children and adolescents, although the prevalence increases with age: 0.3% in pre-schoolers, 1.8% in prepubertal children, 4.7-8.9% in adolescents¹²⁵⁹, 7% in general paediatric wards, 40% in paediatric neurology wards, and 27-59% in child psychiatry clinics. Comorbidity is extremely high in depressed children. Major depression may be more common in males before pubescence, a reverse in sex ratio occurring between the ages of 11-13 years. By 15 years it is twice as common in girls as in boys and this ratio persists thereafter.

The earlier that one develops major depression the more time one has to suffer from it and its effects.

Associations of earlier onset of depression (Zisook et al, 2007)

Never married
Poorer social/occupational function
Poorer quality of life/negative view of life
Increased psychiatric/medical comorbidity
More depressive episodes/suicide attempts
More severe symptoms and suicidal thinking in index episode

The average age of onset of BP disorder is about 22 years. There is no sound evidence to link it to a particular social class.

Admissions, Republic of Ireland (ROI)

Republic of Ireland

Broad category of 'depressive disorders'/100,000 population in 1987¹²⁶⁰ = 235; 21% of male and 41% of female admissions respectively

1992 admissions for depression = 23% in public psychiatric hospitals, 34% in private institutions, and 39% in general hospital units¹²⁶¹

All admissions with depression

1993	29% (33% of first admissions)
1994	27%
1995	28%
1996	26%
1999	30%
2004	29%

Anxiety is highly comorbid with depression in the community and mixtures of the two groups of symptoms are common in GP.¹²⁶² ICD-10 (but not DSM-IV) includes a subsyndromal category of 'mixed anxiety and depressive disorder' where the symptoms of both are mild, i.e. were the symptoms of anxiety and depression considered on their own they would not meet the threshold for either an anxiety or a depressive disorder. Drug abuse is more often associated with affective than with nonaffective psychosis in the US. Major affective disorder may carry a greater risk for tardive dyskinesia than does schizophrenia. (Prien and Gelenberg, 1989) This may relate to something inherent in the affective disorders or to intermittent treatment (as per 'drug holidays') or a relatively older age at onset of treatment. However, the association between tardive dyskinesia and affective disorder is inconsistent. (Chong & Sachdev, 2004) Various studies suggest an increased risk for tardive dyskinesia in schizophrenic patients with a family history of mood

¹²⁵⁹ Hazell (2007) gives a figure of 3-5% of adolescents.

¹²⁶⁰ Compared with 66 for mania and 165 for schizophrenia.

¹²⁶¹ Schizophrenia showed the opposite trend – 24%, 21%, and 14% respectively.

¹²⁶² In fact, such comorbidity 'is the rule (at some point) rather than the exception'. (Deakin et al, 2001, p. 121) Analysis of a Swedish twin sample found that genetic factors for lifetime major depression and generalised anxiety disorder (GAD) were strongly correlated, more so in females. (Kendler et al, 2007)

disorders. Finally, tardive dyskinesia may worsen during depression and lessen during mania.(Chong & Sachdev, 2004)

Is depression becoming more common or are people less happy than heretofore? There have been reports of an increase in depression,(e.g. Compton ea, 2006) eating disorders, and alcoholism in the latter part of the twentieth century, a so-called 'age-period-cohort effect'. Various authors have commented on this finding and wondered if it can be explained by increased alcohol and substance use (not supported by Compton ea, 2006), programmes promoting increased awareness of mood disorders (McIntyre & Nathanson, 2010, p. 1), or a broadening of the concept of depression to include normal variations in mood and habits. Also, cross-sectional data do not translate well into longitudinal (read prospective) data because, e.g., of forgetting or ignoring of past episodes (perhaps undiagnosed) and selective mortality among those who experience severe depression.(Prince, 2008, p. 58) Evidence from the Stirling County Study are against any overall increase in depression during the 40 years since 1952.(Murphy ea, 2000) Even if there is a real increase in 'depression' it may not be explained by a genetico-biological model to the exclusion of socio-economic factors.(Andreasen, 2001, p. 239) Indeed, a Belgian study clearly shows that worsening socio-economic factors and depression are closely related.(Lorant ea, 2007)

Stigma

The RCPsych Defeat Depression Campaign 1992-1996 aimed to reduce stigma, assist GPs and other professionals in diagnosis and management, and to increase public awareness of the extent and treatability of depression. The mass media was employed and surveys of public attitudes¹²⁶³ were undertaken at various stages. People wanted counselling since this was viewed as being more effective than medication, the latter being viewed as addictive. The end point revealed some positive shift in attitude toward depression and medication.(Paykel ea, 1998)

Aetiology

'...the diagnosis of MDD [major depressive disorder] is only descriptive and likely consists of a number of syndromes with related symptoms'.(Lam & Mok, 2008, p. 11)

'These subsyndromal presentations of depression need to be distinguished from normal suffering....'(Ayuso-Mateos ea, 2010)

Depression superficially resembles such phenomena as tribal dominance and hibernation.

Freud postulated that depression ('melancholia') followed not an external loss, such as the demise of a loved one, but rather an internal loss, such as loss of a sense of personal identity or loss of belief in God. Advanced paternal age¹²⁶⁴ (Frans ea, 2008) and maternal age (Menezes ea, 2010) may be risk factors for bipolar affective disorder (BP) in the offspring, presumably by increasing the likelihood of genetic mutation. Early loss of a parent may increase the chances of later depression, but not all researchers have found a connection between early environment and adult affective disorder.(Rodgers, 1990) Indeed, early loss of parent has also been suggested as predisposing to anxiety disorder, bipolar disorder,(Mortensen ea, 2003) schizophrenia,(Agid ea, 1999) dissocial personality disorder, and substance abuse. It has also been suggested that it may lead to abnormal illness behaviour, the person learning to gain attention by complaints of ill health. Also loss of parents because of evacuation in wartime Britain does not seem to have led to an increase in affective illness in adulthood, whereas depression in adult life has been correlated with separation from parents because of marital discord and divorce¹²⁶⁵.(Tennant, 1988; Gilman ea, 2003)

¹²⁶³ Approximately 2000 representative people were used in each survey.

¹²⁶⁴ Advanced age of the father has been suggested as a risk factor for a number of complex neurodevelopmental disorders, e.g. schizophrenia, and autism spectrum.

¹²⁶⁵ Ted Dinan of Cork delivered a talk in Dublin (November 6, 2008) on certain biological aspects of depression (*Depression: Studies from Cradle to Grave*): Separation of rodent pups for 3 hours per day (kept in warm cages) for a period after birth led to raised corticosterone levels together with behavioural change and differences in colonic flora. Male pups were more susceptible to separation experiences than were their female counterparts. In a non-psychiatric population, desertion by or death of parents was found to be associated with raised cortisol level in adulthood. Increases in tumour necrosis factor-alpha (TNFα), a pro-inflammatory cytokine have been reported in maternally separated animals. ACTH shows a blunted response to CRH in major depressive disorder (MDD). Chronic elevation of CRP (**C-reactive protein**) is associated with raised mortality from cardiovascular disease. Baseline CRP is raised in melancholic depression and SSRIs tend to decrease CRP levels. Also elevated during depression are **IL6** and TNFα. Depressives have particular difficulty bringing cortisol levels down after such levels rise. Topical steroids blanch skin but such blanching is diminished in severe depression, suggesting reduced sensitivity of steroid receptors – this may explain why depressives rarely develop a Cushingoid appearance despite hypercortisolaemia. Depression occurring at any time increases the risk for heart disease to the same degree as do smoking 20 cigarettes/day (2-3 times the risk for myocardial infarction [MI]), diabetes, or lack of exercise. Toll-like receptors, originally found in *Drosophila*, recognise patterns (pathogen-associated patterns) and have various functions, e.g. activation of pro-inflammatory pathways and apoptosis. TLR4 recognises gram-negative bacteria. TLR4 is also raised in MI. Other toll-like receptors recognise viruses. Stimulation of toll-like receptors leads to a rise in NF-κB leading in turn to cytokine release. TLR4 is

It has also been proposed that unsatisfactory care in childhood *after* loss of the parent is the crucial factor and that adequate substitute parenting may be protective. Young monkeys who are separated from their mothers vary in the intensity of their responses, e.g. those with more rejecting mothers are most disturbed by the loss. (Hinde & Spencer-Booth, 1970) Osler *et al.* (2005) in a Danish study spanning 1969-2002, failed to find any association between birth dimensions (birth weight and ponderal index – the latter was employed as a proxy measure of intrauterine growth and = birth weight in kilograms divided by [birth length in metres]³) and risk of receiving a discharge diagnosis of depression. However, Costello *et al.* (2007) did find an association between low birth weight and depression in adolescent girls but not boys. Also, Nomura *et al.* (2007) found that perinatal problems (low birth weight, preterm birth, small head circumference) in Baltimore babies increased the risk for later depression, suicidal ideation and high blood pressure.

Another pathway to adult depression in women who had inadequate parenting in childhood might be via premarital pregnancy, an unsupportive husband, and marital disharmony and lack of social support. The sociologist Brown's famous work related depression to being a young working class mother who has young children, a non-confiding relationship with her partner, and not even a part-time job. However, Romans *et al.* (1993) in their Otago study found that marriage and child care were not risk factors for non-psychotic psychiatric disorder in women. Bifulco *et al.* (1991), again in a study of working class mothers, found an association between sexual abuse prior to age 17 years and case depression. Such abuse was also associated with having been divorced or separated or never having married or cohabitated. Child physical abuse and neglect were related to later adult major depression, but child sexual abuse (CSA) was not so related in a study by Widom *et al.* (2007) CSA might be linked more securely to depression in adult women if abuse was severe, with penetration or attempted penetration, although its specificity for depression is doubtful. (Bulik *et al.*, 2001; Gershon *et al.*, 2008) Enns *et al.* (2006) found that CSA and multiple adversities (abuse, deficient parental bonding, parental psychopathology) were strongly associated with future suicidal behaviour. Garino *et al.* (2005) looked at 100 patients at an academic specialty centre for the treatment of bipolar disorder and found that severe childhood abuse occurred in about half of the sample and was associated with early age of illness onset; severe emotional abuse was associated with later drug misuse and recent rapid cycling; severe CSA was linked to lifetime suicide attempts; and multiple forms of abuse was associated with a graded increase in risk for attempted suicide and rapid cycling. Conus *et al.* (2010) found that reports of sexual and/or physical abuse were common among bipolar I patients with a first episode of psychotic mania.¹²⁶⁶ Marital disruption may lead to a first episode of depression in either sex. (Bruce & Kim, 1992) CSA may lead to longterm dysregulation of the hypothalamico-hypophyseal-adrenal axis. Mothers of twins, especially if one twin dies subsequently, may be more prone to depression than mothers of closely spaced singletons. (Thorpe *et al.*, 1991)

One study of women (Kendler *et al.*, 1993) found that the strongest predictors (in order of strength of prediction) of liability to suffer an episode of major depression were stressful life events, genetic factors, a personal history of major depression, and neuroticism. Kendler and co-workers (Fanous *et al.*, 2007) concluded that neuroticism may be a vulnerability factor (but not directly causative) for major depression in men, but that major depression may cause neuroticism.

Depression may be more likely if the personality is obsessional or cyclothmic although not all findings agree. Low self esteem may be more relevant in unipolar than in bipolar patients, (Pardoen *et al.*, 1993) although not all authors agree. (Hirschfeld *et al.*, 1986; Jones *et al.*, 2005) In a general population survey of women who had been depressed for at least 12 months, Brown *et al.* (1988) found that events with a promise of a better future often led to an alleviation of symptoms.

Seligman's¹²⁶⁷ learned helplessness model (Seligman & Maier, 1967) suggests the depressive has learned that nothing one does affects the turn of events and so become like the dog who cannot avoid electric

increased in colonic mucosa in animals deprived of their mothers for a time after birth. Early life stress programmes neuroimmune and neuroendocrine systems. Negative life events trigger events in those who experienced early-life trauma. MDD has a pro-inflammatory phenotype that increases the risk for cardiovascular disease.

There is evidence (Gimeno *et al.*, 2009) that baseline C-reactive protein and IL6 predict cognitive symptoms of depression at follow-up.

¹²⁶⁶ The reader must be wary of drawing conclusions from such correlations. The connection could be causal, spurious, secondary to symptomatic (of BP disorder, secondary alcohol use, etc) parents or offspring (or both), or no more common than in the general population. Future research should address these issues.

¹²⁶⁷ Martin E P Seligman (b. 1942, Albany, NY), Professor of Psychology in Philadelphia, known for 'learned helplessness' and 'positive psychology'.

shocks, just lying there and taking it¹²⁶⁸. Implants of 5-HT-containing pineal tissue and catecholamine-containing adrenal medullary tissue into the frontal cortex of rats may protect them against developing learned helplessness under stress.(Sagen ea, 1990) However, there is no evidence to allow us to deduce a cognition of learned helplessness in lower animals and electric shocks may be non-specific stressors. We cannot capture the human conceptualisation of events, i.e. the same event may evoke widely different emotions in humans because of the different meanings applied by individuals, so-called *attributional style*. Interestingly, Isaacowitz and Seligman (2001) found that pessimists and optimists among older people in the community were at increased risk for depression, the latter being at greater risk for depression whereas the former were more likely to have persistent depression; taking an objective view may be the most protective strategy.

A few cases seem to use 'depression' for manipulative reasons, to gain sympathy, test others, or gain help. A number of studies have linked relapse of depressive illness to life events. Classically, losses (exit events)¹²⁶⁹ precede depression, whereas threatening events precede anxiety. An excess of exit events during the course of a depressive episode may precipitate a suicidal or parasuicidal act. The only truly rigorous approach to examining the effects of life events on the risk for depression is to assess their frequency before the onset of a first episode of the disorder. This would require massive numbers of potential patients. In a study conducted by Dolan ea,(1985) antecedent life events were associated with first episodes of depression and with greater severity of illness, but life events did not distinguish endogenous (DSM's melancholia and ICD's depression with somatic symptoms) from neurotic (depressive neurosis in DSM-III-R, dysthymia in DSM-IV) cases, and there was no relationship between life events and DST status. However, urinary free cortisol levels were higher in those patients with life events. Also, the timing of episodes in relation to psychological stress was more apparent in non-endogenous than in endogenous depressions in a study conducted by Frank ea.(1994) Keller ea (2007) found that different adverse life events were associated with distinct patterns of depressive symptoms: death/romantic breakup with severe sadness, anhedonia, appetite loss, and (for romantic loss) guilt; chronic stress (and to some extent failure) with fatigue and hypersomnia; and, when no adverse event was reported, there were fatigue, appetite loss, and thoughts of self-harm. Kasen ea (2009) found that childhood adversity, earlier high levels of negative life events and marital stress and a more rapid increase in marital stress increased the odds of major depression in women at average age of 60 years. Ambelas (1987) reported that young first admission manics had had a significant excess of life events (less important for older first admission manics) and that later episodes were precipitated by life events of much lower stress value. Life events could lead to help-seeking behaviour rather to illness *per se*¹²⁷⁰. Anyway, they are not specific to affective disorders. Life events may only be significant as precipitants for the earliest episodes of bipolar disorder, the condition apparently becoming autonomous thereafter¹²⁷¹. (Not all researchers found that later episodes of bipolar disorder [BP] were non-reactive to stress.[Hammen & Gitlin, 1997] Also, the likelihood of PTSD is increased in bipolar spectrum disorder, the combination significantly worsening social functioning.[Neria ea, 2008] Not all studies found worsening of BP (perhaps due to a kindling effect) over time¹²⁷². [Baldessarini ea, 2003]) They might also be due to the earliest stages of illness rather than causing or precipitating it.(Pardo ea, 1996) Also, the effects of life events in increasing liability to mood disorder in children of bipolar disorder parents slowly diminish with the passage of time.¹²⁷³

¹²⁶⁸ Seligman continued his experiments on college students who were asked to solve insoluble puzzles.

¹²⁶⁹ Harris (2001) states that losses that involve humiliation or entrapment are especially potent in precipitating depression and anything that instils hope (fresh start) may promote remission. Certainly, being jilted by a romantic partner may lead to dysphoria whereas this may improve if the relationship resumes, a phenomenon not uncommonly seen among overdosing teenagers in emergency departments.

¹²⁷⁰ A similar argument has been made for the excess of depression in women, i.e. that they seek help more often than men do.

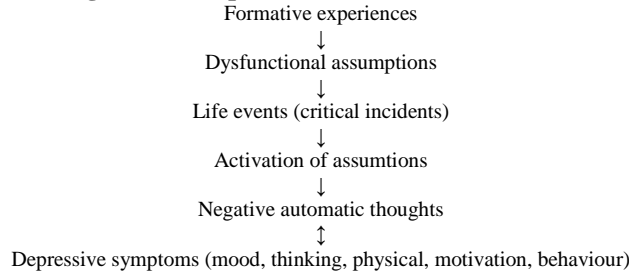

¹²⁷¹ Corbule (2007) reported similar findings for DSM-IV unipolar major depression (ACTUEL survey, N = 13, 377, 66.4% females), although the author admits that the retrospective nature of the study left it open to increased rating bias.

¹²⁷² Some experts do not accept that BP gets worse with time and suggest that the finding that it does get worse may be an example of *Slater's fallacy*: Writing in German in 1938, the British psychiatrist Eliot Slater (1904-1983) reanalysed Emil Kraepelin's data and realised that faster cycling patients (more episodes) were disproportionately represented when pooled samples were used. This problem is avoided when subjects are followed up individually or when groups matched for episode counts is used.

¹²⁷³ Decay of 25%/year.(Hillegers ea, 2004)

Beck's cognitive theory suggests that depression will happen because the person views the future, the world and themselves in a negative way.¹²⁷⁴

Cognitive therapy view of the genesis of depression

Le Masurier ea (2007) found that relatives of patients with major depression show subtle biases when processing emotional information, e.g. they recognised a fearful face faster than controls. Brotman ea (2008) found that bipolar and people at-risk for that disorder (all aged 4-18 years) had equal problems in identifying facial emotions, suggesting that deficits in labelling facial emotions might be a risk factor for bipolar disorder. Schenkel ea (2008), building on earlier work demonstrating theory of mind (ToM¹²⁷⁵) deficits in manic and euthymic bipolar (BP) disorder patients, found that paediatric BP patients also performed poorly in this regard. Moratti ea (2008) found that (female) major depressives demonstrated hypofunction of the right temporoparietal cortex relative to controls during emotional arousal induced by looking at pictures.

A battle has raged since the 1960s when Flor-Henry suggested that affective disorder be linked to the non-dominant hemisphere. His patients were awaiting temporal lobe surgery, were small in number, and were mainly bipolar. Goswami ea (2007) reported that euthymic BP patients had more (and non-age-related soft neurological signs (SNS) than normal controls (whose scores increased with age), but less than the numbers reported for schizophrenia.

One idea is that depression represents a sub-ictal or inter-ictal phenomenon with a focus in the tempero- limbic system. Rapid-cycling BP, which is strongly associated with female sex, might come into this sphere, the latter often responding to anticonvulsants (although this is less certain than was previously believed: Calabrese ea, 2005a) or, e.g. a combination of valproate and lithium. Bradyphrenia, or cognitive slowing, in Parkinson's disease, and psychomotor retardation in depression, may both be due to a common dysfunction of extrastriatal ascending dopaminergic systems. In fact, there is some evidence for increased postsynaptic DA responsivity in BP disorder.(Anand ea, 2000)

An imbalance between rewarding sensations (subserved by noradrenaline) and punishment-like responses (5-HT) in the brainstem-diencephalon might lead to depression. A more modern concept is that there may be a hypoactive reward system subserved by DA in major depression¹²⁷⁶ but an increased response to oral dextroamphetamine.(Tremblay ea, 2002; Tremblay ea, 2005)

Direct evidence for catecholaminergic dysfunction as a trait in major depressive disorder (MDD) comes from a study (Hasler ea, 2008) where unmedicated MDD subjects (n = 15) in full remission and healthy controls (n = 13) were given alpha-methylparatyrosine to induce catecholamine depletion. Depressive and anhedonic symptoms were greater in the patient group. Elevated activity in limbic-cortical-striatal-pallidal-thalamic circuitry on PET were related to the induced symptoms.

¹²⁷⁴ *Criticism of Beck:* It is a controversial point as to whether low self-esteem/negative self-schema comes before or after the experience of depression.(Evans ea, 2005; Ball ea, 2008) Farmer ea (2001) applied the *Dysfunctional Attitude Scale* to depressed subjects before and following recovery and concluded that dysfunctional attitudes were more to do with being depressed than to a familial vulnerability to depression. Harmer ea (2009) found that negative affective bias was relieved by a single dose of reboxetine despite no relief of subjective depression; no such effect was found with placebo. Brain activation (fMRI) in depressed subjects who are expecting events of uncertain emotional valence has been shown to be the same as when expecting negative (but not positive) events.(Herwig ea, 2010) This, of course, does not distinguish between state and trait.

¹²⁷⁵ This refers to an ability to infer what another person is thinking and feeling.

¹²⁷⁶ Dopamine (DA) levels in brain are increased in a number of circumstances, e.g. sexual arousal, ethanol, heroin, and cocaine.

5-HT content in the brain is normally lower in men and older age than in women and youth. It is also dependent on diet (cholesterol, fatty acids, and tryptophan) and alcohol, the latter reducing 5-HT transporter function in the prefrontal cortex. (Malone, 1999) Reduced levels of the 5-HT transporter relative to controls have been reported in depression (including bipolar depression: Oquendo ea, 2007a), in euthymic bipolar I but not euthymic bipolar II patients (Chou ea, 2010), and in suicides. (Owens & Nemeroff, 1998)

Insulin resistance is a determinant of free fatty acids in blood, which in turn are important in tryptophan metabolism and brain 5-HT concentrations. According to Lawlor ea, (2003) people with insulin resistance may therefore have increased 5-HT concentrations and be less prone to depression. However, Timonen ea (2005) found that people with increased insulin resistance seen prior to a diagnosis of diabetes mellitus had greater severity of depression. Andersohn ea (2009) looked at patients receiving at least one new prescription for an antidepressant and found that longterm TCAs and SSRIs in at least modest doses were associated with an increased risk of diabetes; weight gain was not systematically recorded and if drugs were primarily prescribed for atypical depression the results may overestimate the link; and control subjects were matched to case subjects on age, sex and year of cohort entry rather than consisting of equally depressed patient not receiving at least one new prescription for an antidepressant in equivalent dosage for the same duration (assuming everyone takes the drug as prescribed). A prospective Australian study of people aged at least 65 years (Atlantis ea, 2009) found that depressive symptoms more than doubled the risk of developing diabetes regardless of antidepressants.

Schildkraut, in 1965, was the first to suggest the monoamine hypothesis of affective disorders.

Parachlorophenylalanine, which selectively depletes 5-HT, was reported to reverse the antidepressant effects of both TCAs and MAOIs, an effect not found with the catecholamine-depleting agent α -methyl-paratyrosine. These findings were interpreted as favouring a serotonin deficiency basis for depression over a catecholamine depletion hypothesis. However, more recent work suggests that depletion of 5-HT or noradrenaline, whilst not causing depressive symptoms in normal people, increases vulnerability to relapse in people treated with either 5-HT- or noradrenaline-selective reuptake inhibitors respectively. (Delgado ea, 1999; Berman ea, 2002) Parsey ea (2006) found low serotonin transporter binding potential in the amygdala and midbrain of subjects during a major depressive episode compared to healthy controls. There is some evidence linking the genotype of the serotonin transporter gene-linked promoter region to onset of major depression following multiple adverse events. (Wilhelm ea, 2006) Ohara ea (1999) reported a common polymorphism of the variable-number tandem repeat within the serotonin transporter gene associated with major depression and anxiety disorders, particularly generalised anxiety disorder. Platelet imipramine binding (may serve as a measure of presynaptic 5-HT functioning) sites were reported as significantly reduced in depression and this seemed to be independent of treatment with drugs. Plasma NA levels were reported as increased in major depressive disorder, the levels falling if electroconvulsive therapy (ECT) were administered. Of course, this finding may have been due to increased sympathetic tone in depressed patients. When noradrenergic (NA) neurones are destroyed in experimental models drugs affecting the 5-HT system do not have their usual effects, and *vice versa*. This suggests that aetiology may be more complex than single monoamine paradigms might suggest. (Willner & Mitchell, 2002)

One theory of the mechanism of action of antidepressant drugs is that in depression receptors are supersensitive (upregulated). Treatment increases the amount of neurotransmitter acutely but the effect of this over time is to desensitise (downregulate) receptors. Downregulation correlates with clinical effect. There are a number of lines of evidence suggesting widespread GABAergic abnormalities in mood disorders. The most impressive are those that demonstrate reduced concentrations of GABA in plasma, CSF, and cerebral cortex in depressed patients.¹²⁷⁷ MRS suggests abnormal reductions in GABA and glutamate/glutamine¹²⁷⁸ in prefrontal regions in major depression, probably related to reduced glial cell density in these areas. (Hasler ea, 2007) Leonard (2003, p. 36) expressed surprise at the finding of reduced concentration of GABA in depression because of the lack of evidence for cortical excitability in that disorder and suggests that it might reflect decreased availability of glutamate, the excitatory precursor of GABA. A combined fMRI/MRS study (Walter ea, 2009) suggests that aberrant activation patterns of the pregenual anterior cingulate cortex in depression with anhedonia is related to defective glutamatergic

¹²⁷⁷ For a review see Sanacora (2002)

¹²⁷⁸ Ionotropic glutamate receptor genes GRIA3 and GRIK2 may be linked to suicidal ideation arising during citalopram treatment of major depression. (Laje ea, 2007)

metabolism. Cortical inhibitory deficits may play a role in the pathophysiology of major depressive disorder (MDD) according to Levinson *et al.* (2010): they suggest that GABA-B neurophysiological deficits are closely associated with MDD and that greater disorder severity is selectively associated with GABA-A receptor-mediated inhibitory deficits.

Pleasure is associated with DA release in the brain reward system¹²⁷⁹. Bupropion¹²⁸⁰, amineptine,¹²⁸¹ and nomifensine¹²⁸² are the main dopaminergic antidepressants. Pramipexole (Mirapexin), used for Parkinson's disease, is a D2/3 agonist with preferential D3 binding affinity. Whiskey and Taylor (2004) reviewed the literature on the use of pramipexole in depression (unipolar and bipolar) and concluded that whilst the data appear promising further research is required.

Meyer *et al.* (2006), using PET, found increased MAO-A levels in many brain areas in unmedicated depressives. Also, PET has demonstrated elevated MAO-A binding in major depressive disorder following SSRI treatment. (Meyer *et al.*, 2009)

Hypothalamic-pituitary-adrenal (HPA) axis overdrive might lead to central monoaminergic changes in susceptible people under chronic stress, the high levels of glucocorticoid receptors on such central neurones perhaps mediating the alterations.¹²⁸³ Perhaps old-age depression with cognitive impairment might be due to cortisol-induced neuronal damage, although this is still controversial. (Ebmeier & Kronhaus, 2002) Reduced levels of dehydroepiandrosterone (DHEA)¹²⁸⁴ may contribute brain damage due to cortisol (DHEA may be useful in non-major depressed HIV/AIDS cases: Rabkin *et al.*, 2006). It has also been suggested that change in peptides¹²⁸⁵ (that are involved in stress adaptation) in brain areas linked to emotional responses like the amygdala may precipitate depressive illness. It has been asserted that the reason for developing psychotic features in the context of a depressive episode may be enhancement of dopaminergic activity by glucocorticoids. Circulating corticosterone levels modulates the density of 5-HT1A receptors in animals. An excess of cortisol secretion might attenuate limbic 5-HT1A receptor function, predisposing to depression¹²⁸⁶. Also, animal studies suggest that corticosteroid administration causes hippocampal cell loss¹²⁸⁷. Sheline *et al.* (2003) found that hippocampal volume decreased as the number of days of untreated depression increased. However, Lloyd *et al.* (2004) found that smaller hippocampi were associated with late-onset depression only and not with lifetime duration of depression. The authors admit that the latter is difficult to measure accurately and all the patients were on medication. Kronmüller *et al.* (2008) found that smaller hippocampi were associated with relapse of major depression and Chen *et al.* (2010) found that girls at high familial risk of developing depression had small hippocampi compared to those at low risk, i.e. that reduced hippocampal volume precedes depression. Hippocampal volume in depressed patients has increased following ECT. (Nordanskog *et al.*, 2010) Cervilla *et al.* (2004) found an association between incident depressive symptoms and baseline smoker status, low serum cholesterol levels, poorer cognitive function (*esp.* executive function), female gender and increasing age, but not with ECG evidence of ischaemia or arrhythmia, various blood pressure measurements and body mass index. However, despite sustained hypercholesterolaemia¹²⁸⁸, depression does not lead to Cushing's syndrome. Also, HPA axis dysfunction may be a manifestation of acute but not chronic depression. (Watson *et al.*, 2002) Such dysfunction may also play a part in treatment resistance in depression. (Jurueña *et al.*, 2009) It has been suggested that antidepressants and the mood stabilising drugs up-regulate glucocorticoid receptors, so

¹²⁷⁹ See Dunlop and Nemeroff (2007) for review of review of reduced dopaminergic neurotransmission in major depression.

¹²⁸⁰ Used for smoking cessation.

¹²⁸¹ Has a propensity for addiction.

¹²⁸² Carries risk of acute haemolytic anaemia and intravascular haemolysis.

¹²⁸³ Summers *et al.* (2006) found cognitive deficits to be more severe and pervasive in bipolar II than in bipolar I patients, which the authors believe suggests that recurrent depression is more cognitively damaging than are manic attacks.

¹²⁸⁴ A natural cortisol antagonist.

¹²⁸⁵ E.g. corticotrophin releasing factor (CRF).

¹²⁸⁶ Various changes may explain delayed onset of antidepressant action: time required to desensitise presynaptic 5-HT1A autoreceptors and down-regulate postsynaptic alpha-adrenergic and 5HT2 receptors.

¹²⁸⁷ The frontal lobes contain mainly glucocorticoid receptors whilst the hippocampus contains both mineralocorticoid and glucocorticoid receptors – these regions may have some inhibitory action on HPA activity; mineralocorticoid receptors bind corticosteroids with a higher affinity than do glucocorticoid receptors. (Lupien, 2002)

¹²⁸⁸ The literature is inconsistent, e.g. Fiedorowicz *et al.* (2010) conducted a follow-up (median 20 years, max 25 years) of patients who had a fasting total cholesterol evaluation at intake: low cholesterol among bipolar patients (N = 65) predicted a higher proportion of follow-up weeks with manic but not depressive symptoms and cholesterol did not predict depressive symptom burden among unipolar depressives (N = 66).

restoring normal glucocorticoid function in mood disorders.¹²⁸⁹ Also, there is evidence that antidepressants induce neurogenesis,(Santarelli et al, 2003) although this may be a chronic rather than acute effect.(Malberg et al, 2000) According to Duman,(2004) antidepressants cause increased coupling of Gs protein to adenylyl cyclase, increased levels of cAMP-dependent protein kinase, and decreased levels of CREB; the time course of increased cAMP-CREB signalling depends on chronic treatment¹²⁹⁰; activation of CREB increases target gene expression (e.g. BDNF¹²⁹¹) that exert trophic actions on target neurones with increased cell survival and function. In contrast, stress causes a dramatic downregulation of BDNF¹²⁹² in the hippocampus.

Cotter and Pariante (2002) suggest that the pathological changes reported in schizophrenia, bipolar disorder and major depressive disorder¹²⁹³ differ only quantitatively rather than qualitatively¹²⁹⁴. They suggest that the common cause may be (stress-related) glucocorticoid-induced damage. However, DST non-suppression rates in schizophrenia¹²⁹⁵, whilst unsurprisingly higher than in the healthy population, are 'much lower than that described in depression'. They point out that the reduction in hippocampal volume reduction seen in cases of Cushing's disease is reversible after normalisation of cortisol levels and express the hope that neuroprotective therapies may be developed for the psychiatric disorders under consideration.

Whilst autoimmune thyroiditis occurs in about 15% of depression it may occur in up to 50% of cases of rapid cycling bipolars. Absence of the normal TSH surge during the night have been reported in depression; sleep deprivation restores this surge and raises levels of T₃ and T₄.(Arce et al, 2003, p. 228) Transthyretin, a protein made in the choroid plexus, is more important for T₄ than for T₃ transport across the blood-brain barrier. CSF transthyretin levels may be reduced in depression, a situation that has led to the theory of depression as a state of 'brain hypothyroidism' in the presence of normal peripheral thyroid hormone concentrations.(Hatterer et al, 1993) However, major depression may be almost as common in hyperthyroidism (31%) as in hypothyroidism (40%) (Rouchell et al, 1996) and general population studies of hypothyroidism did not find an excess of depression.(Engum et al, 2002)

Brain-derived neurotrophic factor (BDNF) is important in maintaining neuronal viability, including hippocampal plasticity. BDNF binds to the tyrosine kinase receptor TrkB. Under stress, BDNF is repressed. This could conceivably lead to atrophy and perhaps to apoptosis in hippocampal neurones. Depression might be the result. Carriers of the Met-BDNF allele may be at particular risk to develop small hippocampi and depression.(Frodl et al, 2007) Childhood adversity of various types have an impact on depressive symptoms in adulthood. Also, child sexual abuse may be associated with a stronger likelihood of depressive symptoms in adults who carry the Met-BDNF allele (v. the Val/Val allele) or in S (v. the LL group) carriers of the 5-HTTLPR polymorphism (5-HTT gene).(Aguilera et al, 2009)

The three neuropeptides (tachykinins) are substance P (11 amino acids)¹²⁹⁶, neurokinin A (NK-A, 10 amino acids), and neurokinin B (NK-B, 10 amino acids). Since antagonists of substance P did little for pain but had an inconsistent beneficial effect on depressed mood, and since substance P is present in brain areas such as the amygdala that may be important for the emotions¹²⁹⁷, it has been suggested, but not yet proven,

¹²⁸⁹ Suicidal events among treatment-resistant adolescent depressives were associated with FKBP5 polymorphisms (rs1360780TT and rs3800373GG) in a relatively small study (Brent et al, 2010) without a placebo condition. FKBP5 codes for a protein causing glucocorticoid receptor subsensitivity.

¹²⁹⁰ Consistent with the delayed onset of an antidepressant response, although such delay may be much shorter than is generally believed.(Tylee & Walters, 2007)

¹²⁹¹ The so-called *network model* suggests that depression is due to interneuronal communication difficulties and that antidepressant drugs improve such communication. In animals antidepressant drugs increase neuronal turnover and sprouting of synapses. ECT and antidepressant drugs increase BDNF levels (via CREB activation) which stimulates local sprouting of axons. Umene-Nakano et al (2009) found relatively low serum BDNF levels in depressives with or without alcohol dependence. Downregulation of BDNF expression in suicidal subjects may be an epigenetic phenomenon as a result of gene-specific increase in DNA methylation.(Keller et al, 2010)

¹²⁹² Delta-opioid receptor agonists resemble antidepressants in rodents. They increase brain BDNF levels. Sustained sadness decreases capacity for cortical mu-opioid receptor binding. Early reports suggested that opiates might relieve depression (Weber & Emrich, 1988), but hard evidence is lacking. Also, there is some evidence that variation in the mu-opioid receptor gene may influence rates of response to antidepressant drugs (Garriock et al, 2010), although this effect could be either via a placebo or pharmacological action.

¹²⁹³ E.g. enlarged ventricles and smaller hippocampi and frontal brain volumes, as well as reduced dendritic spine density, smaller neurones, a reduction in synaptic proteins, and a deficit in glia.

¹²⁹⁴ Except that the amygdala may be specifically enlarged in bipolar disorder, which might be due to drug treatment.

¹²⁹⁵ Mean of 20% from different studies.

¹²⁹⁶ P standing for powder, the original form in which it was isolated.

¹²⁹⁷ Substance P is elevated in CSF in depression and in PTSD.(Geraciotti et al, 2006)

that blocking neurokinin receptors may improve mood. Ernst et al (2009) found a reduction of tropomyosin-related kinase B (TrkB.T1)¹²⁹⁸ expression in the frontal cortex of a subpopulation of suicide completers that was associated with the methylation state of the promoter region.

Depression as an inflammatory disorder- speculative theory (Leonard, 2007)

In depression:

- Neuronal repair is slowed
- Hippocampal atrophy
- Glia and neurones in prefrontal cortex adversely affected
- Glucocorticoid-mediated cell loss probably involved
- Rise in pro-inflammatory cytokines (PICs) may play a role
- Interferon-alpha, a PIC, may cause depression
- Anterior cingulate is rich in 5-HT transporters (and other neurotransmitters)
- BCL-2 (anti-apoptotic protein) and BDNF genes are important in neuronal plasticity and survival
- BDNF is reduced in depression
- Physical exercise improves depression (not necessarily true: Walker et al, 2010) and promotes rat hippocampal neurogenesis
- Stress reduces hippocampal cell proliferation
- IL-1, IL-6 (potent HPA axis activator), and TNF-alpha are increased in depression/chronic stress and induce depression in rats (less so if on chronic antidepressant treatment)
- Reduction of high cortisol feedback on brain with metyrapone decreases depression
- Chronic antidepressant treatment switches on neurogenesis/repair genes with some benefit
- PGE2 (via COX2 activity) is increased in depression (reduced by antidepressant drugs) – COX2 inhibitors being tested in depression models
- Antidepressants decrease indoleamine dioxygenase (IDO) which converts tryptophan to kynurenine
- The hallucinatory agent and glycine B antagonist ketamine relieves depression for 2 weeks after one dose but safer drugs are needed
- Lithium inhibits brain glycogen synthase kinase-3 (GSK-3)¹²⁹⁹ leading to diminished apoptosis and improved brain repair

Theory: In depression, is tryptophan changed to kynurenine instead of tryptophan in presence of PICs, the latter induced by psychological and physical stress, leading to neurodegeneration/depression? Thus:

- (a) ↑ kynurenine in depression → quinolinic acid (neurotoxic) in microglia → astrocyte and then neurone death
- (b) Kynurenine → kynurenic acid (neuroprotective) is ↓ in depression

There is a suggestion that deficiency of orexins/hypocretins might have a role in causing depression. (Taheri & Hafizi, 2002)

Could infection in utero cause later adult depression? Looking at patients with 'major affective disorder', Machón et al (1997) of Helsinki found an increased likelihood of exposure to an epidemic of influenza (A2/Singapore virus) during the second trimester compared to controls.

Cotter et al (2001) found a reduction in reduced neuronal size and glial cell density in the anterior cingulate cortex of major depressives at postmortem. Relatively small cingulate volumes in children and adolescents with bipolar disorder have been reported, (Kaur et al, 2005) suggesting that such may be the case from early in the illness course.

Geomagnetic storms have been suggested as a cause of depression in susceptible individuals. They might desynchronise pineal circadian rhythms or they might disrupt pineal melatonin synthesis¹³⁰⁰ via actions on serotonergic or adrenergic systems. Such storms could, according to the theory, act on cell membrane permeability, cause increased calcium channel activity, or the retinal rods could act as magnetoreceptors. The circadian timing system may have a role in depression. Light acts on the suprachiasmatic nucleus (SCN) via illuminance-measuring photoreceptors in retinal ganglion cells. The SCN affects the pineal gland via the paraventricular nucleus¹³⁰¹ and this then drives nocturnal melatonin synthesis, the latter being

¹²⁹⁸ Normally, TrkB.T1 is the only TrkB isoform expressed in astrocytes. BDNF-TrkB signalling may be linked to depression and suicide. The TrkB.T1 variant mediated BDNF-induced calcium signalling through astrocyte networks. TrkB.T1 is upregulated by antidepressants.

¹²⁹⁹ GSK3β may have a role in determining regional gray matter volume in the temporal lobe in major depression. (Inkster et al, 2009)

¹³⁰⁰ Melatonin shows significant night-time secretion. Melatonin secretion is fairly constant within individuals but varies widely between individuals.

¹³⁰¹ The paraventricular nucleus neuroendocrine cells have regulatory effects on pituitary hormones; there are also projections from this nucleus to the autonomic nervous system. (Buijs et al, 2003)

suppressed by light. The SCN affects preoptic area, raphe nuclei, and dorsolateral and posterior hypothalamus (all involved in regulating sleep) as well as peripheral 'clocks' in various tissues. Lam et al (2001) suggests that circadian abnormalities lead to sleep disorders (e.g. phase shifts), serotonin abnormalities lead to disorders such as OCD, but combined circadian-5-HT (hypofunction) abnormalities lead to major depression (MDD) or seasonal affective disorder. Turnover of central 5-HT is normally much greater in summer than in winter, as is placebo response in depression. Light therapy added to an SSRI may speed up response in non-seasonal MDD. Also, light therapy may be useful in the treatment of depression lasting more than two years. (Wirz-Jones, 2005) Contraindications to light therapy are relative (retinal photosensitising drugs such as lithium, thioridazine and melatonin; disease of retina; macular degeneration).

Mutation in the mouse 'CLOCK' gene, a core circadian clock gene, is thought to induce mania-like behaviour. (Roybal et al, 2007) However, a study from Japan (Kishi et al, 2009) failed to find any association between the 6 tagging SNPs in CLOCK and bipolar disorder, major depressive disorder, or schizophrenia, although the authors wondered if a study using bigger numbers of patients might produce different results. The RAR-related orphan receptor beta (RORB) is altered in mice lacking the clock gene D-box binding protein (DBP). This has been suggested as a stress-reactive genetic animal model of bipolar disorder (BP). In a study of a paediatric cohort, McGrath et al (2009) found a positive association between 4 intronic RORB SNPs and the paediatric BP phenotype. These findings should be subjected to further research.

Pharmacological, pathological, pathochemical, and related genetic findings in depression (in roughly chronological order)

Reduced prolactin (P) response to fenfluramine (F) in endogenous depression; basal P levels reduced in bipolar (BP) v unipolar (UP) depression, and delusional v non-delusional depression, although there were no differences in P responses to F between these subgroups; basal cortisol (C) levels and C response to F did not distinguish between subtypes
No increase in cerebral glucose metabolism in drug-free, untreated major depressives (normal response is increased metabolism)

Higher lethality suicide attempts associated with lower P response to F

Major depressives (MD) had blunted P response to clomipramine

Tryptophan-deficient amino acid mixture (TDAAM) lowered mood only if there was a family history of major affective disorder

TDAAM evoked depression in women with past recurrent MD but currently in remission and drug free

TDAAM in remitted SAD during summer increases chances of return of depression

Euthymic, drug-free people with a history of MD become depressed if given α -methyl-paratyrosine (catecholamine depletion via tyrosine hydroxylase inhibition)

Since both TDAAM and α -methyl-paratyrosine reverse light therapy effects in SAD both 5-HT and catecholamines may be involved

Lithium may protect against TDAAM-induced mood changes or suicidality in BP disorder

Whole-blood tryptophan was lower in prepubertal child psychiatry in-patients with recent AS

Tryptophan hydroxylase U allele associated with attempted suicide in MD

Dieting reduces plasma tryptophan in females independent of mood status; unlike women with a history of depression, dieting increased prolactin response to tryptophan in women without a history of depression

5-HT_{2A} receptor binding greater in prefrontal cortex (PFC) of suicides – this author agrees with the original researchers that this was due to overrepresentation of violent suicides; teenage suicides had increased levels of 5-HT_{2A} receptor, protein, and mRNA expression in PFC and hippocampus (suggesting emotional, stress, and cognitive elements)

Diffusely decreased 5-HTT (serotonin transporter sites) binding in prefrontal cortex (PFC) of major depressives and localised reduction in ventral PFC of suicides (PET study later showed reduced PFC glucose uptake in high-lethality attempted suicides with MD: Oquendo et al, 2003)

Impaired sensitivity of postsynaptic 5-HT_{1D} receptors that mediate growth hormone release demonstrated in melancholic depression

High plasma β -endorphin levels may be associated with more severe anxiety, phobia and obsessions and compulsions in the depressed

Life events might activate noradrenergic projections from brain stem to hypothalamus, secretion of CRF/ACTH/corticosteroids, and the action of latter at type II corticosteroid receptors in the brain, leading to depression

A blunted TSH response to TRH has been described in depression but is not specific to it

G proteins in mononuclear cells reduced in terms of function and quantity of G_s and G_i in proportion to depth of depression;

normalised with ECT and before mood lifted, predicting good response

Untreated patients with atypical winter depression had decreased G_s and G_i in mononuclear cells, normalising during summer or with light treatment

Increased CRF (CRH)-containing cells and CRH mRNA in paraventricular nucleus of hypothalamus in suicide victims

Increased intracellular calcium in platelets and lymphocytes in both phases of BP but not in UP, euthymic patients or controls

Increased Rap 1 (a protein kinase A substrate) in platelets of untreated euthymic BP, depressed BP, and manic patients, possibly reflecting a problem in cAMP phosphorylation system

Higher than expected prevalence of anti-thyroid antibodies in BP not due to lithium (but latter can exacerbate the process)

Reductions in components of the phosphoinositide signal transduction system in brains of suicides

Prolactin response to citalopram blunted similarly in both acutely ill and recovered major depressives (in favour of impaired 5-HT neurotransmission being a trait)

In MD, the cortisol response to citalopram blunted in ill patients but not in recovered subjects (may represent resolution of hypothalamic-pituitary-adrenal [HPA] axis dysfunction)

Acute tryptophan depletion impairs speed of information processing in first-degree relatives of bipolars and in controls; speed of information processing on a planning task impaired in relatives only; those with BP type I relatives had impaired planning and memory, independent of acute tryptophan depletion. 5-HT appeared to be involved in information processing, verbal and visual memory and learning processes.

Hippocampal sections looking at GAD (glutamic acid decarboxylase, involved in GABA synthesis): density of GAD65 and GAD67 mRNA-positive neurones reduced by 45% and 43% respectively in BP (only 14% and 4% respectively in schizophrenia); GAD65 mRNA-positive neurones in BP significantly diminished in sectors CA2/3 and dentate gyrus; GAD67 mRNA-positive neurones decreased significantly in CA4 in BP (but not in schizophrenia); authors suggest they have found a region-specific deficit in both these isoforms in BP. (Hekers et al., 2002)

Brain weight in suicides not significantly different from the general population.

Immunohistochemistry found increased cell adhesion molecule expression in grey matter of dorsolateral PFC (DLPFC) in postmortem tissue from elderly patient who had been diagnosed MD (suggestive of inflammation and consistent with ischaemia).

Neuroticism did not predict amount of mood change following acute tryptophan depletion in healthy volunteers (but it did moderate performance on a verbal fluency test).

Tryptophan hydroxylase A779 allele more common among deliberate self-harm subjects v controls.

No loss of 5-HT neurones and no neuritic pathology in dorsal raphe nuclei in older depressives, with or without comorbid Alzheimer's disease.

PET: medication-free MD had significantly decreased regional normalised trapping constant (K^*) of α - ^{11}C MTTrp, a proxy for 5-HT synthesis in cingulate cortex; difference in the cingulate cortex was statistically stronger in females; differences between MD and controls in normalised K^* values are mainly in anterior cingulate cortex.

Protein kinase C activity reduced in PFC and hippocampus of teenage suicides.

PET: tryptophan depletion induced transient return of depressive symptoms in remitted MD but not in controls; tryptophan depletion associated with increased regional use of glucose in orbitofrontal cortex, medial thalamus, ant and post cingulate cortices, and ventral striatum in remitted MD but not in controls; therefore, authors suggest that there is an underlying disease-specific 5-HT-related trait dysfunction in MD.

Beta-arrestin-1 levels reduced in white blood cells in depressives and elevated in rat brain by antidepressants.

Haplotype linkage of tryptophan hydroxylase 2 (TPH2 – encodes the rate-limiting enzyme for brain 5-HT synthesis) to suicide attempt and MD and to CSF 5-HIAA provides preliminary evidence of a functional locus potentially within a haplotype block at least 45 kb in size.

Presence of lifetime history of depression in Alzheimer's disease corresponds to increased Alzheimer-related neuropathological changes in the hippocampus – more pronounced if depression occurs early during the disease process.

Haplotype linkage analysis of TPH2 in UP and BP North Sweden isolates provides evidence of protective association in both disorders.

2-dimensional electrophoresis of DLPFC in scz, BP, and mentally normal controls to look for abnormal proteins: scz and BP had differences from controls; mass spectrometry identified 15 scz-associated and 51 BP-associated proteins; most affected were synaptic proteins in scz and metabolic and mitochondrial proteins in BP; majority of abnormally expressed synaptic-associated proteins in BP were isoforms of the septin family; findings are evidence for synaptic pathology in scz and metabolic dysfunction in BP.

Recovered male depressives have normal 5-HTT availability in brain areas considered important in pathophysiology of depression, e.g. anterior cingulate cortex.

MD, SERT-ss genotype and suicide contribute to an enlarged thalamus; the SERT-ss genotype and MD enlarge the pulvinar and limbic nuclei respectively; antidepressant treatments shrink the thalamus.

Link between childhood-onset depression and NTRK3 gene (neurotrophic tyrosine kinase receptor-3 on 15q).

In East Baltimore study 1 or 2 short alleles of serotonin transporter gene carried highest risk of first episode of MD but episodes tended to be relatively short.

Declarative memory impairment in young women at increased risk for depression may be partly related to increased cortisol secretion but no significant effect of 5-HTT allelic status on either memory or waking cortisol secretion was found.

Increased cortisol awakening response among those with current MD and those with remitted MD may indicate biological vulnerability to depression.

Effect of 5-HTTLPR (5-HTT promoter length polymorphism) on antidepressant response is SSRI specific, concentrated in males, and influenced by the single-nucleotide polymorphism rs2020933.

In adolescents at high risk for depression there were higher levels of cortisol in those with the short (s) allele of 5-HTT promoter (5-HTTLPR): s/s > s/l > l/l; subsequent depressive episode was increased in subjects with s allele and higher cortisol, and independently by depressive symptoms at entry, in both sexes.

Using small number of BP and MD cases and muscarinic selective radioligands differences were found between the two disorders.

During a cognitive test battery, near-infrared spectroscopy in BP suggested a discrepancy in PFC function between verbal versus non-verbal processing, indicating possible task-specific abnormalities in haemodynamic control of PFC.

Controlled post-mortem study found a decrease in pyramidal neuronal size in DLPFC in late-life depressives.

Postmortem study of anterior cingulate brain sections (BP, MD, schizophrenia, and controls) determined oxidative stress by analysing 4-hydroxynonenal (4-HNE), a major product of lipid metabolism; 4-HNE levels raised by 59%, 47% and not at all in BP, schizophrenia, and MD respectively; oxidative damage may contribute to BP and schizophrenia

Bulgarian study suggests that rs1800883, an SNP in HTRSA gene (variant of 5-HT5A gene) might confer susceptibility to BP

Postmortem study of habenular complex found significant volume reductions in depressives compared to normals and schizophrenia patients; for the right side, only the depressives had reduced neuronal cell number and cell area

Link between and NTRK2 gene¹³⁰² (neurotrophic tyrosine kinase receptor-2) and suicide attempts in major depression.

Impairment of mitochondrial complex I activity may be associated with increased PFC protein oxidation and nitration in BP.

In a study of polymorphisms in genes regulating the CRF (CRH)-releasing factor system, a SNP within the CRHBP locus is associated with response to citalopram and the T allele of this SNP is associated with poor response to this antidepressant in African Americans and Hispanics.

Significant reduction in neuronal density found in lateral septal nucleus in BP.

Notes: Fenfluramine, an amphetamine, is a serotonin agonist. Clomipramine inhibits serotonin reuptake. Whilst depression may be associated with a blunted P response to 5-HT, weight loss increases P response to 5-HT, and both these can cancel each other out, a point to be remembered when investigating the depressed patient who has lost weight! There have been reports of increased G protein measures in mononuclear cells in mania and in postmortem cerebral cortex in BP.

The 5-HTT binding potential varies with the seasons.(Praschak-Rieder ea, 2008)

The 5-HTTLPR gene variant of the serotonin transporter gene (SERT or 5-HTT) is comprised of a short (SERT-s) and a long (SERT-l) allele.

(DL) PFC, (dorsolateral) prefrontal cortex.

The EEG in depression shows reduced delta sleep and reduced REM latency, but increased REM density. Reduced slow wave sleep correlated strongly with recurrent affective disorder and may be a trait marker, whereas REM dysregulation is most marked during a depressed phase, especially early on in the episode.(Kupfer ea, 1991)

With regard to evoked potentials, psychotic BP patients have been noted to differ in the asymmetry of the M20 (this 20 msec latency somatosensory evoked field component is generated in the postcentral gyrus) from BP patients without psychosis.(Reite ea, 1999) Another study found that relatives of BP patients have reduced P300 amplitude and prolonged P300 latency.(Pierson ea, 2000) Results from a Maudsley bipolar twin and family study (Hall ea, 2009) suggest that auditory P300 amplitude and latency components (but not mismatch negativity) are valid endophenotypes for psychotic BP. Another study (Patterson ea, 2009)¹³⁰³ suggests that the P85 may be an endophenotypes for BP I disorder.

A deficit in P50 sensory gating may be common to BP and schizophrenic patients: the fact that it occurs in euthymic BP cases suggests that it is a marker of vulnerability to psychosis independent of diagnosis.(Sánchez-Moria ea, 2008)

CT studies have shown patients with affective disorders to be similar to schizophrenic patients and significantly different from control subjects in ventricle: brain ratio, sulcal widening, and cerebellar vermian atrophy. Neuroimaging studies in the affective disorders are summarised in the box. Phillips ea (2008) reviewed structural and functional neuroimaging studies of BP patients and found that medication had either no significant effect or ameliorative effects on relevant abnormal structural and functional measures. According to Liddle,(2001, p. 206) structural imaging studies in BP disorder shows focal grey matter loss in the subgenual cingulate gyrus¹³⁰⁴, ventricular enlargement, and deep subcortical white matter hyperintensities. Kempton ea (2008) reported on a meta-analysis of 98 structural imaging studies in BP disorder and found that BP was associated with lateral ventricular enlargement, an excess of deep white matter (but not periventricular) hyperintensities, and, related to lithium use, increased grey matter volume. Importantly, these workers suggest that such studies have appreciable levels of both Type I and II errors. Another meta-analysis of volumetric MRI studies in BP (Arnone ea, 2009) found that patients with this disorder had smaller whole brains and prefrontal lobes as well as larger globi pallidi and lateral ventricles; compared to schizophrenia, BP was associated with smaller lateral ventricles and bigger amygdalae. A number of studies suggested that the closer the lesion is to the frontal pole on the dominant side, and the further away from the pole on the opposite side, the more likely is the person to be depressed. However, Carson ea (2000) found no support for a link between the site of a lesion and risk of depression. A meta-

¹³⁰² NTRK2 gene is the high-affinity receptor gene for BDNF.

¹³⁰³ **P85** is an auditory brain potential at 85 ms. Patterson ea (2009) got P50 and P85 from schizoaffective, paranoid schizophrenic (PS), and bipolar I (BP I) subjects. The P85 *gating ratio* (ratio of amplitude of evoked potential at stated number of milliseconds to the first of 2 paired clicks to the response to the second click) was significantly larger in BP I group compared to other groups. P50 gating ratio was significantly larger for schizoaffective group than for controls but failed to distinguish them from PS or BP I. These results need to be replicated.

¹³⁰⁴ However, Hajer ea (2008) found no subgenual volume abnormalities on MRI in unaffected or affected relatives of BP patients suggesting that this is not an endophenotype. These findings are in agreement with those of Hajek ea.(2009) The subgenual cingulate has been stimulated in studies of deep brain stimulation.

analysis of MRI studies in major depression (Koolschijn et al., 2009) showed large volume reductions in frontal regions (especially in anterior cingulate and orbitofrontal cortex – less so in prefrontal cortex) and moderate reductions in hippocampus, putamen and caudate nucleus. The authors point out that the areas affected are involved in emotion processing and regulation of stress. A meta-analysis of five MRI case-controlled studies found reduced area of corpus callosum, with implications for inter-hemispheric integration of information, in BP patients. (Arnold et al., 2008)

Neuroimaging reports in the affective disorders

It should be noted that much of this research involves using affective cases as controls in schizophrenia research.

CT:

Depressive pseudodementia associated with increased ventricle-brain ratio (VBR) and reduced tissue density

Older depressives have similar changes to patients with Alzheimer's disease but not as severe

In CVA, the closer the lesion is to the frontal pole on the dominant (for speech) side, and the further away from the pole on the opposite side, the more likely is the person to be depressed (but see Carson et al., 2000)

MRI:

Increased T1 values in frontal white matter of unipolar (UP) but not bipolar (BP) cases

9 of 19 cases of BP had subcortical hyperintensities (SHI) - SHI associated with more periods in hospital and greater impairment of fluency and recall

Excess deep white matter lesions in first ever late-onset depression

T2-weighted lesions in basal ganglia and pontine reticular formation associated with treatment-refractory depression in elderly

Severe white matter lesions in over 55s associated with worse outlook at mean follow up of 32 months

Subcortical white matter lesions associated with poorer outcome in BP disorder

Young BP patients have increased volume of abnormal white matter not seen with same-aged UP or controls

Enlarged amygdala in hospitalised manics

Enlarged pituitary in depressives (? due to hyperplasia of ACTH-producing corticotrophic cells – trophic effects of CRF)

Enlarged adrenals¹³⁰⁵ during major depression (MD) return to normal with remission following treatment

Treatment-resistant chronic UP depressives had reduced grey matter density in L temporal cortex, including hippocampus, with a trend to same on R side; L hippocampal grey correlated with verbal memory

In women with recurrent MD (none with cerebrovascular risk factors) SHI not different from controls

Reduced size of L hippocampus in MD

Smaller hippocampi found in adult women with MD only if they had childhood history of severe/prolonged physical and/or sexual abuse

During Stroop task, BP associated with a trait abnormality in L ventral prefrontal cortex; additional ventral prefrontal abnormalities may be associated with specific acute mood states

Greater progression of white matter hyperintensities associated with poor outcomes in geriatric depression

BP in adolescents and adults associated with decreased volumes of amygdala and hippocampus, esp. the amygdala: suggests early manifestations of BP because of similar findings in both age groups

Homozygosity for the long variant (L allele) of the 5-HT transporter polymorphism is associated with reduced hippocampal volumes in patients with MD but not in healthy controls (this has also been shown for late-onset depression)

Young women with MD have reduced size of hippocampi and larger amygdala volumes compared to controls

Genetic risk for schizophrenia specifically associated with distributed grey matter volume deficits in bilateral fronto-striato-thalamic and left lateral temporal regions; genetic risk for bipolar affective disorder specifically associated with grey matter deficits only in the right anterior cingulate gyrus and ventral striatum; genetic risk for both disorders was associated with reduced volume of white matter in left frontal and temporo-parietal regions; findings interpreted as representing a common fronto-temporal disconnectivity

First MD episode in female cancer survivors after cancer diagnosis does not appear to be associated with hippocampal volume, but longitudinal study with healthy comparison group is needed

Reduced hippocampal volumes found in older (primary MD) depressives (28-82 years of age, mean 53.5, s.d. 13.5); those with either early- or late-onset depression, and those with melancholia showed this phenomenon; such reduction was associated with deficits in visual and verbal memory performance

BP children have reduced grey matter volume in L DLPFC

Poor response to antidepressant treatment of major depression associated with subcortical white matter hyperintensities in L hemisphere but not in other brain areas

Drug-naïve BP patients (but not those who received medication) have shape differences of striatum relative to healthy controls

BP (aged 19-39 years) and controls: in BP, mean temporal volumes reduced and, in some cases, deep white matter lesions present

Medication-naïve BP I associated with smaller corpus callosum

¹³⁰⁵ Presumably due to hypersecretion of ACTH. Such hypertrophy has been found in depressives post mortem and in completed suicides.

Reduced orbitofrontal cortex (OFC) volume occurs in older depressives and is associated with worse lesions of white matter; healthy people with APOE ε4 allele have larger OFC volumes

Regional hippocampal surface contractions were significantly pronounced in late- v early-onset elderly depression in anterior of the subiculum and lateral posterior of the CA1 subfield in the left hemisphere – hippocampal surface contractions correlated with memory measures in late-onset cases only

Elderly depressed subjects differed from elderly non-depressed subjects in having seven regions of white matter hyperintensities despite having equal vascular risk factors

White matter hyperintensities are not associated with vulnerability to psychosis in general, or specifically with affective psychoses

Study of cingulate gyrus grey matter volume: initial and progressive changes in first episode affective psychosis (mainly mania) were confined to subgenual cingulate whereas people with first episode scz had widespread initial and progressively smaller volumes

Reduced amygdala volume in major depression with psychosis but not in major depression without psychosis

Dutch twin study found BP was associated with decrease in total cortical volume; decreases in white matter were related to genetic risk of developing BP; and significant environmental correlations were found for cortical grey matter; and *lithium attenuates the decrease in both grey and white matter*¹³⁰⁶

Carriers of the BDNF Val66Met polymorphism (Val/Met and Met/Met) have relatively small hippocampus, parahippocampal gyrus and amygdala

Diffusion tensor imaging (DTI) revealed decreased size of anterior cingulum in BP

First-episode MD (n = 28 in-patients) – significant negative correlation between major life events 3 months before onset of depression and left hippocampal volume in males; no significant association found for females

DTI in BP showed greater white matter fractional anisotropy in the left orbitomedial PFC that decreased with age and with alcohol/drug misuse, as well as reduced white matter fractional anisotropy in the right orbitomedial PFC

Major depression associated with decline in grey matter density of hippocampus, anterior cingulum, left amygdala, and right dorsomedial PFC – remission during 3-year study was associated with lesser changes

DTI showed similar white matter abnormalities in BP and schizophrenia

Treatment-resistant UP and BP depressives showed reduced global cortical folding and lithium may modify cortical folding in BP cases; limitations include overlap with normal controls and inability to distinguish trait and state effects

Looked at type II diabetes (DMII) + depression, DMII without depression, and healthy controls: magnetization ratios significantly lower bilaterally in caudate head in type II diabetes (DMII) + depression group; non-depressed DMII had intermediate values

Looked at anterior cingulate cortex in patients with first psychotic episode in BP-I – males had thicker right subcallosal limbic anterior cingulate cortex that was not explained by medication effects; no differences between female patients and healthy controls (should the patients have compared with BP-I without psychosis?)

Grey matter deficits in inferior frontal regions in patients (N = 56) with mean age of 60.5 years

DTI performed on psychotic BP I cases, unaffected first-degree relatives, and controls: patients had decreased fractional anisotropy in genu of corpus callosum, right inferior longitudinal fasciculus, and left superior longitudinal fasciculus; patients and their relatives had decreased fractional anisotropy across distributed regions of white matter – the structural integrity of key intra- and inter-hemispheric tracts was disturbed in BP and unaffected relatives

Compared to matched controls, DSM-IV BP adults (mean age 60.5 years) had significantly smaller gray matter volumes bilaterally in inferior frontal areas (part of the anterior limbic network)

Amygdala volume of euthymic BP I patients receiving lithium was larger than that of healthy controls whereas amygdala volume of euthymic BP I patients not receiving lithium was similar to that of healthy controls

DTI found ‘early’ changes in course of BP (i.e. patients were adolescent) in areas associated with regulation of emotion, behaviour, and cognition (lower fractional anisotropy in fornix, left mid-posterior cingulate gyrus, all of corpus callosum, fornico-thalamic fibres, and parietal and occipital corona radiata bilaterally)

Healthy people show an inverse relationship between impulsivity and orbitofrontal cortex volume; however, impulsivity may have a different neural representation in BP wherein the anterior cingulate cortex may be implicated

Currently euthymic BP and controls: generalised white matter microstructural abnormalities in BP; these may have been exacerbated by past drug abuse and lessened by lithium

In Women’s Health Initiative Memory Study abnormal white matter lesions related to hypertension in most brain areas and are greatest in frontal lobe than in other lobes; baseline blood pressure level strongly related to white matter lesion volumes

White matter hyperintensities (rather than cortisol levels or cerebral atrophy) are associated with continuing cognitive impairment in depressed older adults

Baseline severity of white matter changes in older subjects independently predicted depressive symptoms at both 2 and 3 years and white matter changes predicted incident depression

Late-onset MD may be associated more with white matter lesions in areas important for cognition and emotion (left superior longitudinal fasciculus and right frontal projections of corpus callosum) than with total lesion load; lesion load correlated highly with smoking

fMRI:

Children and adolescents with familial BP may have abnormal regulation of prefrontal-subcortical circuits

Antidepressant treatment of MD reduces L limbic, subcortical, and neocortical capacity for activation and increases the dynamic range of the L prefrontal cortex in patients shown sad faces

¹³⁰⁶ See van der Schot et al (2009).

A common regulatory variant (5-HTTLPR) in human 5-HT transporter gene (SLC6A4) has a strong modulatory effect on amygdala reactivity to environmental threat, and might represent a susceptibility for affective disorders

Controlled study of juvenile of parents with history of MD showed greater amygdala and nucleus accumbens activation to fear faces and the opposite response to happy faces – these results held true for passive viewing but not for constrained (told to look at the nose only) attention, the latter probably recruiting medial prefrontal cortex to a greater degree

MD, relative to controls, associated with increased response time from neutral to sad words on emotional Stroop task and significant engagement of left rostral anterior cingulate cortex and right precuneus during sad words

Lamotrigine might enhance facial affect recognition in bipolar disorder

BP show abnormal fronto-striatal activity when performing a set shifting task, perhaps excessively engaging emotional brain areas

Whilst controls activated the pregenual anterior cingulate cortex in response to positive and negative words during emotional Stroop task, young people with depressed parents did not activate this area

Men with histories of attempted suicide show different pattern of brain activation in response to angry faces compared to non-suicidal comparison subjects

In MD there is abnormal connectivity of dissociable prefrontal and cingulate regions – increased connectivity of dorsolateral prefrontal cortex during task-induced activation and increased connectivity of anterior cingulate cortex during task-induced deactivation

MD shows weak response in left nucleus accumbens and both caudate nuclei during monetary incentive delay task

In the elderly, during a test that activates lateral prefrontal cortex-anterior cingulate cortex (ACC), anxious depressives seem to expend greater and more sustained effort (involving the ACC) than do depressives

Measuring BOLD signals, authors found that abnormal amygdala-prefrontal effective connectivity to happy faces distinguished BP depressed patients from MD depressed patients

In BP there is relatively greater increases in activation for emotional v neutral scenes in left hippocampus than is seen in healthy controls or schizophrenia patients; there is a positive correlation between mania scores and activation in ACC, and a significant negative correlation between depressive scores and DLPFC activation

PET:

Severely depressed UP and BP had significant L-R prefrontal asymmetry before but not after successful TCA treatment (? state); significant hypofrontality and whole cortex hypometabolism in depressed and treated states (trait?)

5-HT₂ receptor study with [¹⁸F] altanserin – uptake reduced in drug-free UP in R (trend for L to be similarly affected) posterolateral orbitofrontal cortex and anterior insular cortex

Brain 5-HT₂ receptors decreased in MD

Men recovered from depression subjected to tryptophan depletion had reduced neural activity in ventral anterior cingulate, orbitofrontal cortex, and caudate, as well as attenuated cognitive task-related activation in anterior cingulate cortex (small numbers of males on antidepressants)

Healthy women before and after rapid tryptophan depletion: decrease in plasma free tryptophan levels but no effect on mood; decreased cortical 5-HT₂ receptor binding (which may be protective against depression)

Increased anterior paralimbic activation from waking to REM may be related to depressed mood, whereas increased activation of executive cortex may be related to cognitive dysregulation in depressed patients

Magnitude of regional 5-HTT binding potential can provide a vulnerability to low levels of extracellular 5-HT and very negative dysfunctional attitudes

DSM-IV BP manic episode and healthy controls: evidence suggests decreased 5-HT₂ receptors in acute mania

SPECT:

rCBF lower in orbital frontal and anterior temporal regions (especially on R side) in medication-free older physically healthy depressed

Greater degree of depression in UP with diurnal mood variation associated with increased cingulate and other paralimbic perfusion

DA transporter affinity may be increased in basal ganglia in major depression

Patients over 55 years of age with depression (HAM-D) given average of 13.7 weeks antidepressant treatment showed improvement in rCBF in left DLPFC to precentral region (? Represents functional/reversible problem) whereas no real improvement in bilateral medial/dorsolateral/parietal (? Trait-dependent)

MRS:

Decreased GABA in occipital cortex in MD

Myo-inositol/creatinine and choline/creatinine ratios increased in frontal white (but not gray) matter in (major) depressed elderly

Euthymic males with familial BP I: lower levels of N-acetylaspartate and creatinine but normal choline levels in R and L hippocampi; significant negative correlation between N-acetylaspartate concentration in R hippocampus and illness duration

Replication of finding of reduced GABA level in occipital cortex in MD; also, mean glutamate levels decreased in depression; and, decreased solid tissue and the percentage of white matter in the voxel

Young and adult BP patients have decreased N-acetylaspartate (NAA) levels in DLPFC (? underdeveloped dendritic branching and synaptic connections)

Adolescents with MD have increased choline and creatinine in left caudate, likely due to rapid membrane turnover and impaired metabolism

Increased choline-containing compounds (glycerophosphocholine and phosphocholine) in orbitofrontal cortex and hippocampus in euthymic BP patients; since choline is a marker for membrane phospholipid metabolism the increased levels may mean increased membrane breakdown, i.e. cell loss

A low 5-HT level might prime the brain so that if now catecholamine levels rise the person becomes manic, but should they fall depression ensues. Thakore et al (1996) suggest that the finding of blunted d-enfluramine-

induced prolactin release in bipolar mania supports the notion that both BP and UP affective disorder are associated with decreased serotonergic responsivity.

It has been said that intracellular sodium rises in depression, and rises still further in mania. Vanadium poisoning of the sodium pump was a popular suggestion as a cause of affective disturbance during the 1980s, patients being subjected to massive doses of ascorbic acid as a putative antidote.

Many drugs can cause depression (e.g. steroids¹³⁰⁷, alpha-methyl dopa, beta-blockers that cross the blood brain barrier¹³⁰⁸, cimetidine, reserpine, tetrabenazine, vigabatrin (Sabril – up to one third of patients develop visual field defects), and BZDs (do they cause or unmask it?: Tiller & Schweitzer, 1992), or stimulant withdrawal), or have a depressive aftermath (e.g. amphetamines). Isotretinoin (Isotrex, Isotrexin, Roaccutane), a vitamin A derivative used for severe acne, has been blamed for depression, psychosis and suicide. Whilst great care is required to monitor for depression in cases treated with isotretinoin, it should be recalled that acne itself is commonly associated with depression (Anonymous, 2003) and the literature is far from unanimous in its findings re isotretinoin. (Jick *et al*, 2000; Magin *et al*, 2005) Isotretinoin should be prescribed by a dermatologist for severe, refractory acne and it should either be stopped if depression occurs or psychiatric assistance should be enlisted. There has been a report of a florid hallucinatory and delusional state complicating TCA treatment of steroid-related depression. (Hall *et al*, 1978) The most common depressogenic agent is alcohol, either as an adjustment disorder or a direct effect of alcohol on mood. Certainly, comorbid alcohol use disorder, common in BP, increases suicidal behaviour beyond that associated with non-comorbid BP. (Oquendo *et al*, 2010) L-DOPA can cause depression or hypomania. It can also cause confusion/delirium, agitated restlessness, psychosis, and, less commonly, hypersexuality. Depression and physical deterioration are associated with lack of activity. There seems to be an increased risk of coronary artery disease in depressives¹³⁰⁹. Bone mineral density (spine and hip) has been found to be lower in depressives than in controls, especially in females. (Wu *et al*, 2009) Depression may be secondary to such physical disorders¹³¹⁰ as Addison's disease, Parkinson's disease¹³¹¹, heart failure¹³¹², myocardial infarction, stroke¹³¹³, chronic pulmonary disease, hip fracture, and bronchogenic or pancreatic carcinoma. Presumed intrauterine (second trimester) starvation in males during a Dutch famine has been found to correlate with later affective psychosis, but not with neurotic depression. (Brown *et al*, 1995) A report of an association of poor weight gain in infancy and adult suicide may reflect the operation of psychosocial or biological factors. Similar considerations probably apply to the Swedish findings of Mittendorfer-Rutz *et al* (2004) who reported that multiparity and low maternal education predicted suicide attempt in offspring, whereas as restricted foetal growth and teenage motherhood were associated with both completed suicide and attempted suicide in the offspring. Both B12 and folate deficiency may be associated with depression, although they are not always primary. Mania has been reported to occur secondary to many conditions. (see box) Many reports are anecdotal and it is often difficult to make a strong case for direct causation. There is no good evidence to link affective psychosis or mania to problems at birth. DSM-IV does not allow manic-like episodes clearly secondary to antidepressant treatment¹³¹⁴ to count toward a diagnosis of BP I disorder. Overactivity, pressured speech, and racing thoughts during bipolar depression should alert the therapist to enhanced risk for conversion to mania with antidepressant drugs. (Frye *et al*, 2009)

¹³⁰⁷ Corticosteroids change sensitivity of noradrenergic receptors by regulating the brain's beta-adrenoreceptor-coupled adenylate cyclase system; antidepressants activate the cAMP cascade causing BDNF and CREB release leading to hippocampal neurogenesis.

¹³⁰⁸ Beta-blockers, however, may not be as depressogenic as they are normally stated to be. (Long & Kathol, 1993; Ko *et al*, 2002)

¹³⁰⁹ Not totally attributable to other risk factors such as tobacco.

¹³¹⁰ Farmer *et al* (2008) found that people with recurrent depression were more obese than controls and had an excess of gastric ulcer, rhinitis/hay fever, osteoarthritis, thyroid disease, hypertension and asthma.

¹³¹¹ Based on SPECT findings, major depression in Parkinson's disease may be a consequence of advanced and widespread neurodegeneration. (Pålhagen *et al*, 2009)

¹³¹² Heart failure leads to depression and treatment of heart failure with loop diuretics reduces the risk of depression as shown in a Dutch population-based study of elderly subjects. (Luijendijk *et al*, 2010)

¹³¹³ Depression is associated with increased mortality post-CVA. Stroke cases are more depressed than 'similarly disabled' orthopaedic patients. The 5-HTTLPR and the STin2 VNTR polymorphisms of the 5-HT transporter gene may be associated with post-stroke depression. (Kohen *et al*, 2008) SSRI drugs tend to be prescribed, although nortriptyline was superior to fluoxetine in one small study of post-CVA depression. (Robinson *et al*, 2000)

¹³¹⁴ E.g. antidepressant drugs, ECT or light therapy.

Possible causes of secondary mania¹³¹⁵

Delirium
ECT
Huntington's, Wilson's, and Pick's diseases
Kleine-Levin and Klinefelter's syndromes
Post-encephalitic Parkinsonism, GPI, viral encephalitis, HIV
Cerebral tumours or trauma (e.g. closed temporal basal polar injury, diencephalic glioma, suprasellar craniopharyngioma, tumour of floor of fourth ventricle, metastatic deposits in right temporo-parieto-occipital area, right-sided intraventricular meningioma)
Cerebrovascular accident¹³¹⁶ (CVA)
MS
Thalamotomy
Right temporal lobectomy
TLE
Open-heart surgery
Carcinoid syndrome/serotonin syndrome
Uraemia, haemodialysis, dialysis dementia
Hyperthyroidism
Hypoadrenalism, Cushing's disease
B12 deficiency, pellagra
Postpartum¹³¹⁷
Post-isolation syndrome
Drugs (those reported): metoclopramide, L-DOPA, baclofen, cimetidine, cyclobenzaprine, bromocriptine, sympathomimetics, bronchodilators, decongestants, corticosteroids, ACTH, disulfiram, hydralazine, INAH, dapsone, metrizamide (myelography), procarbazine, procyclidine, bromides, barbiturates, anticonvulsants, benzodiazepines, antidepressants, yohimbine, stavudine (d4T), zidovudine (AZT), didanosine, efavirenz, calcium replacement, hallucinogens, cocaine, amphetamines, PCP

Immunological findings in depression have included an impaired lymphocyte response. There are an increased number of circulating neutrophils and a fall in NK (natural killer) cells, T and B lymphocytes, and helper and suppressor/cytotoxic T cells. There are also a reduction in NK cell activity and lymphoproliferative responses to mitogen stimulation. B cell function is also affected. Resolution of major depression in HIV-positive women is associated with increased NK cell activity. (Cruess ea, 2005)
Depressed patients have increased antibody titres to herpes simplex virus (HSV-1) and cytomegalovirus compared to other hospitalised or healthy groups. A greater number of depressives respond to in vitro stimulation with HSV during the acute phase of their illness than during a remission. Ader ea (1995) wondered if there might be a latent herpes infection that becomes reactivated during depression. The finding of an increase in soluble receptors for interleukin-2 receptors in the plasma of suicide attempters might indicate either a state or trait marker.

Genetics

Genetic factors are often thought to be important in severe cases of depression and in cases with somatic symptoms whereas environmental factors may appear to be more important in milder cases of depression. Also, single genetic abnormalities can only explain a small part of all mood disorders. (Baldwin & Hirschfeld, 2005, p. 25) However, the interaction between genes and environment is complicated, e.g. while sensitivity to stress in adulthood may be due to sensitisation as a result of exposure to earlier stressors genes associated with depression may speed up the process of stress-induced sensitisation. (Wichers ea, 2009a, b) El Hage ea (2009), discussing vulnerability to depression, suggest that gene-environment interaction involves complicated involvement of serotonergic genes that modulate responses to stress via the hypothalamo-pituitary-adrenal system.

¹³¹⁵ Referred to as 'disinhibition syndrome' by neurologists, it is often associated with cognitive dysfunction.

¹³¹⁶ Perhaps particularly associated with right-sided vascular lesions.

¹³¹⁷ Sharma ea (2008) looked at 56 consecutive females referred with a diagnosis of postpartum depression and made the following primary DSM-IV Axis I diagnoses: major depressive disorder (46% of cases), bipolar disorder (BPD) not otherwise specified (29%), BPD II (23%), and BPD I (2%). They suggest that misdiagnosis of bipolarity may be common in such cases. Sharma ea (2009) suggest that hypomania after delivery is common and often misdiagnosed; also, bipolar II depression is often misdiagnosed as unipolar major depression and may be inappropriately treated with antidepressants.

The first degree relatives of UP probands have an increased rate of UP. The same relatives of BP probands have increased rates of UP and BP, especially UP. Cyclothymic mood swings may be found in a quarter of adolescent offspring of BP parents¹³¹⁸. Research is complicated by the fact that a number of apparently UP cases have had missed hypomanic episodes or haven't yet had a manic attack, i.e. they are truly BP!

Behavioural disinhibition (extreme tendency to seek novelty, approach the unfamiliar, and display disinhibited speech and action in unfamiliar settings) is increased in offspring of BP parents.(Hirshfeld-Becker ea, 2006) Indeed, impulsivity may be a 'core' feature of BP regardless of illness phase.(Swann ea, 2008)

Twin studies of BP disorder have yielded results similar to those for schizophrenia. Concordance rates for MZ twins (40-60%) are much higher than those for DZ twins. The risk of BP in offspring of MZ twins discordant for BP is the same whether the parent (twin) did or did not develop BP!(Jones ea, 2002)

Major affective disorder has been described in a family in association with the rare autosomal dominantly inherited keratosis follicularis¹³¹⁹. The association of consanguinity and puerperal psychosis in three British sisters suggests a single major susceptibility locus of recessive effect. But these are rare phenomena. Twin studies of major depression suggests that this is an artificial category consisting of depression symptoms of varying severity and duration.(Kendler & Gardner, 1998)

A major Swedish study suggests that schizophrenia and bipolar disorder are genetically overlapping disorder.(Lichtenstein ea, 2009)

Affective disorders: highlights of chromosomal research

Chromosome	Comments
1	?gene or genes predispose some to depression and some to alcoholism; perhaps the depression is alcohol-induced; DISC1 (1q42.1) and BP; 1q21.3-q.32.1 for 'postpartum mood symptoms'
2	Suggestive overlap of bipolar disorder (BP) with schizophrenia at 2p11-q14, e.g. MAL (2cen-q13); CREB1 (cAMP-responsive element binding protein 1 at 2q34 and important in cAMP signalling) and major depressive disorder (MDD)
3	Somatostatin (SST, 3q28, involved in GABA signalling) and BP
4	E.g. D5 dopamine receptor and adrenergic 2C receptor genes; FGF2 (fibroblast growth factor 2 at 4q26-q27 with neuroprotective role); FAT (FAT tumour suppressor homologue 1, 4q34-q35, with adhesion and signalling functions) and BP
5	Possible linkage between locus near the dominant DA transporter and BP disorder
6	Discrepant findings in relation to HLA region; dysbindin polymorphisms may increase susceptibility to BP I; HEY2 (hairy/enhancer-of-split related YRPW motif 2, 6q22, involved in neurogenesis and transcription) and BP
8	Neuregulin-1 may influence susceptibility to schizophrenia and BP disorder; 8p and MDD; possible connection between 8q24 and puerperal bipolar affective psychosis
9	9p24.3-p22.3 for 'postpartum mood symptoms'
11	No evidence between mutations on q arm and manic depression in 5 Icelandic pedigrees Belgian linkage study fails to find linkage between BP and p15 (such a linkage had been found initially in Old Order Amish but did not replicate with bigger group) BDNF (11p13-p12) and BP; SLC1A2 (glial high-affinity glutamate transporter 2 at 11p13-p12 with glutamate removal role)
12	Darrier's disease (12q) cosegregated with BP in two pedigrees ¹³²⁰
13	D-amino acid oxidase activator (DAOA)/G30 locus (formerly G72/G30) may be associated with schizophrenia, major depression, neuroticism, and BP (esp. with persecutory delusions). Overlap of BP with schizophrenia at 13q21-33. DGKH (diacylglycerol kinase eta, 13q14.11) gene codes for an important enzyme in the lithium-sensitive phosphatidyl inositol pathway
15	15q and MDD
16	16p 13 and bipolar affective puerperal psychosis ¹³²¹
17	SLC6A4 (5-HT transporter, 17q11.1-q12)
18	Possible susceptibility gene near centromere in BP disorder; not all studies agree
19	Possible shared susceptibility locus on 19q13 (MAG or myelin-associated glycoprotein at 19q13.1) between BP and schizophrenia in familial cases
20	Discrepant findings
21	TRPM2 (transient receptor potential cation channel M2 at 21q22.3, involved in calcium homeostasis)

¹³¹⁸ Regeer ea (2004) reported cyclothymia in 4.2% of the Dutch general population.

¹³¹⁹ **Darrier's disease:** skin disorder, epilepsy, intellectual disability, with gene at 12q23-24.1.

¹³²⁰ Whilst the gene for Darrier's disease has been identified as ATP2A2, mutations at this gene have not been reported in patients with BP disorder.(see Green ea, 2005) There are reports implicating 12q24 with BP.(Kalsi ea, 2006)

¹³²¹ See Jones ea (2007)

22	Velo-cardio-facial syndrome patients may have excess relatives with BP disorder ¹³²² with early onset; COMT (22q11.2) and BP; ADRBK2 (GRK3) or G-protein coupled receptor kinase 3 (22q11.13-22q12.1, involved in GPR signalling) and BP; APOL or apolipoprotein gene cluster (22q13) and BP
X	No evidence of linkage with BP

Caspi ea's (2003), Kendler ea's (2005) and Otte ea's (2007) work suggests that individuals with 2 short alleles (SS) at the 5-HTT locus¹³²³ have increased sensitivity to mild stressors. While the short allele of the 5-HTT gene may increase vulnerability to mood disorders it may also have a role to play in social phobia/social anxiety disorder (Furmark ea, 2004) and PTSD.(Lee ea, 2005)

There is evidence of widespread dysregulation of mitochondrial energy metabolism and downstream deficits of ATP-dependent processes in BP.(Konradi ea, 2004) This is associated with reduced expression of *nuclear* mRNA coding for mitochondrial proteins in BP subjects.

Genetic liability to depression is in part expressed by a tendency to negative affect in response to minor daily tribulations.(Wichers ea, 2007)

A developmental twin study of anxiety and depression symptoms (Kendler ea, 2008a) suggests that different genetic risk factors switch on and attenuate later at different ages.

A genome-wide association analysis (Ferreira ea, 2008) supported a role for the genes ANK3 and CACNA1C¹³²⁴ (12p13.3; encoding for the alpha subunit of the calcium channel Ca_v1.2)¹³²⁵ with increased risk of BP. Both play a role in ion channels in nerve cells and affect neuronal excitability levels: ANK3, which encodes the protein ankyrin G, is involved in sodium channel regulation, whilst CACNA1C is involved in calcium channel regulation. Could BP result from multiple rare structural variants? A polymorphism (rs1006737) within CACNA1C may confer risk for BP, recurrent MDD, and for schizophrenia.(Green ea, 2009) A genome-wide copy number variant (CNV) survey (Zhang ea, 2008) found that singleton deletions¹³²⁶ more than 100 kb in length were present in 16.2% of BP cases and 12.3% of controls (p=0.007), an effect that was more pronounced for age at onset of mania under 18 years. However, CNVs may be associated more with schizophrenia than with BP.(Grozeva ea, 2010)

Conditions included among affective (mood) disorders

Various depressive syndromes have often been noted to fail to remain stable on follow up.(Young ea, 1990) It is necessary to briefly discuss some of the forerunners of present day nosologies because they still appear in the literature.(van Praag, 2001) are of historical importance, and still appear under different names, and because today's taxonomies are imperfect.

The presence of a precipitant does not decide if a condition is endogenous or exogenous in origin. Mixtures of endogenous and exogenous depression are more common than either is in pure form.(Kendell, 1993) Andreasen ea (1986) found no difference in the rates of depressive illness between the relatives of patients with endogenous versus non-endogenous depression. Psychotic and endogenous are not synonymous. In some cases (atypical, masked, smiling [putting on a brave face], depressive equivalents) affective change is not prominent, although the concept of 'depression without depression'¹³²⁷ has been attacked by Stefanis and Stefanis.(1999) Such cases may present in the form of psychosomatic disorders, pains - such as atypical facial pain¹³²⁸, hysterical conversion syndromes, and hypochondriasis. In fact, according to Paykel (1989), the term atypical depression has three different meanings: marked anxiety and phobic symptoms; reversed functional shift (worse in evenings¹³²⁹); and non-endogenous depression in general. Other suggested guises include depressive pseudodementia (*vide infra*), alcohol abuse¹³³⁰, shoplifting, sexual

¹³²² A high incidence of BP I and II and cyclothymia was noted in patients with velo-cardio-facial syndrome by Papolos ea.(1996)

¹³²³ These alleles involve the promoter region of the 5-HT transporter gene, the latter being involved in serotonin reuptake by cell membranes.

¹³²⁴ **Timothy syndrome** is a rare autosomal dominant disorder with cardiac, digital and facial problems. Autism or autistic spectrum disorder may be found in those who live long enough. Mutations occur in the CACNA1C gene.

¹³²⁵ Drugs acting on this channel might be effective in BP, e.g. verapamil, diltiazem, nimodipine, and flunarizine.(Keers ea, 2009)

¹³²⁶ These are deletions that appear only once in the dataset.

¹³²⁷ *Depressio sine depressione*.

¹³²⁸ Intense, continuous pain; distribution may transcend V nerve boundaries; may have subjective facial swelling.

¹³²⁹ Concept introduced by English psychiatrist John Deryk Pollitt (1926-2005) in 1960.

¹³³⁰ According to Farren (2008) the adjusted odds ratio for comorbid alcohol dependence is 4.6 for BP I disorder and 3.0 for BP II disorder. He also suggests that cognitive therapy and sodium divalproex may be helpful in such cases.

disinhibition, ego-dystonic temper outbursts, behaviour disorder in the elderly¹³³¹, jealousy, new-onset loneliness¹³³², an anxiety state, accentuated personality traits, or an abnormal grief reaction. Increased appetite (craving for high calorie foods), heightened rejection sensitivity, and leaden paralysis ('heavy' feeling in limbs – like wading through water) are atypical features of depression. According to Kelsey ea, (2006, p. 162) atypical depression is characterised by chronic sensitivity to interpersonal rejection with relationship difficulties and overreaction to perceived slights. Sims (2003, p. 314) suggests that smiling depressives may be consciously concealing their low mood from habit of masking emotions or from an attempt to avoid treatment. Mixed states¹³³³ of different affects may occur, e.g. up to 40% of bipolar patients have mixed episodes at some time.(Calabrese ea, 1996) In dysphoric mania,¹³³⁴ mania is said to be present when the criteria for both major depression and mania are met simultaneously – many manic admissions fulfil criteria for mixed states. Bipolar I and II depressions are often accompanied by manic symptoms that may be missed because they are subtle or because they are overshadowed by the depression.(Goldberg ea, 2009) Kraepelin described 6 types of mixed affective state during the early 1920s: depressive/anxious mania, excited depression, mania with poverty of thought, manic stupor, depression with flight of ideas, and inhibited mania.

Pain is common in depression (von Knorring, 1975) and may be the sole symptom.(Simon ea, 1999) Suggested forms of depressive equivalents include sociopathy and alcoholism in male relatives, the same in the index patients, illegal drug abuse, psychocutaneous syndromes, peptic ulcers, and, in children, disorders such as autism, insomnia, theft, gastrointestinal upset, encopresis and school phobia.

Many depressed patients only have physical complaints without a known biological cause; others have symptoms disproportionate to medical findings. Doctors may collude with patients in avoiding discussion of psychosocial factors. Overt depressed mood is less common as a symptom in ethnic minorities and elderly subjects than in the average depressive.

One classification of affective disorders is into *primary* (arising independently) and *secondary* (e.g. due to carcinoma). *Personal depression* infers that the patient can see a connection between his life circumstances and his mood disturbance. In the absence of such a connection the term *vital depression* has been employed.

Another classification of depression was into *pure depressive disease*, especially affecting older men; whose relatives of both sexes showed an equal prevalence of depression, and *depression spectrum disease* affecting mainly young females whose relatives showed a greater prevalence of depression among females, their male relatives tending to be alcoholics or psychopaths. A more modern meaning of depressive spectrum¹³³⁵ disorders is one inclusive of major and minor depression and dysthymia.(Hermens ea, 2004) Depending on the particular nosology, unipolar might mean attacks of depression only, or of depression or mania only, and bipolar may denote attacks of depression and mania or of mania only. Perhaps 5-10% of patients experiencing an episode will develop mania in the future.(Lam & Mok, 2008, p. 31) The RDC distinguish between bipolar I disorder, wherein mania has occurred, and bipolar II disorder¹³³⁶, when only hypomania has been recorded. Some two-thirds to three-quarters of patients admitted with manic illness will suffer at least one relapse requiring hospital admission. This may not take into account missed mild attacks. Hypomania is simply a mild form of mania and is the commoner form seen today. About 5% to 15% of people with hypomania will develop mania some time in the future. DSM-IV-TR defines hypomania as not being severe enough to markedly impair social or occupational functioning, not necessitating hospitalisation, and being non-psychotic, a most unhelpful definition because of variations in

¹³³¹ E.g. the elderly nursing home resident who screams, lashes out, and voids anywhere but the toilet.

¹³³² E.g. an older person requesting re-housing.

¹³³³ **Mixed affective episode:** According to DSM-IV-TR the criteria are met for a manic episode and a major depressive episode nearly every day for a one-week period. ICD-10 requires at least 2 weeks of a mixture that can include extremely fast changes (hours) between 'highs' and 'lows'. Should manic stupor - the smiling but motionless patient - be included under this heading or should it be seen as mania complicated by stupor?

¹³³⁴ Described by Clothier and colleagues in the 1990s. It may be more common in females, carry an increased suicide risk, have a relatively poor outlook, and be comparatively lithium-resistant.

¹³³⁵ Or absence of clear boundaries.(Widiger & Mullins-Sweatt, 2007, p. 7)

¹³³⁶ This distinction between **two types of BP** became official in DSM-IV. The concept of bipolar II disorder is controversial because we do not have an empirically validated, sensitive definition of hypomania.(Angst, 2007) However, there are follow up and family studies that favour the distinction between the two types of bipolar disorders.(Benazzi, 2007) 10% of BP II disorders convert to BP I disorder over 10 years by having a manic or mixed episode.(Coryell ea, 1995) Importantly, BP II disorder is not necessarily less disabling than BP I disorder.(Baldessarini ea, 2000)

demands on patients, local admission (and insurance) policies, and the fact that full mania is not necessarily accompanied by hallucinations or delusions.

Abbreviated DSM-IV-TR criteria

Bipolar I disorder

Current/most recent episode was manic

In past there was at least 1 major depressive, manic, or mixed affective episode

Current/most recent episode not due to schizoaffective disorder and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified

Bipolar II disorder

Present/history of at least one major depressive episode

Present/history of at least one hypomanic episode

No history of manic or mixed affective episodes

Not due to schizoaffective disorder and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified

Symptoms cause clinically significant distress/impairment in important areas of function, e.g. social

Klerman's (1987) classification of BP disorder included six types (I-VI)!

Reactive depression infers the presence of an intrapsychic or environmental precipitant. Sometimes 'reactive' was used as synonym for 'neurotic'.

Neurotic depression was said to typically afflict the young adult who is under stress. It represented an exaggeration of normal unhappiness. The mood varies and distraction gives some relief. There is no consistent diurnal (over 24 hours) rhythm, or the mood may get worse towards evening. Initial insomnia may occur, the sufferer finding it hard to drop off to sleep. The patient projects the responsibility for their problems onto other people or things.

Endogenous depression was said to be most common in middle age. A family history was usual and the premorbid personality is often socially well adjusted. It was held that life events leading up to the breakdown, such as moving house or redundancy, were reported as having been excessive over a period of months. The mood is qualitatively different to unhappiness, the patient may be agitated¹³³⁷ or stuporose and the patient might hear voices saying something like 'You are a sinner'. Common symptoms included hypochondriasis, guilt¹³³⁸ feelings, and even delusions of worthlessness. Intellectual capacity is particularly dulled in severe¹³³⁹ depression. The patient demonstrated retrospective falsification, with no good memories. Early morning wakening (EMW or terminal insomnia), loss of appetite and weight, amenorrhoea, loss of libido, constipation, and a lightening of depression as the day goes on, are common. Obsessional symptoms could be exacerbated or arise de novo.

Whilst both DSM-IV and ICD-10 state that mood in major depressive disorder (MDD) is usually worse in the morning the lowest point in mood may be at any point in the day in practice, and an evening low point, although classically associated with anxious/neurotic/reactive/atypical cases, can also occur in melancholic/endogenous depression.(e.g. Morris ea, 2007)

Involutional melancholia referred to an older patient with neurotic and endogenous depressive features. It is no longer considered as an entity. The family history of such patients shows an increased frequency of affective disorder, not often involutional. Hypochondriasis was the hallmark of this once-popular syndrome.

¹³³⁷ Agitation is not an all or nothing phenomenon and can be episodic, alternating with psychomotor retardation.

¹³³⁸ Guilty feelings are particularly prominent in Western depressives. Shame or humiliation may be the main complaint in some other parts of the world. Comedians who are depressed may become adept at using irony: self-deprecation as a symptom of depression may be missed under such circumstances.

¹³³⁹ There is no generally accepted **definition of severe depression**. Candidates include rating scales with cut-off scores (open to inter-rater variation), hospitalisation (resource and policy driven), suicidal thinking (role of alcohol, personality, exit events, etc – and may occur in mild depression), chronicity (not synonymous with severity), melancholic subtype (ditto), resistance to treatment (ditto), and interference with function (many other factors interact with depression severity to cause dysfunction, e.g. coping style, social expectations, and cultural practices).

A classification of depression dating from the 1960s included *type S depression* on the one hand (functional shift¹³⁴⁰) and *type J depression* (justified depression). These closely resemble endogenous and reactive depressions.

Parker (1978) divided reactive depression into under- and over-bonded types. The *underbonded* depressive experienced some degree of rejection by parents during formative years while the *overbonded* subject was over protected by parents and did not become emotionally independent of them. He subdivided underbonded depression into stunted self-esteem¹³⁴¹, sensitised self-esteem¹³⁴², and mixed forms of the above. In the overbonded patient at least one parent has been overprotective, the second parent may be absent, submissive, or also over protective, and the patient often gets depressed for the first time when he leaves home.

Leonhard described the so-called *cycloid psychoses* in 1957. They were all bipolar disorders, of good prognosis, led to no chronic defect state, and yet were difficult to distinguish from schizophrenia.¹³⁴³

The main classifications are those of ICD-10 and DSM-IV.

Modern classifications of the affective disorders

(a) ICD-10 (F30-39)

F30 Manic episode is divided into hypomania, mania with/without psychotic symptoms, other manic episodes, and unspecified manic episode.

F31 Bipolar affective disorder (at least 2 affective episodes of which 1 must be manic, hypomanic or mixed) asks if the current episode is hypomania, mania (with/without psychotic symptoms), depression (mild/moderate/severe, with/without somatic or psychotic symptoms), mixed (hypomanic/manic/depressive symptoms experienced together or rapidly alternating), other or unspecified.

F32 Depressive episode may be mild/moderate/severe (the first 2 with/without somatic symptoms, the last with/without psychotic symptoms), other (included atypical depression) or unspecified.

F33 Recurrent depressive disorder – the current episode may be mild/moderate/severe (the first 2 with/without somatic symptoms, the last with/without psychotic symptoms), other or unspecified, or the patient may be in remission.

F34 Persistent mood (affective) disorder may be classified as cyclothymia,* dysthymia,** other or unspecified.

F38 Other mood (affective) disorders may be classified as a single episode (state if mixed) or recurrent (state if brief depressive), or other.

F39 Unspecified (a last resort category).

*A persistent instability of mood, involving numerous periods of mild depression and mild elation, usually starting early in adult life, often pursuing a chronic course, remissions are possible, and the patient usually does not relate it to life events. It includes 'affective personality disorder', 'cycloid personality' and 'cyclothymic personality'. The term 'dysthymia' has been attacked as medicalising despair.

**A chronic depression of mood not filling criteria for even mild recurrent depressive disorder in terms of either severity or duration of individual episodes, although the patient may have started off with a mild depressive episode or suffered one at some other stage. It includes 'depressive neurosis', 'depressive personality disorder', 'neurotic depression' with over 2 years' duration, and 'persistent anxiety depression'. According to Michels and Marzuk (1993), 'The boundaries between dysthymia, chronic unremitting major depression, and depressive personality traits remain controversial.' Another view is that dysthymic disorder is a disorder of mood with greater mood fluctuations than in depressive personality disorder. The latter is chronic and lifelong, whereas the former is episodic, can occur at any time, and usually has a precipitating stressor.

(b) DSM-IV

¹³⁴⁰ E.g. early morning waking or EMW, diurnal mood changes where the patient feels worse in the morning, etc.

¹³⁴¹ Preoccupied with not offending others, afraid of incurring criticism, made the object of parental anger or criticism in early childhood, one parent may be absent or passive.

¹³⁴² Feels normal in between bouts of depression, ceases to function well under stress, e.g. when jilted, finds it hard to trust others, and parents may have been emotionally distant and only responsive when he achieved something such as when passing an exam or on being promoted at work.

¹³⁴³ The three types were anxiety elation psychosis (anxiety, ideas of reference, hallucinations, elation, and ecstasy), confusion psychosis (thought disorder, excitement or underactivity and poverty of speech), and motility psychosis (severe changes in psychomotor activity). A number of experts believe that the cycloid psychoses were a variant of bipolar disorder with an unusually sudden onset. Lithium has been shown to reduce the relapse in this group of disorders.

Mood disorders are divided into the depressive disorders (unipolar depression, UP), the bipolar disorders (BP), and two disorders based on aetiology (due to a general medical disorder or a substance). UP (major depression and dysthymia) are different from BP because there is no history of a manic, mixed or hypomanic episode. BP disorders (BP I, BP II and cyclothymia) involve the presence (or history of) of (a) manic, mixed or hypomanic episode(s), usually accompanied by the presence (or history of) of (a) major depressive episode(s).

[1] Major* depressive disorder: at least one major depressive episode (MDE; at least 2 weeks** of depressed mood or loss of interest accompanied by at least 4 additional symptoms from the following: - depressed mood most of the day on nearly every day, greatly diminished interest in most things or reduced capacity for pleasure, significant weight loss/gain or anorexia/hyperphagia, insomnia/hypersomnia, agitation/retardation, fatigue/loss of energy, worthlessness/guilt, reduced ability to think/concentrate/make decisions, recurrent thoughts of death/suicide with/without an attempt/plan).

[2] Dysthymic disorder: at least 2 years of depressed mood for more days than not plus additional symptoms that fail to meet criteria for MDE.***

[3] BP I disorder: at least one manic or mixed episode, usually with MDEs.

[4] BP II disorder: one or more MDEs with at least one hypomanic episode.

[5] Cyclothymic disorder: at least 2 years of numerous episodes of hypomania and depression not meeting criteria for mania or MDE.****

[6] Mood disorder due to a general medical condition or substance-induced.

[7] Mixed episode: at least one week in which criteria are met for both a manic and a MDE every day – rapidly alternating moods (sadness, irritability or euphoria).

[8] Mood disorder not otherwise specified (NOS, e.g. acute agitation).

One can then specify other details, e.g. severity/psychotic/in remission, chronic/with catatonic/melancholic/atypical features, or (if within 4 weeks of delivery) with postpartum onset.

Melancholic features: either of the following during the most severe period of the current episode – loss of pleasure in all/almost all activities or lack of reactivity to usually pleasurable stimuli (does not feel much better, even transiently, when something positive happens), and at least 3 of the following – distinct quality of depressed mood (not as felt after loss of a loved one), depression regularly worse in the mornings, early morning waking (EMW) by at least 2 hours earlier than normal pattern, marked psychomotor retardation/agitation, significant anorexia/weight loss, and excessive/inappropriate guilt.

Atypical features: mood reactivity (cheered by good news) plus 2 or more of – significant weight gain or increase in appetite, hypersomnia, leaden paralysis (heavy, leaden feelings in arms/legs), or a long-standing pattern of rejection sensitivity (not only when ill) that causes significant social/occupational impairment. Seasonal pattern: regular temporal relationship between onset of MDEs in BP I or II or major depressive disorder, recurrent, and a particular time of year; full remissions (or change from depression to mania/hypomania) at a characteristic time of year; in the last 2 years, 2 MDEs that fulfil preceding criteria plus no non-seasonal MDEs have occurred during that same period; and seasonal MDEs substantially outnumber nonseasonal ones over the lifetime of the patient.

Rapid-cycling: at least 4 episodes of a mood disturbance in the past 12 months meeting criteria for major depressive, manic, mixed, or hypomanic episode.

*Implying significant disruption of mental function. Dropping somatic symptoms from the DSM-IV definition of major depression does not seem to make much difference to the end result (Zimmerman et al., 2010) and might be easier to apply to medically ill patients.

**Moore (2001) points out that this duration specifier does not take certain exceptions into account, e.g. very brief depression of the premenstrual syndrome and the extremely transient depression of partial seizures.

***As pointed out by Ghaemi (2003) dysthymia was included in DSM-III to capture those patients formerly diagnosed with neurotic depression. Ghaemi (2003, p. 18) stresses that most dysthymics also have episodes of major depression ('double depression') and often also have generalised anxiety disorder (GAD): 'mild chronic depression and anxiety often go together'.

****Mood changes may be sudden and difficult to predict. After the first 2 years, or 1 year in children and adolescents, one may diagnose superimposed BPI or II if appropriate. Borderline personality disorder (comorbid in at least 10% of cases) and ADHD (stimulants may worsen cyclothymia) must be included in the differential diagnosis.

DSM-IV-TR seasonal pattern specifier

'With seasonal pattern' can be applied to pattern of major depressive episodes in bipolar I or II or recurrent major depressive disorders if there is:

- regular temporal relationship between onset of major depressive episodes and a particular time of year unless there is some obvious reason (e.g. seasonal loss of job)
- full remission/shift in pole between depression/(hypo-)mania at particular time of year
- In last 2 years: 2 major depressive episodes defining above seasonal relationship with no non-seasonal major depressive episodes during that time
- Over a lifetime: seasonal major depressive episodes substantially outnumber non-seasonal major depressive episodes

Some clinical features in depression

Some depressives are agitated, others are retarded, whilst still others show a mixture of the two. In cases of relatively mild severity, resentment of others may be more prominent than guilt. Episodes vary in severity and in degree. They can be as short as days in duration, or they can last for so long as to be difficult to distinguish from personality disorder.¹³⁴⁴ About 10-20% of bipolars may experience a number of depressive episodes before having a manic one, and the risk for bipolar disorder may be higher in adolescent major depression and even higher in depressed children.(Dubovsky ea, 2003) On the other hand, in a 20-year follow-up study of 'unipolar mania' (Solomon ea, 2003) 20 out of 27 patients suffered depressive episodes. In a 15-year prospective study of consenting offspring of bipolar parents Duffy ea (2009) found that major mood episodes began in adolescence and not before this and nearly all index episodes were depressive, as were the first few recurrences.¹³⁴⁵ There were no cases of pre-pubertal mania. Severe, chronic bipolars may have neuropsychological dysfunction even when in remission. Also, sub-syndromal residual symptoms are common in bipolar disorder (Paykel ea, 2006) and are predictive of relapse.(Tohen ea, 2006)

Panic attacks, obsessions and compulsions, and delusions may be confined to depressive episodes and need not portend another disorder. Auditory hallucinations can be imperative, e.g. 'kill yourself!' Unpleasant tastes or smells can be experienced.¹³⁴⁶ A few severely depressed patients experience visual hallucinations. These may take the form of death or other scenes of destruction.

Depression can be associated with impotence in males or amenorrhoea in females.

Children and adolescents may have adult features of depression together with pain (head, abdomen, chest), separation anxiety or school refusal, unexplained fall in scholastic performance, over-eating and increased weight, and new conduct symptoms such as defiance and aggression.

Bipolar (BP) children may present with irritability, rapid cycling, mixed episodes, deteriorating function, and comorbid disorders (e.g. ADHD¹³⁴⁷), whereas adolescents may be psychotic, comorbid (drug abuse, conduct disorder), suicidal, and perhaps (in female manics) pregnant.(Murtagh & McNicholas, 2006) Wozniak ea (2010) found that the morbid risk for BP-I disorder in relatives of children with DSM-IV BP I was increased 4-fold compared to controls and 3.5 times over the risk to relatives of ADHD probands; the relatives of children with BP I also had high rates of psychosis, major depression, multiple anxiety disorders, substance use disorders, ADHD, and antisocial disorder when compared with controls; and familial rates of ADHD were similar for ADHD and BP I probands.

Dementia v Pseudodementia

Wernicke, in the 1880s, replaced the older term vesanic dementia with pseudodementia.¹³⁴⁸ He saw it as a chronic hysterical state. The concept has now broadened. Some of his cases may have had delirium. One common denominator in pseudodementia induction is the ability to impair cognition or to disable the mechanisms by which cognition is expressed. Depression and dementia may co-exist; both occur most

¹³⁴⁴ According to Morey ea (2010) a diagnosis of personality disorder made while the patient is depressed is valid and not an artefact of low mood because in their 6-year outcome study they found that the outcome for major depression 'with comorbid personality disorder' was similar to that of 'pure personality disorder' and much worse than for those with 'pure major depressive disorder'.

¹³⁴⁵ Of the 207 participants, 67 met DSM-IV lifetime criteria for at least one major mood episode.

¹³⁴⁶ One of the author's patients, whose depression only responded to ECT, described experiencing 'unbearable smells' early during a relapse, by which she meant that the smell of the kitchen upset her since she felt guilty at not feeling up to cooking for her family.

¹³⁴⁷ Is this true co-occurrence or criteria overlap? According to Luckenbaugh ea (2009) a period of elevated mood and reduced sleep in children favour a diagnosis of juvenile-onset BP over ADHD. According to Birmaher ea (2010) the preschool offspring of BP parents are at increased risk for ADHD and 'subthreshold' manic and depressive symptoms.

¹³⁴⁸ Arie (1983) defined pseudodementia as '...those disorders which present with the features of dementia but which on closer scrutiny or because of their subsequent course turn out to be of different origin...' and in old age 'the underlying disorder is most often depression'. 'Functional dementia' covers all non-organic dementia.

commonly around the same time in life. Pure depressive pseudodementia is associated with tardy responses, reduced speech output, and poor concentration without dysphasia or agnosia. (Carson et al, 2007, p. 330) The table outlines the main differences between both pure states. Since some cases of depressive pseudodementia will have cerebral atrophy, confusion may arise if CT data are taken in isolation.

Distinguishing pure depressive 'pseudodementia' ('dementia of depression', 'depression without sadness', 'cognitive impairment due to depression') from dementia (early cases)

Dementia

Early stages unclear, family are vague about duration
 Long presenting history
 Absent history of depression
 Slowly progressive symptoms
 No complaints of cognitive dysfunction and any complaints are vaguely expressed
 Patient conceals difficulties, exaggerates minor achievements, and struggles to achieve
 Patient uses calendars or note pads to aid memory
 Patient appears apathetic
 Mood is labile and shallow
 Social skills are often retained
 Behavior is in keeping with cognition
 Symptoms are worse at night
 Faulty attention and concentration
 Patient gives answers that are nearly correct
 Disorientation
 Poor memory for recent events
 Non-specific memory loss
 Fairly constant disability
 Abnormal EEG

Pseudodementia (depressive)

Abnormality obvious early
 Family can date onset and help is sought early
 Condition worsens quickly
 Positive past history
 Complaints of poor cognition
 Patient gives details of problems and emphasises difficulties
 Patient recognises failures more readily than successes
 Patient gives up and stops trying to keep abreast of things
 Patient complains a lot
 Pervasive mood change
 Early, severe loss of social skills
 Incongruent behavior and cognition
 Not worst at night
 Attention and concentration often good
 Unable to answer simple questions
 Appears to forget everything, remote and recent¹³⁴⁹
 Specific gaps in memory
 Variable performance

¹³⁴⁹ Cued recall may be better in depression than in dementia. (Dierckx et al, 2007)

Evidence for cognitive dysfunction before and after the onset of affective disorder

Impaired attentional or executive control of action (Clark ea, 2002; Cavanagh ea, 2002) - each episode may potentially make matters worse

Review of literature on cognitive impairment in bipolar (BP) patients - despite methodological shortcomings, cognitive dysfunction is a core and enduring deficit of illness (Ferrier & Thompson, 2002)
High correlation between depressive symptoms and cognitive impairment ($P < 0.001$) in 500 very old Dutch people - follow up showed accelerated annual increase of depressive symptoms associated with impaired attention, immediate recall, and delayed recall at baseline; but baseline depressive symptoms did not relate to an accelerated cognitive decline during follow up (Vinkers ea, 2004)

Neurocognitive impairment in euthymic BP that was not related to residual mood symptoms or hypercortisolaemia (Thompson ea, 2005)

Premorbid impairment of visuospatial reasoning in BP (and in other psychoses) (Tiihonen ea, 2005)

Healthy twins discordant for unipolar (UP) affective disorder had relatively poor cognitive performance on a wide range of functions, whereas healthy twins discordant for BP performed poorly on tests of episodic and working memory (Christensen ea, 2006)

While depressive symptoms in late life were cross-sectionally associated with impaired cognition they did not lead to cognitive decline (Ganguli ea, 2006)

Unaffected first-degree relatives of BP I patients had impaired psychomotor speed and slight impairment of executive function, but impairment verbal memory relates to the fully developed disorder.(Antila ea, 2007)

UP and BP in remission associated with neuropsychological impairment and such impairment differs between UP and BP cases and impairments are not attributable to affective symptoms or medication.(Stoddart ea, 2007)

Reduced verbal fluency in euthymic BP v healthy controls suggests disrupted prefrontal connectivity, especially in BP cases with many admissions, more episodes, and lifetime history of psychotic symptoms.(de Almeida Rocca ea, 2008)

Meta-analysis found deficient executive function and verbal memory in BP patients and, to a lesser degree, cognitive impairment in first-degree relatives; is this an endophenotype of BP?(Arts ea, 2008)

DSM-IV outpatients with major depression showed poor delayed recall related to current symptoms at presentation with depression but at second visit performance related more to past depression, suggesting a toxic effect (possibly on hippocampus) of depressive illness.(Gorwood ea, 2008)

Prospective UK and Chinese study of non-demented people aged at least 65 years suggests that only depression is predictive of dementia only if the depression is very severe.(Chen ea, 2008)

BP I patients perform worse than controls on measures of memory, attention, executive functions, and decision-making; the more past suicide attempts the worse the decision-making performance of patients and the greater the number of errors in *Stroop Colour Word Test*; small sample study wherein medication status was not controlled for.(Malloy-Diniz ea, 2008)

In DSM-IV major depression (HDRS > 17, aged 20-60 years, N = 48) more perseverative errors (PEs) on shortened WCST at admission predicted poorer clinical outcome at 3 months post-remission and discharge; poor event-based prospective memory and more PEs on the shortened WCST at admission predicted worse social and occupational outcome at follow-up.(Withall ea, 2009)

Cognitive testing on admission and prior to discharge (N = 53) and 6 months post-discharge (N = 20) suggests that cognitive impairment in UP depression are neither selective nor specific and that they resemble traits.(Reppermund ea, 2009)

Late-onset major depression is associated with greater impairment in verbal learning and memory and motor speed but not in executive function than is early-onset major depression, and the two groups did not differ in severity of depression, global cognitive function, intelligence or education; these findings were not due to ageing alone.(Thomas ea, 2009)

Impaired declarative memory is found in young women (age range 16-21 years) with no personal history of depression but with a depressed parent and this may be partly related to increased cortisol secretion.(Mannie ea, 2009)

Longer hospital admission in BP patients is associated with more severe deficits in executive functioning at discharge.(Levy ea, 2009)

Barrett ea (2009) found that first-episode bipolar disorder and schizophrenia subjects, relative to healthy controls, were most impaired in terms of memory, executive function and language but bipolar patients performed much better on tests of response inhibition, verbal fluency and callosal function; and the differences could be explained by the greater likelihood of schizophrenia cases to be globally impaired and to have negative symptoms.

Doyle ea (2009) found cognitive impairments in BP youth (mean age 12.3 years) and problems with abstract problem-solving and working memory in their well siblings (endophenotype?).

Patients with BP or schizophrenia showed deficits in extra-dimensional set shifting (must learn new stimulus-reward associations based on different types of stimuli) and reversal learning (shift of attention to a novel but previously irrelevant stimulus),(McKirdy ea, 2009) probably due to disrupted networks involving ventral prefrontal cortex.

Cognitive impairment and time spent in subsyndromal depression may be associated with worse long-term functional outcome in BP.(Martino ea, 2009)

Drug-free and medicated euthymic BP patients do not differ in their neurocognitive deficits, suggesting that the latter are an integral part of BP.(Goswami ea, 2009)

In a first-episode psychosis study Zanelli ea (2010) patients with schizophrenia had widespread neuropsychological impairments; subjects with other psychoses and depressive psychosis also had widespread problems; and those with BP or mania had less pervasive difficulties but had problems with verbal memory and fluency tests

Results of a large-scale extended Latino pedigree study of cognitive functioning in BP (Glahn ea, 2010) suggested that measures of processing speed, working memory, and declarative (for faces) memory may be candidate endophenotypes for that disorder.

Half of patients aged at least 60 years with DSM-IV major depression had generalised cognitive impairment that persisted after 18 months; at 4 years follow-up impairments persisted but did not decline further, suggesting a trait rather than state relationship.(Köhler ea, 2010)

P2 and late positive event-related brain components examined during a free recall task in 3 groups: current depression, remitted depression, and healthy people: normals and remitted cases (but not the currently depressed) had increased recall of positive self-referent items (SRIs); greater component amplitudes in response to negative relative to positive SRIs were found in current and remitted depressives during automatic processing stage as indexed by P2 component and (indexed by late positive component) in the currently depressed during effortful encoding.(Shestyuk & Deldin, 2010)

Depression in women

Depression in women has been studied by a number of workers. Depressed females are more likely to report a poor early relationship with their mothers, but not with their fathers, low care and high overprotection, a poor marriage, poor current relationships with their own mothers, much poorer relationships with parents-in-law, and more poor family relationships in general.

Fatigue and anxiety symptoms, both psychic and somatic, are said to be very common in depressed women. However, some authors find no difference in symptomatology between depressed men and women.

The puerperal psychoses (usually come on after day five) are psychotic depression (most cases - one in 500 live births), schizophrenia-like (a minority), and toxic confusional ('childbed fever' – rare today).(O'Shea, 2000a; Jones & Smith, 2009) The clinical picture may change suddenly. The patient may appear confused, perplexed, and bewildered. Mood may be low or elevated or extremely labile. The content of delusions and hallucinations may refer to the baby. BP disorder carries a high risk of puerperal psychosis.

It is usually stated that the evidence is against a direct aetiological connection between depression and the menopause¹³⁵⁰,(O'Shea, 2000b) although this important event can mean freedom for one woman and perceived loss of role for her sister (the same applies to conditions such as endometriosis). Freeman ea

¹³⁵⁰ **Menopause:** As the function of ovaries decline, pituitary LH and FSH increase. The latter are best measured shortly after menstruation (their lowest concentration is expected at this time) since levels may rise to premenopausal figures later (with highest recordings midway through the cycle).

(2004) found increased likelihood of depressive symptoms during transition to the menopause and a reduced likelihood after the menopause; increasing oestradiol (estradiol) levels were associated with depression whereas greater age and a rapidly increasing FSH profile appeared to be protective. New onset and recurrence of major depression may be more likely at the perimenopause in women with a history of premenstrual syndrome or postpartum depression. (Parry, 2008) Bromberger *et al.* (2009) found that a lifetime history of anxiety disorder and role limitations caused by poor physical health at baseline and a particularly stressful life event were predictive of first episode major depression in middle-aged women whereas vasomotor symptoms were not. Using the Center for Epidemiological Studies Depression Scale (CES-D) in a longitudinal US community study, Bromberger *et al.* (2010) found that the perimenopause and postmenopause were associated with higher CES-D scores than was the premenopause and the following factors were associated with increased scores: larger increase in testosterone from baseline, less education, being Hispanic, vasomotor symptoms, stressful life events, and low social support.

Mood disorders in youth

Depression is more likely in adolescence¹³⁵¹, especially in females, but is still not uncommon even in early childhood, when it is possibly commoner in boys. Depression before puberty may present as physical concerns, agitation/anxiety/phobia, or avoidance of other people. The depressed adolescent may show poor academic performance, feelings of not being listened to or of not being understood, antisocial or aggressive behaviour, negativism, restlessness, alcohol/substance abuse, or avoidance of other people. Subjective complaints of depression should be sought in childhood because the disorder may be missed if too much reliance is placed on parental information. Childhood depression is often comorbid with other psychiatric conditions such as phobic or conduct disorders. Social disadvantage, parental problems, cognitive difficulties, chronic medical problems (e.g. epilepsy, diabetes, or asthma), and other factors may be positively correlated with early depression. The children of depressed parents with so-called major depression have an increased risk of depression, which may come on early in life, and a variety of behavioural problems, such as drug abuse and accident-proneness. Treating their parents' depression may help to decrease the morbidity levels of the offspring. Having a biological parent who suffers from a severe or chronic depression is associated with future adaptational problems in their offspring. Depression in the mother is generally considered to be more strongly associated with increased psychopathology in the children than is depression in the father. However, depression in the father during the postnatal period can have adverse and persistent effects on the emotional and behavioural status of their children. (Ramchandani *et al.*, 2005; Lewinsohn *et al.*, 2005) Also, Marmorstein *et al.* (2004) found that depressed mothers tend to partner with antisocial fathers, which may at least partly account for depression and conduct disorder in offspring. However, Tully *et al.* (2008), using an adoption paradigm¹³⁵², found that maternal, but not paternal, depression was associated with lifetime diagnoses of major depression and disruptive disorders in adolescents. In one study, compared with early onset unipolar depressives, early onset bipolar cases had experienced delayed language, social or motor development, delay being most marked in those who developed psychotic symptoms. (Sigurdsson *et al.*, 1999) Weissman *et al.* (2006) compared offspring of depressed parents with those of non-depressed parents over a period of 20 years and found a threefold increase in risk for anxiety disorders, major depression, and substance dependence in the former group; these people were also more likely to be socially impaired, and, as they entered middle age, to have increased medical morbidity and mortality. Timko *et al.* (2008) followed up the offspring of depressed parents for 23 years and found that they had an excess of depression and disability in adulthood. Treatment of depression to remission in the mother leads to decreased psychiatric symptoms and better functioning in offspring. (Pilowsky *et al.*, 2008)

Hazel *et al.* (2008) found that continued stress close in time to onset of depression was the most important factor in the association between early adversity and depression in late adolescence. TV exposure and total media exposure in adolescence were found to be associated with increased odds of depressive symptoms in young American adults, particularly in males. (Primack *et al.*, 2009)

¹³⁵¹ The 6-item Kutcher Adolescent Depression Scale (KADS: LeBlanc *et al.*, 2002) is a self-report instrument that asks about mood, self evaluation, energy/motivation, derivation of satisfaction from life, anxiety/worry, and suicidality 'over the last week'. A score of 6 or more indicates a need for more thorough assessment.

¹³⁵² To test for environmental effects as distinct from genetic influences.

The current view regarding treatment of mildly depressed children and adolescents is to try non-drug approaches (e.g. CBT if available) at first but that medication be added if initial therapy fails. For moderate to severe cases combined psychotherapy-medication is advocated with family/parental therapy/education¹³⁵³ as needed. (Schloredt ea, 2008, p. 808; Thapar ea, 2010) Most studies involving SSRIs have tended to include milder, uncomplicated cases (see Bridge ea, 2009), making clinical extrapolation difficult. Medication-placebo differences may be underestimated for severe depression in these trials. Nevertheless, medication studies suggest that 4 out of 10 cases do not respond to medication and that relapse following acute response is very common. Also, the natural history of depression is to remit eventually, with 7 out of 10 cases doing so by 72 weeks. (Goodyer ea, 2003) Emslie (2008) points out that less than half of American children and adolescents receive any treatment for depression and that follow up of cases prescribed medication is infrequent¹³⁵⁴ with the inevitable consequences of low adherence and effectiveness rates. Another reason why medication may not be very effective in childhood may be the high comorbidity levels, the latter not being responsive to antidepressant drugs. TCA trials have tended to be small in numbers and short in duration. There is slightly more evidence for efficacy for the SSRIs than for TCAs in childhood depression. The Committee on Safety of Medicines in the UK has stated that, of the SSRIs, only fluoxetine should be used in young people. In one US study of adolescents with major depression 61% improved with fluoxetine alone whereas only 43% improved with CBT alone, the latter not being significantly better than those on placebo (35%). (Domino ea, 2008) Fluoxetine was more cost-effective than combination treatment at 12 weeks. The FDA in the US labels only fluoxetine for use in children with major depression. Ramchandani (2004) has called for more openness in the making of such dramatic decisions; Wagner ea (2004) found citalopram to be safe and efficacious in depressed children and adolescents; Rynn ea (2007) found short-term efficacy for sustained-release venlafaxine in children and adolescents with generalised anxiety disorder; Whittington ea (2004) has pointed out that the non-publication of trials may lead to erroneous recommendations for SSRIs in childhood; and Pfeffer (2007) tells us that the FDA was not against using SSRIs in children but rather was trying to improve monitoring! The FDA paediatric warning led to a fall in new adult diagnoses of depression and a fall in antidepressant prescribing without a compensatory increase in other treatments such as psychotherapy¹³⁵⁵, (Valuck ea, 2007) and a rise in suicide rates in children and adolescents! (Gibbons ea, 2007a) However, others (Wheeler ea, 2008) found no attributable change in suicidal behaviour in young people in England following regulatory action in 2003 to restrict SSRI use in under 18s. It is difficult to know if these discrepancies relate to clinical reality (including high non-compliance rates) or to problems inherent to statistical analysis (e.g. the definition of clinical significance). (Turner & Rosenthal, 2008)

Review and meta-analysis of 27 paediatric antidepressant RCTs (Bridge ea, 2007)

Overall, small (< 1%) increase in emergent suicidal ideation/attempt (no completed suicides)

Efficacy: strongest for non-OCD anxiety, intermediate for OCD, more modest for major depression

Advise cautious, monitored use of antidepressants as one first-line option

Collaborative discussion with family and patient

Systematic review/meta-analysis of 30 trials of antidepressants in juveniles (Tsapakis ea, 2008)

All antidepressants have more or less modest effects

Fluoxetine possibly more effective, especially in adolescence

Need studies of severe/hospitalised/suicidal depression and childhood depression

More research is needed into interpersonal therapy in this age group. Cognitive therapy may not be as effective in severe as in 'mild to moderate' depression. (March ea, 2004) Also, Goodyer ea (2007) found no additional benefit of adding CBT to SSRIs and routine care in adolescents with 'moderate to severe' depression. Fristad ea (2009), in study involving children aged 8-12 years old with depression or bipolar disorder, compared the effects of adjunctive multifamily psychoeducational psychotherapy (8 x 90 minute

¹³⁵³ However, whilst it is often stated that family discord is aetiologically influential in depressed youth, family therapy, at least in research, may add little. (Schloredt ea, 2008, p. 812)

¹³⁵⁴ Despite FDA advisory of 2003 to provide frequent follow up. (Morrato ea, 2008)

¹³⁵⁵ Libby ea (2009) found that psychotherapy increased for adult but not paediatric cases.

sessions) with treatment as usual and found improved outcomes for the multifamily intervention at follow up.

Longer duration of treatment of adolescents with depression with CBT and/or fluoxetine appears to be more effective than shorter treatment. (Treatment for Adolescents with Depression Study [TADS] Team, 2009)

ECT, whilst rarely used in young people¹³⁵⁶, has been shown to be acceptable to such patients. (Walter et al, 1999)

Childhood bipolar disorder (BP) is diagnosed more often in the US than in Europe. It is associated with irritable mood, cyclical changes in mood, and an increased risk of comorbid ADHD. Mood episodes may be less discrete than those found in adults and BP may instead take a prolonged and undulant course in children. Birmaher et al (2009) reported that bipolar spectrum disorders (BP I and II and NOS) in people aged 7-17 years were episodic, sub-syndromal more often than syndromal, with mainly depression, mixed symptoms, and rapid changes in mood. Tjssen et al (2010) in Munich followed up adolescents and young adults for 10 years and found that persistent affective symptoms in earlier life predicted later development of BP in a dose-response fashion; although hypomanic symptoms were relatively common in adolescence most such cases resolve with the passage of time. The findings of a Dresden (Germany) study by Beesdo et al (2009) of 3,021 community subjects aged 14-24 years at baseline and 21-34 years at third follow-up are shown in the box.

Incidence and conversion of mood episodes/disorders in first 3 decades of life (Beesdo et al, 2009)

Estimated cumulative incidence at age 33 years = 2.9% for manic, 4% for hypomanic, 29.4% for major depressive, and 19% for minor depressive episode

Overall, 26% had unipolar major depression, 4% bipolar depression, 1.5% unipolar mania, and 3.6% unipolar hypomania

Overall, 0.6% and 1.8% had unipolar mania or hypomania respectively

3.6% of initial unipolar major depressives developed (hypo) mania, with especially high rates in adolescent onset depression (< 17 years: 9%)

49.6% of initial unipolar mania cases subsequently developed major depression and 75.6% major or minor depression

These results suggest that unipolar and bipolar cases are more common in adolescents and young adults than was previously believed. However, in an 8-year NIMH-sponsored study, only 62.6% of bipolar I disorder children were found by Geller et al (2010) to have received anti-manic medication at any time, especially so if they were recruited from paediatric (versus psychiatric) sites ($p = 0.006$). They were more likely to get treatment for ADHD or depression. Earlier recovery was predicted by greater length of time on lithium ($p = 0.017$).

Mood disorders in the elderly

Although reported figures vary greatly, about 15% or more of people over age 65 years have significant symptoms of depression, one-fifth or less of these having severe depression. The American ECA study found an overall prevalence of major depression in people over 65 years of age of one in one hundred (1.4% in females, 0.4% in males), and about 20% had subsyndromal depressive symptoms¹³⁵⁷. (Koenig & Blazer, 1992) McDougall et al (2007) found a depression prevalence of 8.7% in over-65s in England and Wales (10.4% women, 6.5% men). For ill understood reasons¹³⁵⁸, the figures for major depression are

¹³⁵⁶ ECT is reserved for treatment-refractory and/or very urgent cases in this age group.

¹³⁵⁷ Subsyndromal depression is not uncommon in the elderly in East Asia, with a prevalence of 8-9%. According to Heok and Ho (2008) risk factors include poor health, brain injury, low B12 and folate, and raised plasma homocysteine levels. Chronic pain in the elderly increases the likelihood of suicidal thinking. Depression is a risk factor for cardiovascular disease and for mortality in coronary heart disease.

¹³⁵⁸ Cohort effect, somatisation (hypochondriacal presentation versus difficulties in differentiating from physical illness), underreporting (e.g. patient unwilling to admit to depression or more experienced at handling difficulties; others viewing low mood as normal in old age), cognitive impairment (dementia of depression), dementia, coexisting disorders, etc.

arguably¹³⁵⁹ lower than in younger people. While some authors claim that depression becomes more common with increasing age, it appears that mania does not. The seriousness of subthreshold cases should not be underestimated.(Beekman ea, 2002) Indeed, when such subthreshold/minor¹³⁶⁰ cases are included rates of depression increase with age,(Snowden, 2001) at least in women.(Wu & Anthony, 2000) The boring atmosphere of the average nursing home is a hotbed of demoralisation. A depressive episode is more likely to follow a manic episode in old age.(Broadhead & Jacoby, 1990) Long-standing inability to form close, confiding relationships may confer vulnerability to depression in the elderly. Müller-Spahn and Hock (1994) listed the most frequent problems in this vulnerable group as social isolation, loss of important support systems, loss of autonomy due to psychiatric and physical illness and physical disability, inactivity consequent upon retirement, loss of reputation and finances, residence relocation, and severe insomnia. (Indeed, sleep disturbance is an independent risk factor for recurrence of depression in the elderly: Cho ea, 2008) It has been suggested that the perception of support may be more germane than the actual level of support. Older people are likely to be taking many different medications, and some of these (e.g. corticosteroids) may act directly or indirectly as depressogens.(Alexopoulos ea, 2001) Confusion/delirium should be considered before mislabelling someone as having drug-induced depression.(Cassem ea, 2004, p. 72)

Cerebral atrophy (Baldwin ea, 2005) and reduced right frontal lobe volume (Almeida ea, 2003) have been described in late-onset depression.

Penninx ea (2001) suggest that depression increases the risk cardiac mortality irrespective of any baseline heart disease and Surtees ea (2008) found that major depression was associated with a persistently increased risk of ischaemic heart disease (IHD) mortality independent of established risk factors for IHD¹³⁶¹. Linke ea (2009), in a study of women with suspected myocardial ischaemia, found that somatic but not cognitive/affective depressive symptoms (using the BDI) were associated with increased risk of cardiovascular mortality and events¹³⁶². These findings were confirmed by Martens ea.(2010) Lavretsky ea (2010) followed up a sample of elders from the community and from memory clinics and 35% died during the study; cognitive impairment, age, male sex, depressed mood, and having lacunes on MRI predicted higher mortality, and having both lacunes and depression was associated with the highest mortality risk. Depressed patients with heart disease are less likely to adhere to diet, exercise, and prescribed medication.(Whooley ea, 2008) Cardiovascular mortality is higher in elderly men whose depression is inadequately treated¹³⁶³ than in those where adequate therapy is administered. Cardiovascular mortality is higher in elderly women who are not given ECT than in those who receive it.(Babigian & Guttmacher, 1984) Of course, the same vascular pathology may play a role in the aetiology of elder depression, (Kim ea, 2004) genes playing a lesser role than in younger cases of depression¹³⁶⁴. It has been suggested that SSRIs may reduce mortality in depressed patients from cardiac disorders by their effects on platelets.(Serebruany ea, 2005) It should be noted, however, that trials of SSRIs and mirtazepine conducted in cardiac patients are few in number.(Anonymous, 2008)

Elderly with risk factors for vascular depression have (vs old depressed people without such risk factors: Alexopoulos ea, 1997)

Increased cognitive impairment and disability

More impaired fluency and naming

More retardation

Less agitation

Less insight

(Represent damage to the striato-pallido-thalamo-cortical pathways and other brain areas?)

¹³⁵⁹ An 8-year Rotterdam follow-up cohort study of community-dwelling elderly (Luijendijk ea, 2008) found the incidence rate of depression to be low except when 'clinically significant' depressive symptoms were accounted for. Most late-life depression occurred in people with a history of depression. Also, recurrence rates were the same for both sexes.

¹³⁶⁰ Dysthymia and minor depression are included in this group.

¹³⁶¹ E.g. an episode of major depression during the previous 12 months meant that a person was 2.7 times more likely to die over the 8.5-year follow-up.

¹³⁶² CVA, MI, and CCF.

¹³⁶³ Ryan ea (2008) suggest that treatment resistance in elderly men reduces their chances of survival.

¹³⁶⁴ Homocysteine might promote cerebrovascular disease and reduce neurotransmitter levels thereby causing low mood.(Folstein ea, 2007)

Cardiovascular disease is overrepresented in patients with a history of mania or hypomania compared to subjects with a history of only a major depressive episode or no mood episode.(Ramsey ea, 2010) Depression in adolescents, older men, and women has been reported to correlate with lower birth weight,(Thompson ea, 2001a; Patton ea, 2004; Gale & Martyn, 2004) perhaps indicating a neurodevelopmental aetiology.

Sackeim ea (2000) emphasise that encephalomalacia¹³⁶⁵ may relate to vascular insufficiency in subcortical water-shed areas¹³⁶⁶. There is a compensatory mismatch between metabolism and cerebral blood flow (CBF), i.e. CBF is diminished but oxygen uptake by tissues increases. CO₂ is a strong cerebral vasodilator. Acetazolamide increased CO₂ levels. However, in the elderly depressed there is a reduced white matter response to acetazolamide, i.e. the hypercapnic challenge with acetazolamide demonstrates a reduced ability to vasodilate.

Tiemeier ea, (2004) in a cross-sectional population-based Rotterdam study, found that atherosclerosis and depression are associated in the elderly. The more severe was extra-coronary atherosclerosis the higher was the prevalence of depression. There was a strong relationship of severe coronary and aortic calcifications with depressive disorders.

White matter changes predate and are associated with late-life depressive symptoms.(Teodorczuk ea, 2007) Lower folate, lower B12, and raised homocysteine may be risk factors for late-life depression.(Kim ea, 2008; Almeida ea, 2008) Comprehensive neuropsychological function and white matter hyperintensity severity on MRI predicted MADRS scores over 12 weeks of sertraline treatment of major depression in subjects aged over 60 years; baseline neuropsychological function differentiated those who would remit from those who would not remit and predicted time to remission.(Sheline ea, 2010)

Depression in the elderly is often missed because it is commonly mimicked by somatic illness and *vice versa* (e.g. weight loss); the elderly often minimise feelings of sadness and are physically preoccupied; and neurotic complaints, such as obsessions, anxiety, and hypochondriasis, may obscure depression.

Neuroticism is itself associated with recurrence of depression in later life.(Steunenberga ea, 2009) Lenze ea (2001) suggest that 85% of elderly depressives have significant comorbid anxiety. The consequences of missing the diagnosis (Müller-Spahn and Hock, 1994) are loss of quality of life, social isolation, increased mortality (suicide), increased vulnerability to certain diseases, admission to a nursing home, and a large financial burden. Depression is common in nursing homes, factors contributing to this being loss of independence and familiar surroundings, reduced contact with family and enjoyed activities, and physical disorders.(Feliciano & Areán, 2007, p. 294)

Chief risk factors for depression in physically ill elderly people (Katona & Livingston, 1997, p. 11)

- Female (but under 85 years of age)
- Positive personal psychiatric history
- Severe physical illness
- Significant functional disability

Note: adjustment disorder with depressed mood is not uncommon in the physically disabled or chronically ill elderly (Blazer, 2003, p. 1546)

Most important symptoms in diagnosing depression in older people (Alexopoulos ea, 2001)

- Sad and downcast mood
- Feeling blue
- Frequent crying
- Recurrent thoughts of death/suicide.

According to Baldwin ea (2002, p. 10) whilst depression in older people often resembles that in younger people, it may be modified by less emphasis on sadness and more on hypochondriacal and somatic

¹³⁶⁵ Synonymous with leuko-araiosis, subcortical arteriosclerotic encephalopathy, hyperintensities, unidentified bright objects or UBOs. Deep white matter lesions have been found on MRI in some young BP cases.(El-Badri ea, 2006) For **diffusion tensor imaging studies** see Alexopoulos ea (2008), and Bruno ea (2008) who found frontotemporal white matter abnormalities (of unknown pathology) in BP.

¹³⁶⁶ Areas with a poor collateral blood supply.

concerns, poor subjective memory function or 'pseudodementia', marked anxiety, and apathy as well as poor motivation. In an Irish community dwelling sample of people aged 65 years and older Gallagher *ea* (2009) found that, compared to early-onset depression, among those with depression commencing at age 60 years or more (late onset) there was less likely to be a positive family history of depression, less reporting of prior hospital admission for depression, greater cognitive impairment, less feelings of guilt, and less thoughts that life was not worth living. Nevertheless, the authors could find no distinct profile of depressive symptoms that helped to distinguish early versus late onset cases at an individual level.

Saez-Fonseca *ea* (2007) found that depressive pseudodementia in the elderly may be a harbinger of dementia with most cases having an established dementia 5 years later!

A Dutch study of depression in people aged 55 years or more (Licht-Strunk *ea*, 2009) found a median duration of major depressive episode of 18 months; 35% recovered within a year, 60% within two years, and 68% within three years; and poor outcome was associated baseline depression severity, a family history of depression, and poorer physical functioning (the latter only improved if the patient recovered from depression).

An American geropsychiatry expert consensus included the following (from first choice onward): the top-rated antidepressants were SSRIs¹³⁶⁷ (citalopram, sertraline, and paroxetine); if a TCA was to be used, nortriptyline was first choice (followed by desipramine); CBT, supportive, problem solving, and interpersonal, but not psychodynamic, psychotherapies were favoured and choice depended on needs and resources; persistence in treating the elderly depressed was stressed; and the duration of successful drug therapy related to number and severity of episodes, difficulty in bringing an episode under control, and persisting anxiety.

Elderly depressives spend significantly longer as in-patients than do their younger counterparts, they take longer to respond to treatment, and relapse is common. They often require indefinite antidepressant treatment. ECT may be more effective in the elderly depressive than in younger patients. (Tew *ea*, 1999) Maintenance ECT, e.g. once monthly, may be required in some subjects in order to maintain a response. Lithium does work in the elderly. However, they are susceptible to illnesses that can reduce glomerular filtration rate (GFR) and thereby precipitate toxicity, and they are often taking drugs that interfere with lithium clearance, especially thiazide diuretics and NSAIDs. According to Baldwin *ea* (2002, p. 67) TCAs may be superior to SSRIs in the treatment of the severely depressed elderly inpatient. Lofepamine is safer than the older TCAs. (Baldwin *ea*, 2002, p. 73) Before starting a TCA the patients blood pressure should be measured lying and standing: a drop of 20 mm Hg or more is likely to make worse by TCAs, with the danger of falls. This is more likely if the patient is taking diuretic medication or has poor left ventricular function. Generally, before starting any antidepressant in the elderly one should steer clear of any drug that might exacerbate any underlying medical illness or interact with other prescribed medication¹³⁶⁸. The importance of psychosocial support cannot be underestimated, even when antidepressant drugs are used. (Roose *ea*, 2004) Guidance (based on algorithms) offered to primary care physicians by care managers and assistance given to older patients with adherence kept patients in treatment, reduced suicidal thinking, and improved outcomes of major depression at two years. (Alexopoulos *ea*, 2009) Steffens and Potter (2008) emphasise the need to help elderly depressives with cognitive problems by focusing on practical problem-solving strategies. (see Alexopoulos *ea*, 2003)

Comorbid axis I disorders, including panic disorder, are common in elderly bipolar disorder patients. (Goldstein *ea*, 2006) Scheurich *ea* (2008) suggest that motivational difficulties influence cognitive difficulties in older depressives and recommend employing goal-setting theory in its alleviation (basically such patients perform better if assigned specific, difficult goals than when asked to reach vague or easy ['do your best'] goals). Thompson *ea* (2001b) could not demonstrate a clinically important difference between CBT and antidepressant medication in reducing depression severity in mild-to-moderately depressed elderly outpatients. Lenze *ea* (2003) found little effect of co-morbid anxiety on outcome of late-life depression treated with interpersonal psychotherapy.

Depression in the workplace

¹³⁶⁷ Risk of hyponatraemia and small increase in risk of falls. (Lam & Mok, 2008, p. 81)

¹³⁶⁸ TCAs may increase the risk of hypotension and arrhythmias (is the patient on quinidine?) in a patient in the cardiology ward. Venlafaxine may worsen hypertension. Drugs that promote weight gain – TCAs or mirtazapine – may destabilise diabetes. Take care with SSRIs and codeine combination or fluvoxamine and warfarin given together.

Excessive workload and extreme time pressures increase the risk of major depression and generalised anxiety disorder compared with low occupational demands.(Melchior et al, 2007) Warning signs of depression in the work situation include absenteeism, reduced productivity, poor moral and lack of co-operation, uncharacteristic accidents, frequent complaints of aches and pains, poor decision-making, indecision, and alcohol or drug abuse.

Recurrent brief depression

This is a relatively new innovation that is said to be common and have a relapsing course. One in twelve people may be affected and the risk of deliberate self-harm may be 13% over ten years. Depressive symptoms last on average for three days. Diagnostic criteria include 3 episodes over 3 months, depressive episode lasting less than 2 weeks, and no association with the menstrual cycle. The usual treatments for depression may be given a trial, although it may be relatively unresponsive to antidepressants (Baldwin, 2003) because episodes may be too short. Problem-solving strategies may reduce any tendency to self-harm.(Baldwin & Hirschfeld, 2005, p. 63) Alcohol and benzodiazepines are best avoided. DSM-IV lists this disorder 'for further study'.

Chronic depression

Scott's (1988) classification of chronic depression

Chronic primary major depression: usually late onset; unresolved major depressive episode without evidence of a pre-existing chronic minor disorder; may have a unipolar or a bipolar disorder

Chronic secondary major depression: unremitting major depressive illness secondary to a physical illness or non-affective psychiatric disorder

Characterological or chronic minor depression: dysthymic disorder, a heterogeneous group of patients with ill-defined onset in early adulthood - it appears to be part of the character style; symptoms are with relatively minor - in 1980, the APA replaced 'neurotic depression' with 'dysthymic disorder'. Dysthymia has been attacked as an ill-defined, catch all, non-specific label.

'Double' depression: acute major depressive episodes superimposed on underlying dysthymia, the patient returning to the latter after recovery; prognosis for minor symptoms is poor and recurrence of major depressive episodes is frequent.

Factors that may predict chronicity are female sex, especially if the premorbid personality contains neurotic traits, childhood adversity¹³⁶⁹, current interpersonal problems, unipolar disorders, and a high family loading for unipolar disorders. Also of significance are the adequacy and appropriateness of treatment received, and the duration of the illness episode prior to starting therapy.

Other conditions

In 1882, the French psychiatrist Jules Cotard (1840-89), described patients with what he called *délire de négation*, the term *Cotard's syndrome* being first used by J Seglas in 1897. This consists of a severe depressive state with nihilistic delusions (e.g. "my bowels are rotten" or loss of money, health, strength, social status, etc). These can expand to negate the patient's whole internal and external world. The hallmark is the delusion of being dead. Associated features include *le délire d'énormité* or delusion of enormous body size or a delusion that urinating will flood the world, and delusion of immortality. Cotard's syndrome may require many applications of ECT to induce a remission. There is even a case report of remission after two grand mal seizures.(Malone & Malone, 1992) Cotard's syndrome has accompanied non-dominant frontotemporal lesions, the delusions subsiding with anticonvulsant therapy. CT studies suggest that Cotard patients may have brain atrophy and medial frontal lobe disease. Cotard's syndrome may be associated with valaciclovir (Halldén et al, 2007) or may complicate Parkinson's disease.(Factor & Molho, 2004) *Prasad's (1985) syndrome* is due to Hashimoto's thyroiditis but presenting as treatment-resistant mania in a patient of good premorbid personality. Antipsychotic drug-resistant cases have responded to thyroid hormone replacement. Onset may be acute.

Lycanthropy is the belief that one is transformed into an animal, classically a wolf or werewolf. This non-specific presentation can be associated with 'hysteria', bipolar affective disorder, psychotic depression, schizophrenia, or organic brain disorders.

¹³⁶⁹ Parental indifference, family violence, sexual abuse.

'Minor depression'

This category is listed in DSM-IV as an area 'for further study'. Essentially, the criteria are (a) one or more episodes of depressive symptoms that fulfil the duration criterion for major depression but there are fewer symptoms and less impairment, and (b) the following diagnoses are outruled: adjustment disorder with depressed mood¹³⁷⁰, depressive disorder not otherwise specified, major depressive episode, dysthymia, cyclothymic disorder, periods of normal sadness, uncomplicated bereavement, mood disorder induced by substance/general medical condition, a history of major depressive /mania/mixed episode(s), and depressive symptoms that occur exclusively during schizophrenia or schizophreniform/schizoaffective/delusional/not otherwise specified psychotic disorders. Baldwin ea,(2002, p. 108) extrapolating from mixed-aged populations, suggest that minor and major depressions may form part of a continuum rather than separate disorders.

Major depressive disorder (MDD) with anger attacks

About one-third of ambulant MDD cases have abrupt, easily provoked anger outbursts associated with autonomic hyperactivity. Anger, verbal or physical, is most commonly directed at loved ones. Such attacks may have a basis in low central 5-HT activity.(Fava and Rosenbaum, 1999)

Mania

The death rate in hospitalised manics before the mid-1930s could be as high as 20%, almost half succumbing to exhaustion.(Derby, 1933) Hypomanic patients rarely present for treatment of their own volition. The differential diagnosis of mania includes cyclothymia, schizophrenia, schizoaffective disorder, frontal lobe syndrome (including leucotomy), secondary mania, medications (steroids, L-DOPA, bromocriptine, INAH, etc.), stimulants (cocaine, amphetamine), and various CNS disorders such as basal tumour, encephalitis, and right hemispheric cerebrovascular disease. Mania may be precipitated by sleep deprivation in people who are euthymic, depressed, or who have no history of prior mania. 'Continual sleeplessness' was listed among the causes of mania by Soranus of Ephesus¹³⁷¹.(Brown, 2004, p. 440) In fact, a study involving university students with cyclothymia or bipolar II disorder and healthy controls suggests that both diagnosis and lack of regular activities predict time to first prospective onset of major depressive, hypomanic, and manic episodes.(Shen ea, 2008) A 'manic switch'¹³⁷² from medication has been reckoned to occur in 11.2% of patients on TCAs, 3.7% of people on SSRIs, and 4.2% of individuals receiving placebo. The risk of such a switch occurring in predominantly unipolar depressives has been put at <1%.(Post, 1994) Bupropion was associated with less manic episodes in bipolar patients followed up for one year than was desipramine in one study (11% v 50%: APA, 2002, p. 597) and, in another study, switches to hypomania or mania in bipolar depressed patients occurred in 3% of paroxetine-treated patients and 13% of venlafaxine-treated cases.(APA, 2002, p. 596¹³⁷³) The combination of an antidepressant and a mood stabiliser leads to less switching into mania in bipolar II than in bipolar I patients.(Altshuler ea, 2006) However, the combination may be no better than using a mood stabiliser on its own.(Sachs ea, 2007) The mechanism of switching is unknown¹³⁷⁴. We do know that chronic TCA treatment reduces sensitivity to DA autoreceptors; such downregulation might cause increased dopaminergic activity and mania. According to Vieta,(2004) quetiapine (for mania) may not be associated with treatment-emergent depression. Current or past substance use in depressed bipolar patients was not associated with longer time to recovery but may have increased risk for switching directly into mania/hypomania/mixed states in an American study.(Ostacher ea, 2010)

Symptoms of mania

'Infectious' jollity - the patient is funny

¹³⁷⁰ Marshall ea (2008, p. 591) speculate that up to one-fourth of cases diagnosed as 'anxiety' or 'depressive' disorders actually have adjustment disorders that will get better without much in the way of intervention.

¹³⁷¹ 98-138 AD.

¹³⁷² From a depressed to a manic state; confusingly sometimes called 'bipolar III disorder' – 'IV' if the switch follows ECT.

¹³⁷³ See also Post ea. (2006)

¹³⁷⁴ Rarely, mania, extrapyramidal symptoms, and akathisia may follow termination of antidepressants.(Haddad & Anderson, 2007)

Pressure of speech¹³⁷⁵

Flight of ideas

Psychomotor overactivity

Distractibility

Sexual disinhibition

Reduced need for sleep

Grandiosity

Poor judgement

Insightlessness¹³⁷⁶

Psychotic symptoms (if present): e.g. grandiose or paranoid delusions

Crying spells

Everything seems clearer - colours are brighter and contours are very sharply defined; patient may say his thoughts are of exceptional clarity

Instead of elated mood there may simply be unconcern and unusual friendliness

Older persons may present with irritability or mixed states with depressive symptoms (ideas have depressive content but are expressed in a jocular way), so-called 'miserable mania'

May report visions, which may have a religious content

Late life onset mania is less likely to be associated with a positive family history compared to early onset cases; it may be due to brain changes, or brain changes might modify early onset cases. First onset mania in later life may be associated with increased vascular risk factors¹³⁷⁷ and relatively high current serum cholesterol levels.(Cassidy & Carroll, 2002) A peak for admissions with a diagnosis of mania in June and July in the British Isles has been described. Women are more likely to experience depressive episodes than mania (men experience both phases with equal frequency) and rapid cycling is more common in females. Mania may be induced in vulnerable people by lack of sleep, crossing many time zones during travel, and shift work.

Bipolar¹³⁷⁸ (BP) v unipolar (UP)

Mania and depression can occur at different times in the same person. Less commonly, they more occur simultaneously in the same person. Sims (2003, p. 313) points out that the opposite of either 'pole' is not mania (for depression) or depression (for mania), but 'freedom from morbid emotion'.

Many patients have recurrent attacks of depression only¹³⁷⁹, less commonly there is bipolar affective disorder. They may have euthymic (normal mood) periods between attacks. Less common are chronic depression, chronic mania (said by some to be rare today but one report of hospitalised cases of mania found that 13% were chronic), and so-called rapid cyclers¹³⁸⁰.

Cycling

Rapid cycling, which is more common in females, is present when there are at least 4 episodes/year

Ultra-rapid cycling is when attacks occur every so many weeks to several days¹³⁸¹

Ultra-ultra-rapid (ultradian cycling) is when attacks are of less than 24 hours duration (or several episodes daily)

Continuous cycling when there is no sustained period of stable mood.

Bipolar I disorder prospective study (Solomon ea, 2009)

N = 219; median follow-up = 20 years; 1208 mood episodes

Major depressive episodes = 30.9%

¹³⁷⁵ In practice, it may be very difficult to distinguish between extremes of schizophrenic and manic speech disorder.

¹³⁷⁶ Recovered manics may realise that they have been sick but still believe that the ecstatic phenomena they experienced whilst ill had some special meaning.

¹³⁷⁷ Hypertension, atrial fibrillation, diabetes mellitus, CVA, etc.

¹³⁷⁸ The French psychiatrist Falret delineated '*folie circulaire*' (manic-depressive illness) in 1851. Manic-depressive illness/disorder/psychosis was dropped in favour of BP disorder because it was seen as being too broad a term, often used synonymously with 'affective disorder' and because not all such patients experience psychosis.

¹³⁷⁹ Farren (2008) suggests that most cases of BP are misdiagnosed (often as UP) and that most of these are misdiagnosed 2-3 times.

¹³⁸⁰ Cycling quickly from depression to mania or vice versa; may be induced by tricyclics or hypothyroidism or be idiopathic.

¹³⁸¹ Some authors define it as episodes lasting a day.

Minor depressive episodes = 13%
 Manic episodes = 20.4%
 Hypomanic episodes = 10.4%
 Cycling = 17.3%
 Cycling + mixed state = 7.8%
 Mixed = 0.2%
 All cycling = 25% of episodes

10-country community study (Lee et al, 2010)

A third to two-fifths of those with lifetime and 12-month BP met criteria for rapid cycling
 Rapid cycling BP associated with younger onset of BP, higher persistence, deeper/more impairing depression, more disruption from mania/hypomania, more anxiety disorders, and greater use of health services

Mood changes in ultradian cycling may be confused with the lability of borderline personality disorder. (Dubovsky et al, 2003, p. 458) Rapid cycling has been reported in 10-20% of BP patients. Nwulia et al (2008) found the best predictors of rapid cycling in familial cases of bipolar disorder to be earlier onset of symptoms (18 v 21 years), comorbid anxiety (47% v 26%), and antidepressant-induced mood switching. Variations within the BDNF gene are associated with susceptibility to rapid cycling bipolar disorder. (Green et al, 2006; Müller et al, 2006)

The frequency of attacks often increases with age. The median age of onset for BP is about 29 years, that for UP is about 46 years. Early onset of BP is associated with more recurrences, chronic mood symptoms, and functional impairment. (Perlis et al, 2009)

Winokur et al (1993), in a study of consecutive admissions, found that BP patients had an earlier and more acute onset, more total episodes, more familial mania, an excess of males, and more hyperactivity as children, whereas UP patients had more lifetime medical and surgical interventions. A NIMH study (Coryell et al, 2009a) looked at BP I and schizoaffective patients who they divided by age at intake into 18-29, 30-44, and over 44 years. Persistence of depressive symptoms increased significantly in the 2 youngest groups. Earlier ages at onset were associated with higher depressive morbidity throughout 20 years of follow-up but did not predict changes in symptom persistence. The proportion of weeks spent in episodes of either pole (depression or mania) correlated across follow-up period in all age groups, although correlations were stronger for depressive symptoms and shorter intervals. Regardless of age at onset, the passage of decades in BP is associated with greater predominance of depressive symptoms in 3rd to 5th decades inclusively and earlier age at onset is associated with greater depressive burden.

Bipolar spectrum disorders are associated with an increased premature mortality rate due to general medical illnesses, a consequence perhaps of unhealthy lifestyle, medication, biology, and disparities in health care. (Roshanaei-Moghaddam & Katon, 2009)

Bipolar disorder with and without comorbid panic disorder¹³⁸² may reflect differing frequencies of alleles for catechol-O-methyltransferase (COMT) and the serotonin transporter. (Rotondo et al, 2002) Zhang et al (2009) found that the low activity allele (Met) of rs4680 in COMT may confer risk for BP in the Han population, the authors suggesting further research in Caucasians.

According to Pavuluri et al, (2002) BP is often misdiagnosed as ADHD or oppositional defiant disorder in children. Prepubertal and early adolescent cases present with irritability, rapid cycling, little inter-episode recovery, and high comorbidity with ADHD and oppositional defiant disorder. Adolescent-onset is associated with substance abuse, anxiety, and an episodic course. Both groups, in contrast to adult cases, have elation, mixed episodes, longer episodes, and poor inter-episode recovery. Adolescent-onset may be misdiagnosed as schizophrenia. If a child has both BP and ADHD, the mood should be stabilised before using psychostimulants.

Bowden (2001) suggested that a bipolar diagnosis in patients who are depressed is suggested by a family history of bipolar disorder, a history of spontaneous or drug-induced mood elevation, a higher frequency of

¹³⁸² Toni et al (2008) found that 16% of their sample of DSM-III-R panic disorder and agoraphobia cases had comorbid bipolar II disorder. The comorbid group had an excess of social phobia, OCD, alcohol-related disorders, and separation anxiety during childhood and adolescence and their relatives had an excess of panic disorder and mood disorders (relative to non-comorbid cases). Comorbidity did not affect outcome, probably because the bipolar II disorder was well controlled.

episodes of depression, more time ill, and symptoms that start and end suddenly. According to Smith and Blackwood,(2004) clues to underlying bipolar affective disorder in a patient is depressed include onset before age 25 years, multiple short-lived episodes (< 3 months), racing thoughts whilst depressed, hyperphagia, increase in weight, lethargy or psychomotor slowing, poor or transient response to antidepressant drugs, close relatives with bipolar disorder, multiple relatives with unipolar depression, psychotic features, postpartum onset, mania secondary to antidepressants or ECT, and hyperthymic personality traits. Forty et al (2008) compared major depression and bipolar disorder patients and found psychosis, diurnal mood variation, hypersomnia during depression, and more frequent short episodes of depression to predict bipolarity.

Relative to Australian major depression cases, BP patients had a more equal gender ratio, were more likely to be widowed/separated/divorced, had higher rates of substance abuse/dependence, spent more days out of role, were more likely to be getting medication, and had higher lifetime rates of suicide attempts.(Mitchell et al, 2004)

Bipolar disorder, manic phase, in people with intellectual disability may present as overactivity, aggressiveness, irritability, and undue elation and laughing, or with public masturbation.

In a systematic review and meta-analysis, Beynon et al (2008) found that CBT (in stable patients), group psychoeducation (supported by Colom et al, 2009) and possibly family therapy may be helpful in the prevention of relapse in BP when used as adjuncts to pharmacological maintenance treatments. However, Lynch et al (2010), in a meta-analytic review, found no evidence that CBT prevented relapse in BP. Castle et al (2010) found that group-based psychosocial intervention did reduce relapse risk in BP, although there may have been problems of expectation among patients and clinicians ('unmasked') who conducted follow-up telephone calls and 'clustering effects' may have occurred between and within groups.

Depression and cancer

If a person becomes depressed in middle age, especially if it is for the first time and if no precipitant can be found, should be rigorously investigated to exclude physical disease. One theory of the connection between cancer and depression is that tumour protein excites antibody formation, the latter then interfering with 5-HT transmission.

Affective disorders may be an early precursor of clinical cancer, especially with cancer of the pancreas (more than with gastric cancer). Depression may predate physical clues to cancer by many months. Depression may persist despite successful cancer treatment. One example of a successful programme for treating depression in people with cancer involves nurse-delivered education about depression and its treatment (including antidepressant medication), help with coping strategies (problem-solving), and communicating with the oncologist and GP.(Strong et al, 2008)

Seasonal affective disorder (SAD)

SAD is officially one of the affective disorders, although there have been many detractors for its acceptance as a discrete entity.(e.g. Kendell, 1993; Goodwin, 2004; Baldwin & Hirschfeld, 2005, p. 29) Kendell (1993) pointed to a need for prospective studies on less selective groups and the possibility that light therapy may act as a placebo. Other criticisms include the inclusion of mildly depressed outpatients, the difficulties of establishing an adequate placebo group, low numbers in light therapy studies, lack of comparison with established treatments, uncontrolled studies, apparent seasonality (non-seasonal episodes on follow-up), and the finding of peaks in all seasons, including spring-summer depression. Levitan (2007) states that subsyndromal SAD, a mild version of the disorder, affects 'many adults' and opines that seasonality could be a dimensional rather than a categorical/discrete syndrome. DSM-IV-TR views a *seasonal pattern* as an additional specifier of recurrent major depressive disorder or bipolar I or II disorders. DSM-IV-TR criteria for seasonal pattern specifier excludes cases where there is an obvious seasonal-related psychosocial stressor, such as not being employed during the winter months.

Classically the patient becomes depressed in autumn or winter and the condition remits by the following spring or summer over at least two years (reversed in the Southern Hemisphere). Schlager et al (1993) found that healthy women, but not men, had more symptoms (anxiety, somatisation, depression) in the two weeks before testing in winter than at other times. They used the Hopkins Symptom Checklist. Follow up of patients has shown considerable variability in the sense of change of season during which depression is experienced and changes in both directions from SAD to non-SAD. According to one relatively small

study, recent negative life events and poor social support may increase seasonality in mood disorder.(Michalak ea, 2003)

Attempts to examine the photoperiod (shorter daily length of exposure to natural or artificial light increases SAD rates) or latitude (higher rates further north) theories of SAD have provided major challenges for researchers.(Levitan, 2007) For example, Levitt and Boyle (2002) were unable to confirm a relationship between latitude and SAD rates in Ontario, Canada.

SAD is said to affect almost 10% of Alaskans, where young and female cases are in the majority (although, young male Alaskan natives have a very high suicide rate: Gessner, 1997). Affected subjects are reactive to changes in some environmental factor, e.g. climate, latitude or environmental light. It may be related to hibernation in animals. Relatives seem to have high rates of alcoholism. It may also simply be an exaggeration of normal familial seasonal changes in mood.

Goikolea ea (2007) followed up 125 cases of bipolar I and II patients for 10 years. 25.5% were considered seasonal. A seasonal pattern was associated predominantly bipolar II disorder, depressive onset and mainly depressive polarity. Demography and severity indicators¹³⁸³ did not distinguish seasonal from non-seasonal cases.

Allen ea (1993), using the family history method, found that the genetic loading for mood disorders was similar for both SAD and non-seasonal mood disorders. N-acetyl-5-methoxytryptamine (melatonin) is a pineal hormone derived from 5-HT. Melatonin secretion was reported in the past to be normal in SAD. However, nocturnal plasma melatonin and mean 24-hour concentration has also been reported as being reduced in depression (Rabe-Jablonska and Syzmanska [2001] found mean melatonin concentration in depression to be *higher* than normal at some points during the night). As well as this, amplitudes of melatonin circadian rhythm may be smaller than usual whilst people remain depressed.(Sou  tre ea, 1989) Most people with low melatonin levels are not depressed.(Schulz, 2007) Antidepressants are not consistent in their effects on melatonin, e.g. fluoxetine has been found to reduce and both fluvoxamine and TCAs have been reported to increase melatonin levels in both patients and controls. It has also been reported that SAD is associated with enhanced sensitivity to melatonin suppression by bright light in winter but not in summer.¹³⁸⁴

M-chlorophenylpiperazine (m-CPP), a 5-HT receptor agonist, causes euphoria or activation during a depressive episode in SAD patients but not in non-SAD cases in controlled *but* different studies.(Levitan, 2007) The binding potential of the serotonin transporter (5-HTT) varies with season.(Praschak-Rieder ea, 2008) The short allele polymorphism for the 5-HTT was found to be more common in SAD cases than in healthy people. Patients with two long alleles may have milder symptoms than if they had at least one short allele. Other research found no support for a role of this short variant in susceptibility to SAD but found modest evidence for an effect on seasonality.(Johansson ea, 2003) However, the literature in this area is at present discrepant.

Bright, full-spectrum lights are used in treatment. Light is known to have a ‘profound placebo component’ (Lewy ea, 2007) and methodological problems bedevil research in this area.(Anonymous, 2009)The finding that green light is better than red light and similar to white light has been interpreted to support the hypothesis that retinal photoreceptors mediate the antidepressant response in SAD. The depression may be characterised by weight gain, hypersomnia, overeating and carbohydrate craving. There may be less suicidal ideation and early morning worsening of mood than in non-seasonal mood disorder patients. The depression may improve by travelling toward the Equator and worsen with proximity to the Poles. Patients with SAD have recovered with phototherapy but relapsed when the light was withdrawn. Early guidelines for winter depression suggested that eyes should be exposed to full visible light. The light should be sufficiently intense and the treatment sufficiently prolonged (e.g. 2,500 lux for at least 2 hours). Treatment is given daily throughout the seasonal period of risk (early autumn to early spring). Light therapy is therefore inconvenient but worthwhile for many sufferers. Portable bright light visors may reduce the need to sit in front of a light for long periods. There is evidence that the timing of light therapy is not crucial. However, use close to bedtime may be too alerting. The eyes may become slightly irritated or reddened initially but this is generally transient.

¹³⁸³ I.e. psychosis, admission to hospital, or suicidality.

¹³⁸⁴ According to Nurnberger ea(2000), euthymic BP I patients relative to euthymic UP cases may have reduced melatonin if exposed to light and peak melatonin levels during dark nights.

Bright white light is no better than dim light in non-seasonal depression (and any effect may not last: Martiny ea, 2006), and extra light given during the day is just as good as extra light during the hours of darkness. Light therapy non-responders tend to be melancholic¹³⁸⁵. Because rapid tryptophan depletion reverses gains from bright light therapy, serotonergic mechanisms may be involved in its therapeutic action.(Neylan ea, 2003, p. 985)

Dawn simulation¹³⁸⁶ may be at least as effective as bright light treatment.(Avery ea, 2001)

Negative air ion concentration tends to be higher in summer than winter and in humid than dry environments. Negative air ion generation, used at home, is currently being studied for winter depression.(Howland & Thase, 2002) However, it may also be effective for chronic non-seasonal depression, as may bright light be.(Goel ea, 2005) Dawn simulation and negative air ion generation were effective for SAD in the Terman and Terman study.(2006)

A morning walk has been reported to be effective in SAD,(Graw ea, 1991) as have cooling and dark glasses in patients with regular summer onset of depression.(Wehr ea, 1987) Antidepressants are effective in SAD, probably as effective as light treatment.(Lam ea, 2006) Mood and appetite changes in SAD may respond to fenfluramine.(O'Rourke ea, 1989) Partial sleep deprivation¹³⁸⁷ plus bright light treatment might boost the effects of antidepressant drug treatment.(Coryell, 2008, p. 517)

One review (Anonymous, 2009) suggests that mild/moderate SAD may be treated with early morning bright light (using a light box or dawn simulation) with or without CBT or medication; severe SAD requires treatment with antidepressant medication with/without light therapy/CBT.

Dexamethasone¹³⁸⁸ suppression test (DST)

Almost half of primary depressives have increased cortisol levels and there may be increased adrenal gland size. Failure of exogenous dexamethasone to suppress endogenous cortisol was reported to be of value in differentiating endogenous or biological depression from other types of depression. Plasma cortisol levels fall in the second half of the day in healthy people but were noticed to remain high in some depressives. Also, non-suppression increases with age, especially in the elderly. Carroll (1981) claimed an overall specificity of 96% and a sensitivity of 43% for the DST, i.e. a positive DST (non-suppression) can be used with high confidence to support a diagnosis of melancholia, but a negative DST will not necessarily rule it out. However, the DST had a poor specificity in a group admitted to an in-patient crisis unit when it was used to detect TCA responders. It was also unhelpful in predicting response to ECT. Increased plasma cortisol concentrations may be simply a non-specific symptom of psychosis or of acute distress.(Tyrer & Silk, 2008, p. 4) A childhood neurotic symptom pattern of excess anxiety, agitation, initial insomnia, aggression and stressful events was reported to be associated with a positive (non-suppression of cortisol) DST by Abou-Saleh (1985) but others found no significant association between depression in children and DST results.(Tyrer ea, 1991) Keane and Soni (1992) found the DST to be valueless as a diagnostic tool among the intellectually disabled in the community. Manic patients have a high cortisol level. Tricyclic withdrawal interferes with the DST. A list of situations associated with positive and negative DST results is to be found in the box. The DST might be useful in determining the need for maintenance therapy after successful treatment for depression. Peselow ea (1989) found that a positive DST predicted a response to antidepressants rather than to placebo. Bowie ea (1987) found that a persistent suppression of the DST during the index illness was a predictor of good prognosis. In their literature meta-analysis, Ribeiro ea (1993) found that baseline DST results did not provide prognostic information but that if cortisol remained non-suppressed after treatment there was a good chance of a poor outcome.

Depressed patients do not become cushingoid despite evidence for increased glucocorticoid levels. Dinan (1994) suggests that this might be due to reduced glucocorticoid receptor activity: perhaps increased CRF leads to downregulation of pituitary CRF receptors and decreased ACTH response to CRF¹³⁸⁹. Finally, it should be noted that dexamethasone itself may have some antidepressant properties!(Arana ea, 1995)

¹³⁸⁵ Retardation, worse in the morning, suicidal, depersonalised, anxious, early and late insomnia, anorexic, guilt.

¹³⁸⁶ Low intensity light that gradually increases illuminance before patient awakens.

¹³⁸⁷ Sleep deprivation (wake) therapy can involve once-off or repeated deprivation of all night sleep (total), partial (often second half of night), or selective (REM deprivation) parts of sleep. Total sleep deprivation may be the most beneficial, irrespective of what component (REM or N-REM) sleep is lost most.(Hajak & Popp, 2008, p. 79)

¹³⁸⁸ Dexamethasone is used for suppression because (unlike prednisolone) it does not show up as cortisol in a radioimmunoassay.

¹³⁸⁹ Depressives who are non-suppressors in the DST have higher CSF CRF levels than do depressed people who have a normal DST. This may result from excess CNS CRF secretion: actions of CRF at various brain sites could account for various manifestations of

'False'* positive and negative DST results

'False' positives

BZDs, anticonvulsants**, barbiturates, reserpine, α -methyl DOPA, methadone, morphine, spironolactone, cyproheptadine, alcohol, excess caffeine

Diabetes mellitus, dementia, cerebral tumour, cardiac failure, Cushing's disease, dehydration, pregnancy, any acute medical illness/trauma (systemic infection and hepatic disease), weight loss, sleep deprivation

Anorexia (36-100%)*** or bulimia (35-67%) nervosa, mania, (0-40%) schizophrenia, (0-20%) panic disorder, (25%)**** borderline personality disorder¹³⁹⁰, (8%) OCD, (2%)

Normals (4-27%)

'False' negatives

Corticosteroids, high-dose benzodiazepines, dextroamphetamine, Addison's disease, hypopituitarism

*False in the sense that one assumes for argument's sake that the test is only valid in depression! **Carbamazepine accelerates metabolism of dexamethasone and may give a false positive DST in patients being investigated for possible Cushing's syndrome.(Ma ea, 2005) ***Compare with 45% in melancholia. ****Low percentages in anxiety disorders and bereavement would be an argument as a non-specific stress response explanation. Generalised anxiety patients often have low normal baseline cortisol levels but may fail to show suppression during the DST and non-suppression may diminish as the condition responds to treatment.(Tiller ea, 1988)

The *combined dexamethasone/CRH test (dex/CRH)*¹³⁹¹ may have better sensitivity for detecting small changes in HPA axis function, the result being abnormal in twice as many major depressives as have an abnormal DST. Also, at-risk first-degree relatives of affective disorder cases have higher cortisol and ACTH responses than controls but less than people suffering major depression.(Holsboer ea, 1995) This may represent trait vulnerability. Bipolar (BP) patients may also have an elevated cortisol response to dex/CRH that fails to normalise during clinical remission¹³⁹²; this finding has also been suggested to represent a trait marker for BP.(Watson ea, 2004) Elsewhere Watson ea (2002) suggest that HPA axis dysfunction may be a manifestation of acute but not chronic depression.

Nelson's syndrome (low corticosteroid and high ACTH levels)¹³⁹³ patients are not noted for being depressed.(Kelly ea, 1980) Does this point the finger at cortisol rather than ACTH as of aetiological importance in depression?

Pregnancy

One should never assume that a woman is sexually inactive because she has a mental disorder, and whilst unplanned pregnancy is very common in the community it is especially frequent likely if the woman is mentally ill.(Abel, 2007, p. 637) A Danish study of psychiatric readmission (Munk-Olsen ea, 2009) found that mothers with a psychiatric disorder were less likely to be readmitted¹³⁹⁴ compared with childless women with a psychiatric disorder; that the first postpartum month is associated with increased risk of readmission; and that bipolar disorder carries a particularly high risk of postpartum readmission. Findings of somewhat higher rates of gestational hypertension/pre-eclampsia in women taking SSRIs do not discriminate the possible causal effects of treatment from the mood disorder being treated.(Toh ea, 2009)

depression. Reduced density of frontal cortical CRF receptors has been found in completed suicides.(Nemeroff ea, 1988) Animal and human research suggests that early abuse and neglect may lead to persistent HPA axis/extra-hypothalamic CRF overactivity, sensitising the patient and increasing the risk of later depression.(Nemeroff & Gutman, 2002, p. 108)

¹³⁹⁰ See Carrasco ea (2007).

¹³⁹¹ 1.5 mg dexamethasone orally at 11 pm. 100 micrograms human CRF (CRH) IV at 3 pm next day. HPA axis dysfunction shows up as **increased** release of ACTH and cortisol relative to control cases. HPA axis dysfunction normalises before full response to treatment of depression.

¹³⁹² BP patients had increased cortisol response to combined dexamethasone/CRH test compared with controls, a similar response being found in remitted and non-remitted cases.

¹³⁹³ **Nelson's syndrome** was more common when bilateral adrenalectomy was used to treat Cushing's syndrome.(Nelson ea, 1960) The post-operative lack of cortisol removed the normal negative feedback on the pituitary and allowed any pre-existing pituitary adenoma to grow unchecked. Both ACTH and MSH levels are increased. Typical clinical features include hyperpigmentation and muscle weakness.

¹³⁹⁴ Of course, mothers may be reluctant to go into hospital if they have children at home.

Maternal death related to pregnancy: 536,000 women die each year, 99% of these in the developing world, from complications of pregnancy and childbirth.(Obaid, 2007) A report from the Royal College of Obstetricians and Gynaecologists in the UK (Lewis & CEMACH, 2004; Anonymous, 2004a) found that 40% of maternal deaths were attributable to indirect causes with depression and suicide a particular concern. 35% of the women studied were obese, higher than among women in general. Obesity may act via lifestyle factors such as smoking and a sedentary existence.

Depression during pregnancy is not uncommon (about 10% during any trimester), contrary to popular belief (Kitamura *et al*, 1993; Dietz *et al*, 2007), although not all research agrees.(Vesga-López *et al*, 2008) Major and minor depression are equally common in gravid and non-gravid women.(Burt & Hendrick, 2003, p. 1516) Women with a prior history of recurrent affective disorder who stop their medication are especially at high risk for relapse during pregnancy. There may be an association between early gestational depression and psychosocial factors, such as first or unwanted pregnancy, poor marital relationship, unsatisfactory living conditions, less maternal care in own childhood, and having remarried. Parry *et al* (2008) found that night-time plasma melatonin levels, especially during the morning hours, were relatively low in depressed pregnant women but relatively increased in depressed postpartum women; also, the timing of melatonin production was advanced in pregnant women with a personal or family history of depression. Suicide (and deliberate self-harm) is rare during pregnancy,(Appelby & Turnbull, 1995) although it may have been more common in the past, although teenage and single mothers may represent high-risk groups.

It should also be noted that obsessive-compulsive disorder (OCD) often worsens in pregnancy and/or the puerperium.(Neziroglu *et al*, 1992) Evidence as to whether a first episode is commoner during pregnancy is conflicting. There may be obsessions of infanticide (which may be extreme, e.g. beheading) but the clinician must still encourage the mother to interact with her baby. Panic disorder may be exacerbated during the puerperium, and Cohen *et al* (1994) suggest that this possibility may be heightened by not treating panic disorder during pregnancy.

The **postpartum/maternity blues/reactivity** affects over 50% of mothers on days 3-5 postpartum and is generally resolved by day 10. There are transient labile emotions (heightened responsiveness to good and bad stimuli), tearfulness, mild hypochondriasis, irritability, and anxiety. It can occur with hospital or home deliveries.

Aetiology (unclear)

Primigravida

History of third trimester depression or premenstrual dysphoria

Psychological, e.g. no longer pregnant, responsible for baby, effects of having a baby on relations with other adults, including the father of the child

Lack of sleep¹³⁹⁵ and fatigue

Psychoanalysts stressed unresolved feelings towards one's own mother from childhood, sexual identity difficulties, and re-experiencing of earlier sibling rivalry (such postulations could equally apply to problems during pregnancy or other postnatal psychiatric difficulties)

Fall in progesterone levels

Increase in platelet beta-adrenoreceptors before and during the blues (Metz, 1983)

Management consists of waiting, reassuring, and forewarning. Particularly severe cases should prompt a search for another psychiatric disorder.

Postnatal (postpartum) depression (PND) occurs after at least 10% of births¹³⁹⁶, (O'Shea, 2000e; Wisner *et al*, 2002; Crotty & Sheehan, 2004) and a significant minority of such cases are a continuation of depression from pregnancy.(Watson *et al*, 1984) Sixty percent are fully recovered inside a year. Others may show some level of chronicity. Mood varies from day to day. There is anxiety¹³⁹⁷, irritability, tiredness, despondency, and initial insomnia. Murray *et al* (1995) found no symptomatic difference between early versus late PND or

¹³⁹⁵ Debate exists as to whether sleep disruption is more important before or after delivery; the same applies to night-time labour.

¹³⁹⁶ Cooper *et al* (2007) are sceptical about the differences between PND and non-PND depressive episodes, e.g. reduced early morning wakening could be due to having a new baby! Young *et al* (2010, p. 635) and Brockington (2010, p. 722) suggest that there is little difference between the prevalence of postnatal depression and depression in non-gravid women.

¹³⁹⁷ High levels of anxiety early on may predict PND.(Teissedre & Chabot, 2003)

between PND and non-PND depression. PND is more common with a past history of psychiatric disorder or high interpersonal sensitivity or neuroticism, (Boyce ea, 1991) young age, early postnatal blues (debatable: Miller & Rukstalis, 1999), delivery by forceps/vacuum/caesarean section (cs),¹³⁹⁸ poor marital relationship (Patel ea, 2004) or single status, severe life event in the previous year, (Marks ea, 1991), no social supports, in-law difficulties, (Lee ea, 2004) ambivalence about the pregnancy, and perinatal death. Murray ea (1995) found that women with PND had poor relationships with their own mothers and occupational instability. Depressed women without PND on the other hand had at least three children and manual employment that they disliked. Vigod ea (2010) conducted a systematic review and reported that mothers of preterm infants are at increased risk of depression compared with mothers of term infants in the immediate postpartum period; risk continued throughout the first postpartum year for mothers of very low birth weight infants. High scores on the *Edinburgh Postnatal Depression Scale* at 6 weeks are associated with single marital status, unemployment, unplanned pregnancy, public patient status, and bottle-feeding. There is evidence from Nigeria and South Asia that pre- and post-natal neuroticism may be largely caused by psychosocial factors (Aderibigbe ea, 1993; Patel ea, 2004) and psychological vulnerability to PND may be similar to that for depression at any other time. (Jones ea, 2010)

Maes ea (2001) found that plasma tryptophan falls at term and after delivery but bore no relationship to the risk for PND. High-expression 5-HT transporter genotypes may be a risk factor for depressive symptoms following childbirth. (Sanjuan ea, 2008)

There is no evidence to incriminate progesterone withdrawal in postpartum depression – despite this, and lack of evidence of effectiveness, progesterone is often prescribed¹³⁹⁹. A particularly low evening serum cortisol concentration just after delivery may be more common in PND cases. There is a suggestion that thyroid antibody positive status may increase the risk for this disorder, (Harris, 1994) but giving thyroxine does not prevent PND in such cases. (Harris ea, 2002) There is preliminary evidence that increased levels of placental corticotropin-releasing hormone (pCRH)¹⁴⁰⁰ at 25 weeks gestation predicts postpartum depression. (Yim ea, 2009)

In a study of 483 women, the prevalence, incidence, and nature of non-psychotic psychiatric disorder in the twelve months following delivery failed to distinguish it from such disorders arising at other times, (Cooper, ea, 1988) although others have found that women with a past history of non-PND depression who now experience an episode postnatally may revert to their original pattern whereas women who had their first episode of depression after delivery may be at risk only for postnatal recurrences. (Cooper & Murray, 1995) It has been suggested that the closer the onset of depression to the birth the greater the likelihood of neuroendocrine factors being operative. Management involves a package of counselling, psychotherapy, family work, chemotherapy (e.g. fluoxetine), and practical assistance. Evidence has been reported for efficacy in PND for cognitive behaviour therapy¹⁴⁰¹, (CBT: Appleby ea, 1997; Chabrol ea, 2002) interpersonal therapy, (O'Hara ea, 2000) and non-directive counselling. (Holden ea, 1989) Cooper ea, (2003) found that psychodynamic¹⁴⁰² produced a decrease in depression at 4.5 months, but that no of the active treatments were superior to the control intervention at 9 months. As far as prevention is concerned, Dennis (2005) concluded that diverse psychosocial and psychological interventions do not significantly reduce the number of women developing PND, but that there is some support for the prophylactic efficacy of intensive support from a health professional. There is evidence from Canada (Dennis ea, 2009) of a prophylactic effect of telephone-delivered support delivered by people with a self-reported history of and recovery from postnatal depression for women at risk¹⁴⁰³ of postnatal depression.

Transdermal oestrogen (e.g. 17 β oestradiol) may be worth trying in severe cases. (Gregoire ea, 1996)

However, the efficacy of oestrogen without a co-prescribed antidepressant remains controversial. (Wisner ea, 2002) It has been suggested that breast feeding might be unwise because of the associated

¹³⁹⁸ Patel ea (2005) did not find support for this contention.

¹³⁹⁹ In fact, there is more evidence that progesterone can make depression worse in these patients. (Lawrie ea, 1998)

¹⁴⁰⁰ In contrast to the negative feedback of cortisol on the HPA axis cortisol *stimulates* **placental CRH** production. Therefore, pCRH levels in mother's plasma increase exponentially throughout pregnancy. In fact pCRH levels reach those of hypothalamic CRH in the median eminence during acute stress. Removal of the placenta at delivery leads to a precipitous drop in pCRH levels. This CRH withdrawal state results in short-lived suppression of hypothalamic CRH release and dysregulation of the HPA axis.

¹⁴⁰¹ Treatment based on CBT has been delivered by community health workers in resource-poor settings (Rahman ea, 2008; Patel & Kirkwood, 2008) and by health visitors in England. (Morrell ea, 2009)

¹⁴⁰² But not routine primary care, non-directive counselling, or CBT.

¹⁴⁰³ Identified using the *Edinburgh Postnatal Depression Scale*.

hyperprolactinaemia. Recognition is important in order to reduce chronicity. The woman must be allowed to ventilate her feelings, e.g. guilt, anxiety about baby, suicidal or homicidal thoughts, loss of interest in sex, fears that the baby might not be hers, or fears that the child is deformed. There is evidence for adverse emotional and cognitive effects on the infant.(Murray ea, 1991; Patel ea, 2004)

'Neurotic disorders' other than depression may occur during the puerperium, e.g. phobias (including agoraphobia), anxiety, or OCD.

Postnatal psychotic depression complicates 0.2% of births¹⁴⁰⁴. Suicide and infanticide are real possibilities. The risk of recurrence in another puerperium is at least 20%, higher (40%) if there is a history of episodes of affective illness unrelated to childbirth. At least 50% experience a later non-puerperal depressive episode. The following factors may be associated with an increased risk of admission to a psychiatric unit with puerperal psychosis: the first 30 days postpartum, primiparae, single marital status, cs, perinatal death, and a history of BAD¹⁴⁰⁵ or schizoaffective disorder.(Blackmore ea, 2006) However, while hospitalisation for psychiatric morbidity before delivery is common in such cases,(Harlow ea, 2007) puerperal psychosis can occur in women with no psychiatric history. It was suggested that postpartum psychosis may be associated with supersensitivity of DA receptors, perhaps triggered by a sharp fall in oestrogen levels following parturition, but this has not been confirmed.¹⁴⁰⁶

Symptoms, which usually commence within two weeks of delivery, include guilt, despair, psychomotor retardation or agitation, perplexity, lability of affect and disorientation. Management involves admission of the mother and if at all possible her child, careful observation, ECT if indicated, and antidepressants. Mixed affective state may carry a higher suicide risk than postnatal psychotic depression. The requirement for mother and baby unit beds has been estimated at 8/million total population.

Special risks for infanticide¹⁴⁰⁷ include young motherhood and poor education. The infanticide rate in the USA was at least 9/100,000 live births during the period 1988-91. The Irish forensic dimension has been explored by Mulryan ea.(2002) A marked decrease in the number of women admitted to Ireland's only 'special' hospital on charges or conviction for infanticide may reflect altered judicial attitudes. The authors suggest that the barriers to the movement of pregnant women to Britain during World War II may explain a dramatic increase in the number of infanticide cases appearing before the Irish Central Criminal Court between 1940 and 1946.(Mulryan ea, 2002)

It should be noted that women with a history of psychotic disorder may have an increased risk of stillbirth and neonatal death.(Howard ea, 2003) They should be the focus of optimal antenatal care, including counselling on smoking and substance misuse.

Treatment strategies

Treatment options include supportive psychotherapy¹⁴⁰⁸, cognitive-behaviour or interpersonal therapy (when available), cognitive remediation therapy¹⁴⁰⁹, marital therapy (especially if there is accompanying marital distress) environmental manipulation (e.g. re-housing), assertiveness training, prompting, shaping, general measures (e.g. feeding), sleep deprivation¹⁴¹⁰ (in depressives), stereotactic psychosurgery (rarely),

¹⁴⁰⁴ Are postpartum psychoses getting less common (Tschinkel ea, 2007) or is what that are included under this rubric shrinking?

¹⁴⁰⁵ According to Yurgelun-Todd (2007, p. 146) 30% of women with postnatal psychosis will be diagnosed as having bipolar disorder, and 30% of women with BAD will receive a diagnosis of postnatal psychosis whereas only 1 in 1,000 women in the general population experience postnatal psychosis.

¹⁴⁰⁶ Depressive symptoms in women taking anovulant pills were associated with the amount of oestrogen relative to progesterone.(Hall ea, 1980)

¹⁴⁰⁷ **Infanticide** was employed for centuries in China as a means of population control. Today, infanticide, especially in the first days after the birth, may indicate social reasons (the unwanted and disguised pregnancy) rather than psychiatric disorder. In the US, white female infants have greatest risk of all white females of being murdered.(Malmquist, 2006, p. 4)

¹⁴⁰⁸ Among the approaches used are psychoeducation, dealing with stigma/low self-esteem/interpersonal problems/legal difficulties/social and occupational consequences. Miklowitz (2008) looked at 18 trials of individual and group psychoeducation, systematic care, family therapy, and interpersonal or cognitive behavioural therapy as adjuncts in bipolar patients and found that they improved symptoms and function over 2 years; emphasis on medication compliance and recognition of early mood changes had stronger effects on mania, whereas emphasis on cognitive and interpersonal coping strategies had stronger effects on depression.

¹⁴⁰⁹ Elgamal ea (2007) improved cognition in 12 cases of major depression with computerized cognitive remediation (targeted, repetitive) exercises despite no change in depression scores.

¹⁴¹⁰ Wu ea (2009) used *chronotherapeutic augmentation* (sleep deprivation, bright light therapy, and sleep phase advance) in 49 outpatients with BP depression (measured with HRSD) and reported a rapid and sustained antidepressant response. Two patients experienced hypomania which resolved spontaneously within 24 hours.

ECT, repetitive transcranial magnetic stimulation¹⁴¹¹, antidepressants¹⁴¹², 'anti-manics'¹⁴¹³, light therapy, dark therapy¹⁴¹⁴, and, rarely, psychosurgery for depression. Except for the mildest cases (where 'watchful waiting' may be appropriate) the earlier treatment is instituted the better. Immediate response to antidepressant therapy may constitute a placebo effect; such cases are prone to early relapse. Many people imagine antidepressants to be non-efficacious or addictive, and many have magical expectations of counselling. Apart from giving medication, it is important to address any persistent dysphoria, low self-esteem, or confounding psychosocial issues. Arguably, physical exercise, such as running, may alleviate less severe forms of depression and anxiety (Greist et al, 1979; Mather et al, 2002), but is this due to exercise, lack of inactivity, or a third unknown factor? (Wilkinson, 2008, p. 248; De Moor et al, 2008) Also, exercise was not effective in one study in preventing depression in older adults in one study. (Walker et al, 2010) In general, cognitive therapy may be less effective for severe depression or for those cases with an abnormal EEG profile. Four different psychotherapeutic strategies for depression are summarised in the box. Couple therapy may help in cases where relapse appears to be precipitated by having a critical partner. According to Keck, (2004) psychoeducation may be better at preventing manic than depressive relapses in bipolar disorder, with the opposite effect for family-focused therapy.

Five approaches to psychotherapy in depression

*Psychodynamic*¹⁴¹⁵ (e.g. Freud, Kohut). Ego regresses due to losses in childhood. Therapist must understand past, defences, ego distortions, superego defects, and provide role model and permit catharsis. Aim at personality change. Employ expression/reflection. Be empathic. Analyse/explore transference/resistance. Confront defences. Clarify ego/superego distortions. Utilise therapeutic alliance for benign dependence/empathic understanding. Treat individual in confidence. Apart from emergencies, exclude others.

Interpersonal (e.g. Sullivan, Klerman). Unsatisfactory interpersonal (IP) relations/bonds. Aim to solve current IP problems, reduce stress, and improve communication skills. Aim to relieve symptoms. Clarify maladaptive relationships and learn new ones via communication/social skills training. Didactic teaching re illness. Explore/prescribe. Use positive relationship. No interpretation of transference. Active therapist: influence/advocacy. Use partner and his/her role in patient's disposition to depression. Look at illness effects on relationship. Interpersonal psychotherapy is an alternative to medication in the depressed breast-feeding mother.

Cognitive (e.g. Beck). Distorted thinking due to learned negative views. Change target thoughts. Modify false assumptions. Increase self-control over thinking patterns¹⁴¹⁶. Aim at symptomatic relief¹⁴¹⁷.

Cognitive-behavioural approach (CBT): record/monitor cognitions/correct distorted themes using logic and by testing them in vivo/provide alternative thought content/give homework assignments/educate and shape/use positive relationship/avoid transference/and collaborative empiricism for joint logical task. Use partner as objective reporter/couples therapy if relationship disturbed/thoughts sustained by relationship.

Behavioural. Such approaches are based on learning theory, e.g. use of operant conditioning to develop a structured daily action plan. Ekers et al (2008) conducted a meta-analysis of 17 RCTs (1109 subjects) and found pure behavioural therapy to be effective with equal outcomes compared to CBT.

Supportive (L. to carry). Commonest approach. Here and now. Adjunctive. Avoid transference. Didactic, empathic, active. Draws on many schools of psychotherapy as needed. Can be used with any other suitable

¹⁴¹¹ No better than sham treatment according to Mogg et al. (2008)

¹⁴¹² Patients with significant medical illness are more prone to adverse effects and those with secondary major depression may respond to relatively low doses. (Hanretta & Fogel, 2003)

¹⁴¹³ E.g. neuroleptics, lithium, anticonvulsants for the treatment or prevention of mania or antidepressants for the treatment or prophylaxis of depression.

¹⁴¹⁴ Barbini et al (2005) report that extended darkness may reduce manic symptoms when given early in an episode (pilot study).

¹⁴¹⁵ Taylor (2008) argues that whilst the effects of CBT may be relatively acute, those of short-term psychodynamic therapies may continue to increase following treatment, and longer-term psychodynamic approaches may have wide positive effects on personal function as well as improving symptoms of depression.

¹⁴¹⁶ Mindfulness-based cognitive therapy (Teasdale et al, 2002) aims to prevent relapse of depression by instilling meta-cognitive awareness (a normal person knows that his thoughts and feelings are products of his mind and not objective truths about the self).

¹⁴¹⁷ Fournier et al (2008) found that paroxetine worked faster than cognitive therapy for depressives with personal disorder and a meta-analysis found only a small effect for CBT in the management of major depression.

measure, e.g. environmental manipulation. Partner and others (e.g. housing authority, bank manager) may be approached (with permission).

Luty ea (2007) found interpersonal (IPT) and cognitive-behavioural therapies effective in depressed outpatients, with the latter being more effective than IPT in cases with MADRS score above 30 ('severe'). Therapist-delivered CBT for depression on the internet seemed to be effective and to remain beneficial over 8 months in one RCT based in primary care. (Kessler ea, 2009) Psychotherapy may have a role in preventing depression. (Cuijpers ea, 2008¹⁴¹⁸)

Interpersonal and social rhythm therapy may improve occupational functioning in BP I patients. (Frank ea, 2008a)

Cuijpers ea (2010) chose RCTs of the use of psychotherapy in the treatment of adult depression on the basis of 8 quality criteria (e.g. 2 independent coders and participants meeting diagnostic criteria). The results of their meta-analysis suggested that while psychotherapy had significant effects such effects are much smaller than was previously understood.

Whether to start treatment with a TCA (cheap, toxic in overdose, etc) or an SSRI (expensive, sexual side effects) is controversial¹⁴¹⁹ (Harrison & Geddes, 1995) and the decision should be based on an understanding of a number of variable such as economics, overdose potential, treatment history, and physical status. Cipriani ea (2009) compared the efficacy and acceptability of twelve 'new-generation' antidepressants in a meta-analysis: mirtazapine, escitalopram, venlafaxine and sertraline were more efficacious than duloxetine, fluoxetine, fluvoxamine, paroxetine, and, the least efficacious, reboxetine. The authors suggest starting with sertraline (Lustral, Seretral) when treating moderate/severe major depression in adults because it had the best balance between efficacy, acceptability, and cost. Uher ea (2009) found that escitalopram improves observed mood and cognitive symptoms more than does nortriptyline whereas the opposite applies to neurovegetative symptoms. (see also Uher ea, 2010)

The common method of defining a response on the basis of a 50% reduction in Hamilton score does not necessarily mean that the patient is clinically recovered¹⁴²⁰; the same criticism applies to Y-BOCS scores and OCD. Baldwin ea (2002, p. 75) point out that older people are more likely to overdose with analgesics than with antidepressants.

Past personal response to a particular antidepressant or a family history of such a response is a good argument for using it again during the index episode. It has been suggested that patients with the lowest pre-treatment evening TSH secretion have a low response rate to antidepressant drug therapy. MAOIs may be chosen (for responsible of supervised patients who fail trials of other drugs) because of a reverse neurovegetative symptom cluster – hyperphagia, anergy, and psychomotor retardation – although patients with classic melancholia may also respond to this class of drug. Howland & Thase (2002) suggest that MAOIs are effective in about 50% of depressions resistant to other drugs.

The old idea of reducing a therapeutic dose to a maintenance or prophylactic one after symptoms remit was mistaken: the patient should be kept on the dose that worked for at least 6 months. No one knows how long an individual episode will last. It is the author's practice to *aim at* 2 years treatment, followed by a slow taper if history and symptoms/function suggest it is safe to do so. Not everyone who needs long term antidepressant treatment gets it or receives it for long enough. (Holma ea, 2008) Depression is a long term illness. (Montgomery, 1994). Geddes ea (2003) conducted a systematic review of 31 randomised trials of continuation antidepressant drug therapy and found that whilst treatment effects seemed to last over 3 years, most trials were only a year in duration; average relapse rate on drug therapy was 18%, 41% on placebo; and 18% of active drug treatment cases stopped the drug, 15% on placebo. The authors wondered if treatment effects would have been superior with better adherence. Williams ea (2009) conducted a meta-analysis of long-term antidepressant drug therapy and found relapse rates of 23% and 51% for active drug and placebo respectively, and time on treatment significantly influenced the relapse rate.

Agomelatine (Valdoxan) acts at melatonergic receptors (agonist) and 5-HT_{2C} receptors (antagonist). This antidepressant seems to have a sleep restorative effect without suppressing REM sleep.

¹⁴¹⁸ NNT to prevent 1 case of depressive disorder was 22.

¹⁴¹⁹ If prescribing an SSRI concurrently with a TCA lower doses of the latter should be used since SSRIs raise TCA plasma levels.

¹⁴²⁰ Fava ea (2007) suggest that 'recovery' from major depression should include psychological well-being.

Gynaecologists may have been more inclined to opt for oestrogen as a first line treatment of depression in women that would psychiatrists.(Studd, 1992) Nevertheless, transdermal 17-beta oestradiol may improve mood in perimenopausal women.

The neurotic-endogenous and other aetiological distinctions or the presence of life stresses or 'understandability' of depression are no longer regarded as important in defining the presence of disorder and the need for antidepressant drug treatment. Psychotic depression requires the addition of a neuroleptic (e.g. olanzapine plus sertraline: Meyers ea, 2009), the response to antidepressant drugs being poor. ECT may be required. There have been reports of psychotic depressives responding to SSRI on their own, but with high drop out rates due to side effects.

Phases of depression and usage of antidepressant drugs

<i>Acute</i>	Build up to therapeutic dose (TD) from starting dose (lower starting dose in elderly)
<i>Continuation</i>	At least 6 months; use TD to avoid return of symptoms (relapse)
<i>Prophylactic*</i>	Debatable duration (? two years before slow monitored taper; longer if recurrent)

*Suggested indications for maintaining people on longterm antidepressants include highly recurrent depressive disorder (yearly for years; illness cycle < every 3 years; many episodes within 5 year period), severe and incapacitating episodes, protracted episodes, chronic major depression¹⁴²¹, double depression, and residual dysthymia. It is the author's experience that many patients require indefinite treatment.

Even mild atypical cases of depression may respond to medication, classically MAOIs like phenelzine. Pure dysthymia and 'double depression' (dysthymia plus major depression) have been demonstrated to show a complete or partial response to desipramine. Dysthymia may respond to 40 mgs of fluoxetine a day should 20 mgs fail. Dysthymia is not thought to respond to ECT.(Weiner ea, 2001)

Augmentation strategies¹⁴²² may be employed in cases of resistant depression (Cf. below), e.g. lithium added to an SSRI or TCA (this strategy has been said to require an adequate serum lithium level, although as low as 0.3 mmol/L (mEq/L) has been shown to work, and a long trial before declaring it to be ineffective).(Dinan, 1993) However, Birkenhäger ea (2004) found that lithium added to imipramine¹⁴²³ was superior to lithium added to fluvoxamine for treatment of severely depressed inpatients. There is evidence from a small trial (Dinan & Barry, 1989) that TCA-resistant patients respond equally well with either ECT or a TCA-lithium combination. Folkerts ea,(1997) in a study of depressed patients who failed to respond to pharmacotherapy, found ECT to be much more efficacious in the short term than paroxetine. Some patients who fail to respond to a course of ECT (especially unilateral) may respond to a similar course after a gap of, say, some weeks. The occasional patient seems to get more depressed early during a course of ECT only to improve thereafter. Adding an atypical antipsychotic to an antidepressant in major depression may be effective but at the risk of discontinuation due to adverse effects.(Nelson & Papakostas, 2009)

The literature on driving and being on antidepressants is full of so many interacting variables that it is safest to err on the side of safety when counselling patients.(Edwards, 1995a) Whilst it is probably true that depression has a more profound effect on driving than antidepressants, that does not automatically render the latter without potential hazard.¹⁴²⁴

Lithium is not as useful as antidepressant drugs for the prophylaxis of UP depression, and the combination of the two does not seem to confer any benefit. Lithium may have some effectiveness in the treatment of acute depression, but is not comparable to treatment with antidepressants.

Various recommendations have been made as to which antidepressant is safest in epilepsy, e.g. the TCAs trimipramine, protryptiline and doxepin¹⁴²⁵. SSRIs are considered less epileptogenic than TCAs.

¹⁴²¹ Chronic MDD in DSM-IV-TR = full MDD lasting for at least 2 years.

¹⁴²² The decision to augment rather switch an antidepressant may be influenced by a partial (as distinct from no) response to the first drug.

¹⁴²³ Imipramine (Tofranil), withdrawn 2006.

¹⁴²⁴ The Irish reader is referred to the Road Traffic (Licensing of Drivers) Regulations, 1999(Department of the Environment and Local Government, 1999) for further information.

¹⁴²⁵ Latter not available after November 2006.

Clomipramine, bupropion (especially if dose > 450 mgs/day), and maprotiline (if dose > 200 mgs/day) are particularly likely to induce seizures. MAOIs should be avoided where possible in asthmatics. If they are used, then only steroid-based inhalers should be employed.

Alternatives to lithium in bipolar disorder have been reviewed.¹⁴²⁶ (O'Shea, 1993; Vieta *et al*, 2008a) Initial reports that successful lithium prophylaxis could not be reintroduced with the same success after it had been interrupted may have been unduly pessimistic. Most prophylactic therapies are better at preventing manic than depressive episodes. Lithium prophylaxis may be more successful if there is a family history of response to this drug.¹⁴²⁷ (Grof *et al*, 2002) Although subject to individual circumstances, the author recommends prophylaxis with lithium for patients with a history of one manic attack or one episode of hypomania and one of depression. The usual recommended prophylactic lithium levels range from 0.8-1.0 mmol/L, which may reduce relapse rates but increase side effects over lower levels (0.4-0.8); a balance has to be struck in individual cases. The more rapidly lithium is discontinued the shorter the time is to relapse. Continuation of mild mood swings whilst taking lithium may be a strong indication of relapse on cessation of the drug. Carbamazepine (therapeutic range: 4-12 µg/ml) induces its own metabolism after a few weeks of therapy (autoinduction) so the dose may need to be increased, a problem not found with sodium valproate (therapeutic range of valproic acid: 50-100 µg/ml; according to Allen *et al*, [2006] levels above 94 µg/ml may give the best response in acute mania). The latter may cause much nausea and vomiting. If carbamazepine has to be combined with lithium, then the dose of lithium may need to be reduced. Some bipolars seem to relapse less often when taking a depot neuroleptic. (Mannion *et al*, 1999) Lithium plus divalproex sodium resulted in a lower risk of relapse in a pilot study of bipolar I patients (Solomon *et al*, 1997) when compared with monotherapy. Bipolar I patients stabilised on quetiapine plus lithium or divalproex took longer to relapse than did those on placebo plus lithium or divalproex. (Suppes *et al*, 2009) A randomised open-label trial (BALANCE Investigators and Collaborators, 2010) found that, for patients with BP-I disorder (irrespective of baseline severity) who require longterm treatment, lithium plus valproate and lithium on its own were more likely to prevent relapse than was monotherapy with valproate.¹⁴²⁸ Lamotrigine (Lamictal), a sodium channel blocker, may have modest antidepressant utility in bipolar depressive episodes¹⁴²⁹ (Geddes *et al*, 2009) and act as a prophylactic for depressive episodes in BP disorder. (Keck, 2004) Lamotrigine may be associated with a severe skin rash, dizziness, tremor, somnolence, headache, and nausea. However, in one study of BP I patients the only side effect more often seen in the lamotrigine group over placebo was headache.¹⁴³⁰ Obese BP I patients¹⁴³¹ may lose weight on lamotrigine and gain it on lithium. (Bowden *et al*, 2006)

Treatment of depression in bipolar patients ('bipolar depression') is a common clinical scenario which is still being debated. If the patient is not on prophylactic treatment and the depression is mild, one may try lithium (or an anticonvulsant) or interpersonal or cognitive therapy; if it is severe, one may combine lithium with an antidepressant or increase the dose of lithium (Nemeroff *et al*, 2001). In general, mood stabilisers may be moderately effective for acute bipolar depression but the available research is somewhat compromised by brevity and high dropout rates. (Van Lieshout & MacQueen, 2010) Breakthrough depression during prophylaxis may respond to optimising prophylaxis¹⁴³² or, if severe, adding an SSRI. MAOIs may be more efficacious than TCAs. (Himmelhoch *et al*, 1991) A combination of olanzapine and fluoxetine (Symbax) is available for bipolar depression in the US. Refractory cases may require ECT. (Müller-Oerlinghausen *et al*, 2002) According to Farrelly (2008) treatments with an NNT of < 10 are olanzapine-fluoxetine, lithium-SSRI, quetiapine 300 and 400 mg, and lamotrigine. Studies of treatment in acute mania often excluded persons incapable of giving informed consent; exclusion criteria do not reflect clinical reality; high dropout rates are common; response is usually defined as at least

¹⁴²⁶ Vieta *et al* (2008) suggest that the hopes associated with new anticonvulsants, apart from lamotrigine, have not been fulfilled in either bipolar disorder or epilepsy.

¹⁴²⁷ A family history of bipolar disorder, mania followed by depression, and good compliance are associated with good response to lithium; poor compliance, substance misuse, paranoid tendencies, and rapid cycling are associated with a relatively poor response.

¹⁴²⁸ Benefit for the first 2 approaches was demonstrated for up to 2 years. The study was not able to pronounce of the difference in efficacy between lithium monotherapy and lithium plus valproate.

¹⁴²⁹ The advantage over placebo may be larger in more severely depressed patients. (Geddes *et al*, 2009)

¹⁴³⁰ Lamotrigine may interfere with the efficacy of the contraceptive pill and there may be an increased risk of oral clefts in offspring when it is employed during pregnancy.

¹⁴³¹ A Brazilian study (de Almeida *et al*, 2009) found an excess of obesity (35.7%) in BP patients compared to the general population.

¹⁴³² Adjusting dosage, adding another prophylactic agent.

50% drop in manic symptom ratings (placebo response being 20-40%). Whilst the evidence is that combined second-generation antipsychotic agents and mood stabilisers represent the most efficacious treatment for acute mania, (Scherk ea, 2007) more research evidence is needed on when and if to taper drugs used in combination, e.g. valproate plus an antipsychotic drug. (Keck, 2003) ECT, lithium and anticonvulsants have all proven efficacies in mania. Higher plasma levels of lithium are used for acute treatment than for prophylaxis, e.g. 1.0-1.5 mmol/L in supervised in-patients for treatment of mania and 0.5-0.8 for the prevention. Low-grade hypomania in-patients who can be supervised outside hospital can sometimes be treated with lithium alone if follow up is frequent enough. Lithium has the advantage of being less likely than neuroleptics of causing a switch into depression, but the disadvantage of a delayed effect. Antidepressants may cause a manic swing. Bupropion may be less likely to induce a switch to mania.

Withdrawal of antidepressant drugs may abort a manic episode if done early enough.

Antipsychotics are used more often than lithium for acute mania because they bring the patient's behaviour more quickly under control. A combination of chlorpromazine and a barbiturate was the 'cocktail' of choice in the past. This was replaced in turn by haloperidol, which has been challenged in turn by atypical antipsychotic drugs (risperidone, olanzapine, quetiapine, aripiprazole¹⁴³³, and clozapine) with or without a benzodiazepine. (Green ea, 2000; Khanna ea, 2005; Vieta ea, 2005) Antipsychotic drugs may have specific anti-manic effects that are independent of sedation or an anti-psychotic effect. (Cookson, 2008) In addition, some typical agents may be associated with depression following mania¹⁴³⁴, an effect less likely when atypical are employed. Clozapine may bring mania under control when other approaches fail or are associated with excessive side effects. Olanzapine was superior to divalproex in one study of the treatment of mania, (Tohen ea, 2002) but with a different side effect profile: weight gain, dry mouth, increased appetite, and somnolence versus nausea respectively. Olanzapine was reported as being superior to divalproex in the treatment of acute mania but to be no better than divalproex in terms of rates of relapse of bipolar disorder. (Tohen ea, 2003) However, Tohen ea (2005) found it better than lithium in preventing manic and mixed episode relapse/recurrence over 12 months in bipolar patients acutely stabilised with both olanzapine and lithium, whereas both drugs were comparable in preventing depressive relapse/recurrence. The combination of olanzapine and carbamazepine was not better than carbamazepine alone for mania in another study¹⁴³⁵. (Tohen ea, 2008) A review of RCTs of the comparative safety and efficacy of carbamazepine and lithium in acute mania and as maintenance therapies for bipolar disorder suggested that both drugs may be equivalent. (Coron-Litvoc ea, 2008) According to Yatham ea (2004) quetiapine combined with lithium or divalproex is more effective over 3-6 weeks for mania than lithium or divalproex given alone. Also, Calabrese ea (2005b) found that quetiapine monotherapy was effective in treating bipolar depression. Because of effectiveness and cost issues, Wassef ea (2005) recommend starting with generic valproic acid and only switching to delayed-release divalproex if intolerance occurs. The literature on oxcarbazepine suggests that it might be more efficacious for mild to moderate mania at best. (Grunze, 2008) A combination of ECT and medication might work better than the drug given alone because of putative blood-barrier changes with ECT leading to greater central penetration by the drug. (O'Shea ea, 1983; Skidar ea, 1994) Bilateral ECT given three times weekly for mania has been found to be superior to lithium for the treatment of mania. There is at least one report that unilateral and bilateral ECT had equal efficacy in mania. ECT should mainly be considered where mania does not respond to medication or when the risks attached to drug therapy are unacceptable. (Maixner & Taylor, 2008, p. 60) ECT thrice weekly seems to work faster to relieve depression whereas given twice weekly it has less effect on cognition. The latter frequency is often employed with elders.

Tobacco smoking is probably associated with worse treatment outcomes in mania. (Berk ea, 2008) In general, the combination of BP and substance use disorder is very difficult to treat. (Levy & Weiss, 2009) Scarná ea (2003) describe the use of a palatable drink containing only three branched-chain amino acids (leucine, isoleucine, and valine). These amino acids compete for brain entry with phenylalanine and

¹⁴³³ Aripiprazole may be added to other drugs, such as lithium or valproate, in the management of mania to improve response. (Vieta ea, 2008b) It may also be used solo. (Young ea, 2009) Aripiprazole may also prove useful for residual anxiety in patients treated for depression with an SSRI. (Adson ea, 2005) Aripiprazole is relatively less likely to leave patients feeling 'drugged'. Akathisia and tremor should be sought out and managed appropriately. Hyperprolactinaemia and sexual dysfunction are unlikely. A benzodiazepine may be added whilst sedation is necessary. (Fagiolini, 2008)

¹⁴³⁴ At least some such depressions may be due to extrapyramidal side effects (*akinetik depression*).

¹⁴³⁵ Combination therapy was associated with weight gain and hypertriglyceridaemia.

tyrosine and seem to attenuate central dopamine neurotransmission. In their study, (Scarná ea, 2003) relative to placebo, administration of this mixture to manics lowered Beigel mania ratings acutely over the first six hours. Further work is needed on its longterm effects. An Iranian study (Behzadi ea, 2009) of acute mania in BP I patients (using the Young Mania Scale) found that adding folic acid to sodium valproate was effective in reducing manic symptoms.

The human body normally contains about 0.1% of the therapeutic level of lithium. The peak level determines side effects. Therapeutic effects are related to the 12-hour (since last dose) level. The author tries to test lithium patients' serum lithium level (12 hours post-dose) every 3 months and renal (serum creatinine) and thyroid function (TSH) twice yearly. A pre-lithium ECG is prudent. A recent myocardial infarction (MI) is a relative contraindication to lithium use because of the possibility of an arrhythmia. Patients on anticonvulsants should have their serum levels checked; it is also prudent to check the white cell count and liver function from time to time.

Depression often remits when a patient remains abstinent from alcohol. Less lipophilic beta-blockers such as atenolol or nadolol or the use of ACE inhibitors may help to avoid iatrogenic depression.

In the elderly, it will be recalled that TCAs carry problematic side effects, e.g. urinary retention and postural hypotension. Blurring of vision may be catastrophic for an elder whose sole outlet is reading. Nortriptyline has a role in severe depression. SSRIs are generally more acceptable, but sexual side effects can be a problem 'even' in old age. ECT can be used for a rapid response or where the patient is psychotic.

Rapid cycling

Rapid cycling was more likely to occur in a 13.7 year follow up study (Coryell ea, 2003) if the bipolar disorder (BP) had an early onset (< 17 years old). Reducing TCA intake did not help. Depressive morbidity (esp. if lithium was used without an added TCA), shifts into mania/hypomania, and serious attempts at suicide were common. Alcohol and substance abuse, including cannabis, (Strakowski ea, 2007¹⁴³⁶) may contribute to the phenomenon of rapid cycling and need to be addressed. (APA, 2002, p. 557) The presence of PTSD worsens outcome of BP (Quarantini ea, 2009): patients are less likely to recover, there is an increased proportion of rapid cycling episodes, an increased risk of attempted suicide, and reduced quality of life.

Rapid cycling should be managed by avoiding or stopping antidepressant drugs, by optimising mood stabiliser treatment (starting/adding – Calabrese ea [2005a] found no difference between lithium and divalproex sodium in the treatment of rapid cycling), or, when necessary, adding levothyroxine. (Müller-Oerlinghausen ea, 2002) ECT is reported to induce, be ineffective for, and to abort rapid cycling. (Kho, 2002) Vagal nerve stimulation (VNS) might have some efficacy¹⁴³⁷. (Marangell ea, 2008) Prevention may require early intervention and restricted prescribing of antidepressants. (Schneck ea, 2008)

Resistant (refractory) depression

Assuming the diagnosis to be correct, nonresponse to antidepressant drugs may be due to non-compliance, treatment intolerance, or true treatment resistance. Interestingly, sleep deprivation does not improve anxiety disorders. (Labbate ea, 1998)

Preskorn and Burke (1992) suggest commencing treatment of depression with a TCA or an SSRI. If an adequate trial (full dosage and adequate duration¹⁴³⁸) fails (inadequate response or excess side effects) they would switch from a TCA to an SSRI or vice versa. Should there have been a partial response with the initial agent they would either switch to an alternative drug or attempt augmentation. Should this fail they would try a 'second-line' agent such as the aminoketone bupropion or they would use ECT. (Rush ea, 2006; Trivedi ea, 2006) Rush ea (2008) looked for factors associated with remission with or intolerance to a variety of second-step medications in patients who had an unsatisfactory outcome with citalopram: remission was more likely in the socially stable, non-suicidal patient who who had shown citalopram intolerance and perhaps some response to that drug but it was less likely in people with concurrent anxiety disorders, severe or melancholic depression, or substance misuse, and intolerance for citalopram predicted intolerance for sertraline. Combined MAOI and TCA treatment should be left to specialists. A combination

¹⁴³⁶ Strakowski ea (2000) found that BP patients used alcohol when depressed and cocaine and cannabis when manic.

¹⁴³⁷ Marangell ea (2008) gave open-label VNS for 40 weeks to 9 DSM-IV-TR outpatients with treatment-resistant rapid-cycling bipolar disorder patients and noted a mean improvement of 38.1% over the 12-month study period. Common problems were voice alteration (during stimulation) and hoarseness.

¹⁴³⁸ Ruhé ea (2006) conducted a systematic review of major depression with insufficient response to standard doses of SSRIs and found an increase in dose before 4 weeks to be ineffective and later increases to be of equivocal value.

of a monoamine reuptake inhibitor (MARI) and an MAOI may cause hypotension or the serotonin syndrome¹⁴³⁹. Clomipramine should never be combined with an SSRI or MAOI¹⁴⁴⁰. A TCA can be combined with thyroid hormone, e.g. 25 µg of T3. Potentially, T3 may exacerbate anxiety, cause weight loss, and induce cardiac arrhythmias. T3 appears to be more effective than T4 as an augmenting agent in unipolar depression.(Joffe & Singer, 1990) T3 may be more effective in women than in men.(Coryell & Geddes, 2008, p. 487) Intrathecal TSH has improved some cases of resistant depression. After an initial 2-week drug-free period, a single IV dose of ketamine (NMDA antagonist) led to an antidepressant effect within 2 hours in treatment-resistant major depression.(Zarate ea, 2006) Lithium and an SSRI or TCA is another possibility. Olanzapine added to an SSRI may speed up response rather than improve the longer term effectiveness of an SSRI on its own.(Coryell & Geddes, 2008, p. 487) Venlafaxine has been claimed to produce good results in some refractory depressions as has a combination of mirtazepine and an SSRI.¹⁴⁴¹ Indeed, Blier ea (2010) reported doubling of response rates over fluoxetine monotherapy when the latter was combined with mirtazapine and with mirtazapine-venlafaxine or mirtazapine-bupropion combinations, all combinations being well tolerated. All medications were given from the start of treatment in this study. Testosterone gel has been shown in a preliminary study to alleviate refractory depression in men with low testosterone levels when added to an existing antidepressant regimen.(Pope ea, 2003; see also Shores ea, 2004) Amphetamines are used in the USA in some cases. Modafinil (Provigil) may be efficacious as adjunctive therapy in bipolar depression.(Menza ea, 2000; Frye ea, 2007) ECT should not be seen as a treatment of last resort, an attitude that may lead to excessive delay in its use. Sometimes a second course of ECT works where the first did not, possibly because the illness has moved to a different stage. If an antidepressant does not work before ECT it is unlikely to offer prophylaxis after ECT – consider a different antidepressant or augmentation. Pharmacological treatments need to be continued concomitantly with ECT.(Kennedy & McDonough, 2003) Pindolol¹⁴⁴² is a beta-blocker with 5-HT_{1A} (autoreceptor) blocking properties. Blocking 5-HT_{1A} autoreceptors on cell bodies frees these cells from feedback control and increases serotonin release from nerve terminals. However, beta-blockade could also be the main mechanism whereby pindolol augments SSRIs.(Svensson & Mathé, 2002) It has been used in combination with SSRIs with some useful effect on depression but may promote irritability. Adrenal steroid suppression with metyrapone¹⁴⁴³ may help major depressives already on antidepressants to respond.(Jahn ea, 2004) Metyrapone can cause light-headedness, headache, nausea and fatigue. Alpha-2 blockade using an agent such as idazoxan has also been tried. Many antidepressants, including TCAs and MAOIs, down regulate beta-receptors or the associated NA-sensitive adenylate cyclase. There is a little evidence favouring this approach.

Vagal nerve stimulation (VNS) therapy for refractory depression is undergoing early trials. There is evidence from open trials for its efficacy,(Rush ea, 2000; Corcoran ea, 2006) which may increase over time¹⁴⁴⁴, but more knowledge is required about side-effects, e.g. cough and vocal cord palsy from surgery. Most refractory depressions will eventually remit, although it may take a long time to happen.

Physical treatments in physically ill depressives

Doses should be started low and increased slowly. MAOIs are best avoided because of potential drug interactions. TCAs have analgesic effects. Poor renal or hepatic function, low plasma protein concentration, and drug interactions alter antidepressant metabolism. As a general but not absolute rule, avoid ECT in the following situations: recent cerebral bleed, raised intracranial pressure, brain tumour or other large intracranial masses, recent ventricular dysrhythmia, sickle cell disease, large anaesthetic risk, aortic or

¹⁴³⁹ **Serotonin syndrome:** delirium, agitation, restlessness, diarrhoea, hyperthermia, unstable vital signs, ataxia, dysarthria, rigidity, myoclonus, hyperreflexia. Drug causes include agents that increase formation (L-tryptophan), release (Fenfluramine, phentermine, amphetamine, cocaine, L-dopa, LSD, pethidine, mirtazapine), reduce uptake (SSRIs, SNRIs, opioids, and bromocriptine), act as agonists to (buspirone and triptans like sumatriptan), increase the sensitivity of postsynaptic receptors for (lithium), and decrease metabolism of (MAOIs including the antibiotic linezolid) serotonin.(Ahuja & Cole, 2009)

¹⁴⁴⁰ That being said, some experts have used clomipramine plus an SSRI for refractory OCD.

¹⁴⁴¹ Patients should be monitored for the serotonin syndrome.

¹⁴⁴² Evidence for augmentation with pindolol or valproate was described as poor (Joubert, 2007) but doses of pindolol may have been too low in early studies; there is evidence that pindolol may hasten response rather than increase rates of response.(Coryell & Geddes, 2008, p. 487)

¹⁴⁴³ Inhibits P450_{11β} that allows 11β-hydroxylation, the final step in adrenal cortisol production.

¹⁴⁴⁴ Median time to response of 9 months in Schlaepfer ea.(2008)

cerebral aneurysm, and recent CVA. TCAs are best avoided under the following circumstances: recent MI, heart block, congestive cardiac failure (CCF, danger of hypotension), closed angle glaucoma, enlarged prostate, renal failure, epilepsy (see above – do not use maprotiline!), liver failure (lower doses if necessary in mild cases, avoid if severe), cimetidine (raises TCA levels), constipation, agranulocytosis, and porphyria. MAOIs are best avoided in the presence of CCF, hypertension (enhancement of antihypertensives), carbamazepine, CVA, liver failure (use reduced dosage), phaeochromocytoma (do not even use moclobemide), and hyperthyroidism (avoid tranylcypromine and moclobemide). Lithium may cause problems if used in certain scenarios: CCF (excretion reduced by ACE inhibitors and diuretics), hypertension (diuretics reduce excretion and methyl dopa increases chances of neurotoxicity), renal failure (toxicity), Parkinson's disease (CNS toxicity if combined with sumatriptane), severe diarrhoea, Addison's disease, and hypothyroidism. SSRIs may be problematic in epilepsy (levels increased by phenytoin and carbamazepine), GIT disorders (nausea), and fluoxetine plus selegiline¹⁴⁴⁵ in Parkinson's disease may cause a confusional state. Amphetamines are sometimes used in the USA. (Lingam ea, 1988)

Prognosis

'Depression and diabetes are alike in burden, and both have chronic courses marked by periods without symptoms and by occasional emergencies'. (Andrews, 2001)

'The long-term outcome of depression still shows high recurrence rates and does not appear to have changed in the last 20 years.' (Kennedy ea, 2003)

Finding in studies of prognosis may depend on factors such as what is measured (e.g. readmission or relapse), who is studied (e.g. confined to patients with multiple admissions), and the degree of effort made to validate diagnoses. (Kessing ea, 2004) Contrary to earlier opinion, Angst (1992) pointed out that most depression is recurrent, there being a 78%¹⁴⁴⁶ recurrence rate after 10 years in one study. Major depression has a high rate of recurrence, especially in the first months following recovery. According to Angst (1990) one and three episodes of depression carry a 50% and 90% chance of recurrence. Similarly, Delgado and Gelenberg (1996) put the recurrence rate for major depression after one or two episodes at 50% and 80-90% respectively. The risk of recurrence does not differ for depression whether it is related to bereavement or not (Karam, 1994) and the validity of the bereavement exclusion for the diagnosis of major depression in DSM-IV has been questioned because of the similarity between depression caused either by bereavement or other stresses. (Kendler ea, 2008b) A multi-centre prospective (6 years) follow-up in Japan of an inception cohort (N = 95) of previously untreated unipolar major depressives found that less than half the patients remained virtually without symptoms for 2 or more years post-recovery, and that residual symptoms at recovery predicted earlier recurrence. (Kanai ea, 2003; see also Nierenberg ea, 2010) A Cambridge (UK) follow-up of mainly severe recurrent depressives found that 92% recovered during follow-up, two-thirds then suffering a recurrence, 17% suffered from an episode of depression of at least 2 years duration, and the more severe the illness the poorer was the outcome. (Kennedy ea, 2003) An American 20-year follow-up of major depression (Coryell ea, 2009b) found that persistence of symptoms does not change as patients age and that earlier age at onset seemed to predict greater morbidity. Prophylactic medication reduces the risk of recurrence by more than half. There seems to be a trend toward increasing severity with subsequent episodes that may not be affected by prophylactic measures. All antidepressants are probably effective prophylactics, although not all have been rigorously tested for this property. Do antidepressants lose their efficacy over time? According to Demyttenaer, (1999) this can affect up to one in three patients. Should they do so we must consider non-compliance, loss of placebo effect, pharmacological tolerance, increased disease severity, change in disease pathogenesis, accumulation of a detrimental metabolite, unrecognised rapid cycling, and prophylactic inefficiency. In a NIMH follow up of major depression over 5 years, 20% failed to recover from the index episode, developing a chronic course instead. (Keller ea, 1992) Anxiety in depressed people is associated with a poorer response to antidepressant treatment. (Fava ea, 2008) However, in a population survey, Mykletun ea (2009) found a mortality hazard ratio of 1.52 for case-level depression (for smoking it is 1.59) but co-morbid anxiety lowered the mortality risk.

East Baltimore prospective study of major depression (MD) (Eaton ea, 2008)

¹⁴⁴⁵ Selegiline is a selective, irreversible MAO-B inhibitor. Dietary precautions are required for higher (9 or more mg) but not lower (6 mg) doses of selegiline.

¹⁴⁴⁶ Figures vary.

23-year follow-up (13 years minimum), population-based
 3481 household residents in 1981, including 92 first episode MD
 Greater likelihood of onset of MD, longer episodes, and (slight) increase in recurrences in females
 Sex did not predict recovery
 Median episode length = 12 weeks
 15% of the 92 had no year without a recurrence

Married women with major depression may have a particularly good outlook if they rate the marital relationship as good. A long delay before receiving treatment for major depression and high premorbid neuroticism predicted symptom persistence in a study by Scott *et al.* (1992) Initial diagnosis of personality disorder in unipolar depression augurs poorly for very long term psychiatric and social outcome. (Newton-Howes *et al.*, 2006) It also delays recovery in major depression (Gorwood *et al.*, 2010) and may reduce the efficacy of interpersonal psychotherapy. (Joyce *et al.*, 2007).

Psychotic depression is associated with a lifetime illness of greater severity than non-psychotic major depression. Also, not all of their episodes are necessarily psychotic. Mood-incongruent psychotic features in mania and depression predict a poorer outlook¹⁴⁴⁷, as do residual symptoms after treatment of major depression. There may be genetic overlap of bipolar affective disorder with schizophrenia. (Goes *et al.*, 2007) Some authors regard the prognosis for depression in the elderly as being good if only it were treated aggressively enough, while others view it as being relatively poor. According to Chew-Graham *et al.* (2004) it has not changed since Millard's (1983) article, i.e. a third improve, a third remain unchanged, and a third disimprove. There is even some evidence for a better prognosis relative to younger depressives. Early onset, recurrence, and poor premorbid personality functioning have been described as poor prognostic factors in the depressed aged. Whatever treatment works, it should be maintained to prevent relapse: Chew-Graham *et al.* (2004) suggest that we adopt a chronic disease model for the elderly depressed. The results of some studies of prognosis in the depressed elderly are summarised in the table.

Prognosis in the elderly depressed

Year	Results	Comments
1993	47% improved at 15 months 71 % better at 4 years	Treatment (drugs and ECT) resistant cases
1993	Less likely to be recovered at one year if spouse or adult child had psychiatric symptoms (especially depression, anxiety, somatisation), if carer finds role difficult or is in poor physical health	Elderly admissions, RDC major depression
1997	Cognitive impairment = poor prognosis	Chronically hospitalised patients
1997	60% of elderly hospitalised patients remained well or had treatable relapses/recurrences; 15-20% of developed chronic symptoms; worse prognosis in community (? low rates of treatment)	Meta-analysis
1997	Persistent anxiety in remitted depression is associated with earlier relapse	
2002	Cognitive decline more common if depressed, esp. if persistent rather than episodic	Large sample from Nantes; cognitive decline = drop of at least 3 points on MMSE* at 4-year follow-up
2005	Review of 24 publications	Episodes remit but relapse rate higher than in middle life because of medical co-morbidity and recurrent depression from earlier life
2006	85 or older in Leiden – depression is common and persistent	No formal diagnosis of depression; low MMSE score led to exclusion (< 19)

*MMSE, Mini-Mental State Examination

Up to 60% of BP cases are unable to return to premorbid levels of social and vocational functioning. (MacQueen *et al.*, 2001) Severe anxiety during BP mood episodes seems to mark an illness of significantly greater long-term depressive morbidity. (Coryell *et al.*, 2009c) Over 80% of patients who have a

¹⁴⁴⁷ But do not obviate the diagnosis.

manic episode will have one or more recurrences. Patients who switch from one pole of BP disorder to another without an intervening normothymic interval may have a poorer prognosis than those who experience euthymia between episodes. (Maj et al, 2002) An outcome study of children with a prepubertal or early adolescent-onset BP disorder found that 65% recovered after a mean of 36 weeks of treatment, and 55% relapsed at an average of 38.6 weeks following recovery. (Geller et al, 2002) In adults with a diagnosis of childhood BP I disorder the 44.4% frequency of manic episodes reported by Geller et al (2008) supports continuity between child and adult BP I disorder. Geller et al (2008) also found similar rates of substance use disorder in people who developed BP I in either childhood or adulthood.

Common reasons for recurrences in bipolar cases are inadequate management (e.g. too low a lithium serum level) and non-compliance. Reasons for non-compliance in patients with affective disorders include side-effects¹⁴⁴⁸ like memory problems, weight gain, co-ordination difficulties, tremor, polydipsia; a wish to avoid stigma; symbolism between prophylactic regimen and having a chronic illness; attribution of all sorrow to the world or the self; reduced creativity¹⁴⁴⁹; not wanting treatment when feeling well; medication being seen as a sign of moral cowardice or weakness; lack of insight¹⁴⁵⁰; advice from third parties; and storing tablets for an intended overdose. Pseudo-compliance is not rare, e.g. the patient who takes their lithium for a few days before each phlebotomy. Non-compliance with lithium, the commonest reason for relapse in bipolars, has been estimated to affect 18-53% of cases. The patient should have his medication and the reasons for it explained. Written information is helpful, as are simple regimens. The patient should be encouraged to state frankly if the medication is later abandoned.

Affective disorder patients may be at particular risk of developing tardive dyskinesia.

The average failure rate for lithium prophylaxis is 33%, failure being defined as an episode needing admission or the addition of further drug treatments. Only one-fifth of patients who are suitable for lithium can expect to have no recurrences.

Depression in general practice¹⁴⁵¹ (GP)

GPs, at least in the UK, appear to increasingly use symptoms rather than diagnostic labels to categorise illnesses such as depression. (Rait et al, 2009) GPs see more (typical, younger and milder) cases of depression than psychiatrists, they initially miss the diagnosis relatively more often than psychiatrists (but may pick it up eventually: Kessler et al, 2002; Mitchell et al, 2009), they may diagnose depression when it is not there (Mitchell et al, 2009), they may be relatively reluctant to search for depression in the elderly, (Chew-Graham et al, 2004) and they are less likely to give adequate doses of antidepressant drugs (apart from SSRIs and perhaps lofepramine) than are psychiatrists. (e.g. Blacker & Clare, 1988; Maddox et al, 1994) However, even psychiatrists are not immune from inadequate dosing. (Macpherson & Robson, 1994) According to one meta-analysis, GPs might improve their diagnostic yield if they re-assessed cases over a longer time period rather than relying on a once-off examination. (Mitchell, 2009) GPs also see more mixed pictures of anxiety-depression. Also, one meta-analysis suggested that low doses TCAs (75-100 mg/day) are superior to placebo and that higher doses confer no improvement in efficacy but do increase the dropout rate from side effects. (Furukana et al, 2002) MacGillivray et al, (2003) in their systematic review and meta-analysis, found that antidepressant efficacy studies in GP had significant methodological shortcomings. However, a Cochrane systematic review (Arroll et al, 2009) suggests that TCAs and SSRIs are effective treatments for depression in primary care settings. GPs should consider referral to a psychiatric colleague if the diagnosis is uncertain, to have questions concerning management clarified, if treatment efforts fail, if specialist supervision of treatment is required or if non-drug therapies are being considered (assuming the resources are in place). (see HSE & ICGP, 2006) Further reasons include those situations where in-patient investigation is needed, the disorder is severe, the patient is violent (with adequate forewarning by the GP) or suicidal, there is self-neglect, or the patient is psychotic. Depression associated with another problem, such as alcohol abuse schizophrenia or an eating disorder should also be considered for referral. Referral is

¹⁴⁴⁸ Adverse effects are only one factor in non-compliance. Greater compliance with SSRIs relative to TCAs has not been a universal finding. (Lader, 2007)

¹⁴⁴⁹ The relationship between mental illness and genius is controversial. (Keynes, 1995; Schildkraut & Otero, 1996; Andreasen, 2001, pp. 200-1; Pandarakalam, 2005) Whilst a Swedish prospective study (MacCabe et al, 2010) found an almost fourfold increased risk among adolescents doing well at school for later bipolar disorder it also found a modest association between those with the lowest school grades and later bipolar disorder.

¹⁴⁵⁰ E.g. psychotic depression or severe mania.

¹⁴⁵¹ King et al (2008) suggest that depression and anxiety disorders may be more common in GP in some European countries (UK and Spain) than in others (Slovenia, The Netherlands).

also indicated where the relatives want it, where the GP's advice is not accepted or believed, or when the GP needs support because of, for example, an angry patient or family. Simply asking if the patient (a) often felt bothered by feeling down/depressed/hopeless or (b) often been bothered by little interest or pleasure in doing things (both [a] and [b] during the past month) could detect most cases of depression in GP in one study.(Arroll ea, 2003)

Thompson ea (2000), in the Hampshire Depression Project, found that educating UK GPs in depression detection and treatment (using clinical practice guidelines) failed to improve recognition or outcome. An observational study of risk factors for depression in GP (Bottomley ea, 2010) suggests that it may be more productive to try and tackle proximal than distal risk factors because the latter may be more entrenched.

Carer stress

Stress among carers looking after BP disorder patients arises from the patient's symptoms and role dysfunction. It also comes from the effects of the disorder on the carer's occupation and leisure time. Perceived stress may be greater if the relative feels that the patient should be able to control his illness or symptoms or if the relative feels helpless in controlling these phenomena. A full understanding of the seriousness and prognosis of the disorder may also increase stress.(Perlick ea, 1999) Depression in carers may develop follow erosion of coping powers secondary to perceived stigma.(Perlick ea, 2007)

Suicide and Parasuicide¹⁴⁵²

Attempted suicide (AS)

The term AS is associated with Stengel. Alternative terms are parasuicide (Kreitman), deliberate¹⁴⁵³ self-harm (Morgan) and act of self-harm (Bateman, who avoids implying intent or motive). AS is about ten times more common than completed suicide¹⁴⁵⁴. Factors reported to increase the likelihood of AS are shown in the table. In the real world, any psychiatric disorder may be accompanied by suicidal behaviour or self-harm. The complex role of unemployment has been discussed by O'Shea.(2000c; see also Gavin ea, 2010) Rates of parasuicide rose in most Western countries in the 1960s. Pathways to CS may differ significantly for different ethnic groups living in the same country.(Clarke ea, 2008) People who present to hospital emergency departments with a specific and spontaneous complaint of suicidal ideation with no accompanying act of self harm are more likely to have a personality disorder or to be alcohol dependent than to have a depressive illness according to Hawley ea.(1991) Indeed, individuals presenting *with* self-harm often have histories of dependent, harmful or hazardous drinking that may easily be missed unless careful inquiry is made, including the use of an alcohol screening instrument such as *AUDIT*.(Holdsworth ea, 2010) 6.5% of over 75,000 people (aged 16-64 years) discharged from psychiatric inpatient care in England were admitted at least once in the following year (Gunnell ea, 2008); risk of self harm was associated with recent admission for self harm, female sex, being young, depression, personality disorder, substance abuse, and brief admission. Most cases of AS probably do not present to hospital.(Hawton ea, 2002)

Canadian survey: people aged 15 years and older (Robertson Blackmore ea, 2008)

0.6% endorsed a 12-month suicidal act

Risk factors - female sex, separated or divorced marital status, being unemployed, having a chronic physical health condition, and experiencing major depression during the same 12 months as the act

Scottish survey: 15-16 year old pupils (O'Connor ea, 2009)

13.8% reported self-harm (girls: boys = 3.4:1) and 71% of these self-harmed in past year

Risk factors in both genders – smoking¹⁴⁵⁵, bullying, sexual orientation concerns, self-harm by family, and anxiety

¹⁴⁵² See O'Shea ea (2000) and Hawton and van Heeringen (2009) for reviews. Walsh (2008) reminds us that suicides once had their remains hung from the Five Lamps in Ballybough, Dublin!

¹⁴⁵³ 'Deliberate' is often dropped by authors who stress the heterogeneous nature of this group. Also, some patients may perceive it as pejorative.

¹⁴⁵⁴ Non-fatal suicidal behaviours in adolescence and young adulthood may be more common than suggested by cross-sectional studies or parental reports.(Brezo ea, 2007)

¹⁴⁵⁵ Boden ea (2010) suggest that cigarette smoking may even cause depression.

Risk factors in girls: drug use, physical abuse, serious boy/girlfriend problems, self-harm by friends, and low levels of optimism

Germany/Midwestern USA: school going adolescents (mean age 14.8 years, range 14-17 years)(Plener et al., 2009)

25.6% endorsed at least one act of non-suicidal self-injury, 9.5% of these having hurt themselves more than 4 times; 6.5% had a history of AS; adolescents in both geographical areas were similar in terms of self-injury and suicidal behaviours

Having a friend who committed suicide increases the likelihood of suicidal ideation in the self.(Hawton et al., 2002) A cross-sectional, 17-country study (Nock et al., 2008) found that 60% of changes from ideation to plan and attempt occurred within a year of having the idea, and consistent risk factors included female sex, relative youth, low education level, single marital status, and having a mental disorder; the strongest nosological risk factors were mood disorders in wealthy countries and impulse control disorders in low/middle income nations. In the opinion of Simon and Savarino (2007) suicide attempts are not caused by antidepressants but reflect referral patterns.

Factors affecting 'attempted suicide' (AS) rates¹⁴⁵⁶

The reader will notice apparently contradictory reports, e.g. relating to Christmas Day. Also, the direction of causation may be difficult to disentangle. *Not everyone agrees that mental disorder is always present and AS is not unique to any psychiatric disorder. Chiles & Strosahl (2005, p. 260) suggest that suicidality is associated with an underlying psychiatric disorder in 50% of cases.*

Of self-harm 'cases' presenting to Irish emergency departments in 2007 17% were repeat visits. 17,000 deliberate self-harm (DSH) presentations (9,218 individuals) were made to Irish A & E departments in 2008; the rate increased from 188 to 200/100,000 from 2007 to 2008, representing rises of 11% and 4% in males and females; and the peak rates for males and females were in the age groups 20-24 and 15-19 years respectively. 11,966 people with DSH presented to Irish hospitals in 2009.

Increasing

Adolescence – much serious mental illness starts at this age and suicide is the third leading cause of death in 15-19 year old in the USA; 17% of high US school students consider suicide and 8.4% attempt suicide at least once during the past year; parents are often unaware that anything is wrong and only a minority give a warning;(Friedman, 2006) impulsive aggression (highly heritable) may be a common end result of many factors (suicide seen as a solution, poor cognitive flexibility and problem solving abilities, difficulty inhibiting inappropriate responses); suicidal behaviour may be transmitted in families independent of psychiatric disorders (a genetic basis is supported by adoption studies); childhood abuse/neglect may compound genetic vulnerability (Brent & Mann, 2006); and local poverty is associated with suicidal thoughts and attempts.(Dupéré ea, 2009) Emotional unavailability of mother in early life is another predictive factor.(Weich ea, 2009)

Alcohol/substance abuse/misuse – smoking tobacco¹⁴⁵⁷; high scores on AUDIT common in psychiatric admissions of both sexes and alcohol misuse strongly associated with suicidality (McCloud ea, 2004); in an Irish context alcohol consumption was evident in 41% of episodes of deliberate self-harm (48% males, 38% females)(IMO Position Paper, 2008, p. 5)

Anxiety - Fairweather ea (2006) found that AS differed from suicide ideation, not on the levels of depression and anxiety, but by unemployment, poor physical health, and relationship problems.

Availability, e.g. paracetamol¹⁴⁵⁸; co-proxamol¹⁴⁵⁹ (paracetamol + dextropropoxyphene) accounted for 5% of all suicides in England & Wales during 1997-99 – the odds of dying after co-proxamol OD was 2.3 that for TCAs and 28.1 that for paracetamol.(Hawton ea, 2003a)

Bipolar I disorder – risk factors for lifetime AS among French patients admitted for mania were multiple admissions, depressive or mixed polarity in first episode, stressful life events before illness onset, younger age at onset, no well intervals, female sex, more prior episodes, and cyclothymic temperament.(Azorin ea,

¹⁴⁵⁶ From the literature.

¹⁴⁵⁷ Perhaps by causing 5-HT deficiency (Malone ea, 2003) or by background factors and life circumstances common to smoking and suicidal behaviour.(Boden ea, 2008)

¹⁴⁵⁸ **Paracetamol:** A common reason for liver transplantation; the specific antidote, intravenous N-acetyl-cysteine, has to be given within 10-12 hours to achieve maximum effect; if this is not available one can use oral methionine. A toxic breakdown product of paracetamol is scavenged by glutathione; when the body runs out of glutathione (common in alcoholics) the paracetamol metabolite attaches itself to liver cells and kills them. From 2009 in Ireland paracetamol must be supplied by a pharmacist.

¹⁴⁵⁹Withdrawal of co-proxamol in England Wales (2007) appears to have led to less deaths from this agent and no substitution with other analgesics for the purposes of suicide.(Hawton ea, 2009)

2009) Fiedorowicz ea (2009) found that polarity did not predict future suicidal behaviour whereas age, helplessness, and active substance abuse did. In this 25-year prospective NIMH study, 909 participants met criteria for major depression or bipolar disorder. 4,204 mood cycles were recorded.

Bipolar II disorder – in a review and meta-analysis, Novick ea (2010) found that while BP II disorder was associated with significantly increased AS rate there was no significant risk between this an AS rate in BP I disorder

Birth length - short male birth length increases chances of violent suicide attempt as adult¹⁴⁶⁰

Bullied and bullies in Finnish schools had increased suicidal ideation; being bullied in New South Wales correlated with psychosomatic complaints and poor mental health; bullied Irish adolescents was associated with depression and suicidal ideation.(Mills ea, 2004)

Certain dates/times of year, e.g. St Valentine¹⁴⁶¹, Christmas Day; female admissions increased during 2-4 January in Edinburgh. Female admissions in Edinburgh increased during summer (others report spring/early summer excess).

Child neglect or maltreatment/maladaptive parenting¹⁴⁶²

Child sexual abuse – **American data suggests a later connection with AS, especially in early adolescence, mediated mostly, but not completely, by psychopathology. Melhem ea (2007) found such abuse to be one factor (with mood disorder, impulsive aggression, parental AS, and self-reported depression) preceding early-onset suicidal behaviour in offspring of mood-disordered parents. Sexual abuse as a child in Quebec, especially if abused by immediate family.(Brezo ea, 2008¹⁴⁶³). The 2000 British National Survey of Psychiatric Morbidity (Bebbington ea, 2009) found that sexual abuse is a significant antecedent of suicidal behaviour, more so for females.**

Childhood behaviours contradicting typical gender norms¹⁴⁶⁴ has predicted suicidal ideation by 15 or suicidal acts by 18

City life, e.g. Limerick, and possibly other urban Irish areas.(Corcoran ea, 2003; National Suicide Research Foundation, 2002)

Comorbid psychiatric disease in depressed women in the community (McHolm ea, 2003)

Criminal record

Depression: For one reason or another, those who commit AS fail to tolerate similar levels of depression suffered by those who do not harm themselves deliberately.(Malone ea, 1995) Depression and hopelessness and important ingredients in adolescent self-harm (Webb, 2002) and hopelessness in adolescent AS is often disproportionate to other features of depression.(Mann ea, 1999) DSM-IV major depression risk factors for AS incl. severity of depression, lack of a partner, previous AS, and time spent depressed.(Sokero ea, 2005) Hopelessness and poor social integration in elderly depressives.(Dennis ea, 2005) Severity of depression during current episode.(Vuorilehto ea, 2006) Unipolar depression plus gray matter hyperintensities on MRI may increase likelihood of AS.(Ahearn ea, 2001) AS in bipolar disorder is associated with atypical depression, family history of suicide, depression at index episode, and cluster B personality disorder.(Sánchez-Gistau ea, 2009)

¹⁴⁶⁰ *J Epidemiol Community Health* 2008;62:168-73.

¹⁴⁶¹ February 14.

¹⁴⁶² Perhaps via severe interpersonal problems in adolescence.

¹⁴⁶³ In this study externalising behaviour was also associated with AS.

¹⁴⁶⁴ E.g. aggressive girl, dependent boy.

Dissocial personality disorder/impulsive aggressivity/conduct problems/identity problems (e.g. Brezo ea, 2006)

Early discharge against medical advice¹⁴⁶⁵ and **first year after discharge**

Female sex – However, males 55 years and older showed an increase in AS in Oxford during 1990-2000 and there are other findings to suggest that the disparity between the sexes may be narrowing in Manchester, UK

Hallucinations in first-episode psychosis

Homelessness and housing problems

IQ. Batty ea (2010) looked at how early adulthood IQ influenced subsequent AS in Swedish males with and without psychosis and found that men without psychosis with low IQ scores were at increased risk (although the authors state that their research may have ‘slightly overestimated’ any effect) but there was no evident association among men with psychosis

Low cholesterol. Is cholesterol a CNS marker for serotonin? Also, excess alcohol may increase high-density lipoprotein levels and hence the amount of cholesterol transported peripherally, causing a lowering of the serum cholesterol. Could interleukin-2 be affected? Statins may induce depression. Not all studies find a connection with low cholesterol levels, e.g. Almeida-Montes ea.(2000) Low lipid concentrations have correlated with self-injury and borderline features in patients with dissociative disorder.(Agargun ea, 2004) Dietary cholesterol supplementation reduces aggression in sufferers from Smith-Lemli-Opitz syndrome.(Lalovic ea, 2004) In a study by Garland ea, (2007) low plasma essential fatty acids plus low cholesterol concentrations were associated with self-harm as well as impulsivity and affect, but not related to platelet serotonergic measures. The same group (Hallahan ea, 2007) reported reduced indices of self harm in repeated self-harmers given long-chain omega-3 essential fatty acids.

Low self-esteem

Low socio-economic status (Taylor ea, 2004)

Menstrual cycle (late luteal and follicular phases¹⁴⁶⁶) and **premenstrual syndrome** (Saunders & Hawton, 2006)

Panic disorder¹⁴⁶⁷

Parental concern. Parental concern may be more accurate than clinician risk assessment in predicting repetition of self-harm.(Cassidy ea, 2009)

Past psychiatric treatment.(Vuoriletho ea, 2006)

Personality disorder.(Vuoriletho ea, 2006) Borderline personality disorder, especially if they show aggressiveness.(Keilp ea, 2006)

Prefrontal dysfunction e.g. impaired visuospatial conceptualization, spatial working memory, inhibition, and visual attention.(Raust ea, 2007)

Previous AS (in self or parents or friends)

Relationship problems (e.g. Sinclair & Green, 2005)

Sexual identity problems/gays/lesbians/bisexuals (Warner ea, 2004)

SSRIs (strongly disputed by, e.g. Gibbons ea, 2007b) Emergence of suicidal ideation during citalopram treatment may be associated with genetic markers within genes encoding ionotropic glutamate receptors.(Laje ea, 2007) Predictors of self-harm such as a history of self-harm suicidal ideation, family conflict, and drug/alcohol abuse may be more important than being on SSRIs.(Brent ea, 2009¹⁴⁶⁸)

Teenage mothers (e.g. Ekéus ea, 2006)

¹⁴⁶⁵ AMA – 8% in UK in 1991 increasing to 17% in 1997 in one cohort study.

¹⁴⁶⁶ Low oestrogen levels.

¹⁴⁶⁷ Comorbid depression or alcohol abuse may be more important than panic disorder *per se*.(Vickers & McNally, 2004)

¹⁴⁶⁸ This was a study of depressed adolescents who did not respond to one SSRI. Patients were given another SSRI or venlafaxine, with/without CBT. Episodes of self-harm, when they occurred, occurred in the first few weeks of treatment. These authors found higher risk for venlafaxine (possibly given for ‘deeper depression’) and benzodiazepines (possible disinhibition). This requires further study. It must be remembered that analysis of many variables is likely to ‘throw up’ results that may or may not have clinical implications as distinct from media interest.

Unemployment - *Not surprisingly, job insecurity is associated with feeling depressed* (Meltzer ea, 2010)

Withdrawal of antidepressants - Discontinuation of SSRI or tricyclic antidepressants was associated with a five-fold increase in suicidal behaviour in unipolar depressives.(Yerevanian ea, 2004)

Possibly decreasing

Antidepressants in adults (Stone ea, 2009)

Antiepileptic drugs in bipolar disorder (Gibbons ea, 2009)

Caribbean origin in UK for psychotic older people, but such protection is absent for psychotic younger persons (McKenzie ea, 2003)

Christmas Day Female admissions in Edinburgh decreased during winter, especially during Christmas Day; self-poisoning less likely on Christmas Day

Early detection/treatment of first episode schizophrenia (Melle ea, 2006)

'Phoning patient a month after discharge from emergency department after deliberate self poisoning.(Vaiva ea, 2006)

School holidays (Hawton ea, 2003b)

Time-limited CBT (Slee ea, 2008)

Neutral

No monthly/seasonal pattern for male admissions in Edinburgh

Offering a **crisis support telephone call** did not influence repetition rate

Properly conducted trials in schizophrenia that use placebo (Storosum ea, 2003)

CYP2D6 and CYP2C19 polymorphisms¹⁴⁶⁹ in schizophrenia (Kobylecki ea, 2008)

Psychodynamic and cognitive-behavioural approaches may help in reducing suicide risk. The latter may correct cognitive distortions leading to hopelessness. Establishment of a therapeutic alliance is essential. The therapist should address any underlying fantasies such as the wish to punish oneself or another person, to manipulate, or to put a stop to suffering. Has the patient internalised the capacity to contain psychic stress, does he find solace in keeping suicide as a future possibility should circumstances deteriorate, or does he harbour a wish to die simultaneously with a wish to live? Has he integrated the conflicting (good and bad) parts of his personality? Has he become calm because he is resigned to self-termination or because his depression has lifted or because his girlfriend is returning to him? The therapist must not collude with the patient who is in denial concerning the threat to his life.

Services for self-harm patients are often poorly planned and delivered.(Suominen ea, 2004) These patients are often either seen by trainees in psychiatry or by no psychiatrist at all.(Anonymous, 2010) There is wide variation in terms of disposal and implementation of recommended service structures.(Bennewith ea, 2004) Also, up to 50% of AS cases fail to keep follow-up appointments¹⁴⁷⁰. Follow-up GP appointments for first episode patients may even have adverse effects!(Bennewith ea, 2002) Whilst there is no substitute for an assessment of suicidal risk and the formulation of a care plan,(Edwards, 1995b) one relatively short follow-up of psychosocial intervention found that one needs to intervene in twelve cases to prevent self-poisoning in one person.(Kapur ea, 2002) Also, whilst Hasan and Owens (2003) found that 53% and 26% of 237 patients who later self-poisoned saw their GPs in the previous month and week respectively the patients recounted that their main expectations concerned prescriptions, sick-notes and physical check-ups. Even more interesting, in Ireland only 23% and 8% of CSs during 1997-8 visited their GP and mental health professional respectively within one month of death.(Departments of Public Health, 2001) Emergency department staff may rate more cases as at high risk of repetition than do specialist staff, and high-risk approaches to prediction suffer from the fact that many repeaters are in the lower risk groups.(Kapur ea, 2005)

¹⁴⁶⁹ Such polymorphisms are associated with either drug accumulation or rapid elimination of psychoactive drugs.

¹⁴⁷⁰ In a study of teenage school pupils only 12.6% of those who reported deliberate self-harm in the previous year said that they had been seen at a hospital.(Hawton ea, 2002)

Apart from a past history of AS, repeated AS is associated with past psychiatric history, non-adherence, drug misuse, hopelessness, high suicidal intent, a forensic history, low social status, and being unemployed. Impairment in problem solving is associated with deliberate self-harm. The person attacks him/herself instead of looking at different ways of directly changing the situation, trying to distract him/herself, avoiding or resigning him/herself to difficulties, seeking comfort from others, avoiding being preoccupied with the problem, showing annoyance with those causing the difficulty, or engaging in self-comforting thoughts. Passivity and problem avoidance, with associated lowering of self esteem, may be helped by intensive aimed at improving problem solving ability.(McAuliffe ea, 2006)

Suggestions for a plan to reduce suicidal behaviour (Platt ea, 2005¹⁴⁷¹)

Increase opportunities to:
Develop life skills
Achieve educational qualifications
Get a suitable job
Undertake meaningful activity
Participate in community life
Prevent concentration of vulnerable people in areas with drug/alcohol problems

AS is associated with increased risk of dying from natural causes, accidents, and homicide, not just from suicide.(Hawton ea, 2006)

Completed suicide (CS)

'The patient has a direct relationship with his own death in suicide....the clinician's role and room to influence the outcome is quite often exaggerated'.(Oyebode, 2005)

'There may be controversy about the risk posed by antidepressants, but there is none about the risk associated with untreated depression'.(Friedman & Leon, 2007)

Suicide is the intentional taking of ones own life. It is often ultimately impulsive. Legally, suicide means that a person 'acting alone'¹⁴⁷² did the act that led to death and the act was done in order to cause death, and intent at the time of the act must be shown beyond reasonable doubt. Practicising psychiatrists will already have experienced CS by one or more patients or will do so in the future.(Simon, 2008, p. 1639) According to most of the literature, mental illness,(e.g. Agerbo ea, 2002) *or at least great distress*, is the most common accompaniment. Long term follow up shows that psychiatric patients kill themselves much more often than those who do not have such a history.

Risk of CS following AS (Tidemalm ea, 2008)

Aim – relationship between co-existing psychiatric disorder and CS after AS
Cohort study, 21-31-year follow-up of people (53% female) admitted to hospital for AS 1973-82
A high proportion of CS took place in the first 12 months
Highest short-term risk – bipolar and unipolar affective disorder and schizophrenia
Strongest predictors of CS for whole period –schizophrenia and bipolar and unipolar affective disorder
Other disorders associated with increased risk – other depressive disorder, anxiety disorder, alcohol misuse (in females), substance misuse, and personality disorder

Professionals are obliged to take reasonable care to protect vulnerable charges from harming themselves. It is important to elicit whether suicidal thoughts are present or absent and if present if they are **active** (e.g. has settled personal affairs and stored tablets or bought a rope) or **passive** (e.g. feels like not going on but wouldn't do it because, e.g. of religious or family reasons).

Under the *Irish Suicide Act 1991* complicity in another person's CS or AS is a criminal act that may lead to a long term of imprisonment. The *Suicide Act 1961* in England and Wales removed CS and AS act from the list of crimes but left similar prohibitions regarding complicity in suicide (manslaughter under *British*

¹⁴⁷¹ Addressed to statutory agencies.

¹⁴⁷² Creating problems for cases of suicide pacts and assisted suicides.

Homicide Act 1957). (Cf. suicide pacts later) Suicide *per se* ceased to be a crime in Ireland in 1993 (*Criminal Law [Suicide] Act, 1993*¹⁴⁷³). A study of Irish coroners' attitudes towards CS and its prevention (Farrow *et al.*, 2009), albeit one with a 62% response rate, suggested that they are open to discussing CS and prevention initiatives; about 1 in 4 see CS as a right or a justifiable resolution; and only 23% agree that CS is usually due to mental illness. The Catholic Church now allows full funeral rites and a Christian burial for suicides. Factors reported to increase the likelihood of CS are shown in the table. When reading this list one cannot escape the conclusion that one is reading a potted history of the rapid social changes that characterised the latter part of the twentieth century. This is suggested by increasing suicide rates in Russia¹⁴⁷⁴ where social and economic disintegration are important, as may gun ownership in some areas. (Webster, 2003) Men were often considered more likely to choose highly lethal methods of suicide such as hanging, whereas women were considered more likely to opt for self-poisoning. However, according to the National Parasuicide Registry, (Allen, 2005) in 2001 the percentages of male and female suicides employing drowning or hanging were not dissimilar (see Hawton *et al.*, 2008¹⁴⁷⁵), and the figures for overdoses among parasuicides for 2002 did not support large differences between the sexes. Also, Biddle *et al.* (2008a) found that CS by hanging¹⁴⁷⁶ in England and Wales increased among young women since the mid-1990s and had overtaken self-poisoning as the most common method. Additionally, Värnik *et al.* (2008) examined suicide methods in Europe and hanging was the most common method among males (except in Switzerland where firearms was more common) and, in eight countries only (including Ireland) among females; firearms was the second most frequent method in five countries but it was the least common method in Scotland; and women were more likely to drown themselves than were men (except in Luxembourg).

European female suicide methods (Värnik *et al.*, 2008)

Hanging – most common method in 8 countries

Poisoning with drugs - most common method in 5 countries

Jumping from a height - most common method in 3 countries

According to Brendel *et al.* (2008, p. 733) the most common method of committing suicide for both sexes in the US is by firearm (50-60% of CS). Other common methods are shown in the table.

Most common methods of committing suicide in the US (Brendel *et al.*, 2008)

Men

Guns

Suffocation

Poisoning

Notes

Suffocation includes hanging; poisoning include ingestion of drugs

Method of unsuccessful suicide attempt is a factor in determining prognosis, e.g. in Sweden the risk of completed suicide is higher for such violent methods as hanging, jumping, shooting or drowning than it is for poisoning (Runeson *et al.*, 2010)

Women

Guns

Poisoning

Beautrais (2003) found that the same risk factors¹⁴⁷⁷ were common to CS and 'serious' AS in persons aged less than 25 years; they were discriminated by gender and method used; these findings are hardly surprising since the more serious the attempt the less likely is survival, i.e. 'serious' cases may be true failed suicides. McClure (1994) drew attention to a rising CS rate since the 1970s in England and Wales in males aged 15-

¹⁴⁷³ This allowed coroners to bring in a verdict of suicide for the first time since the act was no longer a crime.

¹⁴⁷⁴ Rates per/100,000: 26.4 in 1990, peak of 42.1 in 1994, 39.7 in 2001; 6 males for 1 female; highest rate in males 45-54 years; highest female rate in over 75s.

¹⁴⁷⁵ 28-year period of non-fatal hanging and strangulation: M:F ratio of almost 3:1; cases had high suicide intent, relatively low use of alcohol associated with the act, and high future CS; and females had more psychiatric care, personality disorder, and previous self-harm.

¹⁴⁷⁶ Hanging accounted for 5.7% and 47.3% of female CS among 15-34 year olds in 1968 and 2005 respectively, self-poisoning falling from 64.1% to 35.5% during the same time period.

¹⁴⁷⁷ Mood disorder, history of psychiatric care, stressful circumstances.

19 years.¹⁴⁷⁸ This was associated with an increase in hanging and poisoning with vehicle exhaust gas. The author suggested that psychosocial factors played a role in this worrying trend. Methods vary around the world and in different cultures and circumstances, e.g. young Indian women living in the UK during the 1970s-80s often chose self-burning. In fact, self-burning is commonest in schizophrenic patients and in Asian women¹⁴⁷⁹. Tobacco growers in parts of Brazil (which has a relatively low reported suicide rate: Mello-Santos *et al.*, 2006) often employ organophosphate pesticides to commit suicide whereas in Sri Lanka oleander seeds are often used for the same purpose. Sartorius (2001) points out that ingestion of phosphor-based insecticides comprise the main method employed by young Chinese women to kill themselves. Eddleston and Phillips (2004) and Li *et al.* (2008) call for efforts to reduce the availability of such highly lethal poisons.

Opinions differ about suicide and cancer, e.g. most likely soon after diagnosis (Bostwick & Rundell, 1999) versus rare or held as a late option. (Fawzy & Greenberg, 1999) However, the risk *is* increased relative to the general population. (Whitlock, 1986)

Risk factors may affect the sexes differently, e.g. a Danish national registry study (Qin *et al.*, 2003) found that males were more likely to kill themselves if they were single, unemployed or had a low income, but living in an urban area might be protective; females were protected by having a young child but experienced increased risk if they had a psychiatric disorder, lived in an urban area, or (to a slight degree) if they had a family history of suicide.

Economic crisis (Gunnell *et al.*, 2009) can have serious mental health consequences and the suicidogenic potential of job loss is not confined to those with a mental disorder. It is important that social welfare supports are sufficient to help people to weather the worst aspects of economic downturns and that society responds supportively to those who lose jobs or are financially compromised.

Intellectual disability *per se* does not seem to increase the risk for CS, and being a male with intellectual disability might reduce the risk somewhat. (Popper *et al.*, 2003, p. 885)

Factors affecting completed suicide (CS) rates¹⁴⁸⁰

Suicide is the endpoint of the convergence of multiple influences acting on a person and on the society he or she lives in. Influences on population-level CS (e.g. stable, cohesive society) as distinct from individual-level CS will often be different (e.g. depression, alcohol¹⁴⁸¹). Genetic/familial transmission of suicidal behaviour appears to be independent of psychiatric disorder transmission. (Brent *et al.*, 1996) Women are diagnosed with depression more often than men but men, in most countries, commit suicide more often than women. Most depressed people do not kill themselves. The same parasuicidal act may have different implication in different people, e.g. trivial acts in the elderly must be taken very seriously. (Harwood, 2008, p. 557) In order to weigh risk for CS, risk factors should be considered in aggregate and viewed within the context of an individual patient's life circumstances and experience. (Kutcher & Chehil, 2007, p. 5)

Correlation and risk factors are not synonymous with causation. The list of risk factors is potentially legion and individual cases will vary in the importance of each factor. TCAs may be lethal in overdose but many authors feel that they prevent many more than they cause. Some TCA deaths may be due to underdosing by the prescriber, non-compliance, or lack of efficacy. Newer drugs might be given to people at risk of overdosing, but older drugs might be given to the severely depressed. One reason for the finding of increased suicidal behaviour in the first weeks after prescribing an antidepressant may be the lack of an immediate lifting of mood. (Jick *et al.*, 2004) However, it may be that most of these people were not taking the antidepressant. (Isacsson *et al.*, 1994) In part because of the significant methodological issues involved, (Simon, 2006) authorities differ on whether antidepressants reduce suicide rates, (Rihmer, 2001;

¹⁴⁷⁸ This must be seen against an overall trend of decreasing suicide rates in England and Wales across the 20th century. (Gunnell, 2005)

¹⁴⁷⁹ Women and girls in Afghanistan may self-immolate in order to escape forced marriage or violence/abuse. (Raj *et al.*, 2008)

¹⁴⁸⁰ From the literature.

¹⁴⁸¹ Power and Brophy (2008) found that CS rates in older adults during 1975-2005 increased and decreased in Ireland and the UK respectively and suggested that increased alcohol intake as well as a higher level of depression might account for this disparity.

van Praag, 2005)¹⁴⁸² and any tendency to increase such rates may differ between children and adolescents (an increase) and adults (no increase). (Olfson ea, 2006) As pointed out by Brent (2007), it is more likely that suicidal behaviour leads to treatment than that treatment causes suicidal behaviour. Problem-solving abilities, tolerance levels for stress, life events, locus of control, and other factors must interact to push someone to suicide, whether or not they are depressed. (Chiles & Strosahl, 2005, p. 65) Also, as stated by Goldney and Beautrais (2007, p. 525) individuals with few reasons for living are more like to choose CS irrespective of mental status. CS in rural south India (Manoranjitham ea, 2010) may be more related to psychosocial stress and social isolation than to psychiatric morbidity. Preventive factors (stigma, fear of death/suicide, cultural/moral/religious issues, family/child responsibilities, pregnancy, support network, survival/coping skills [e.g. non-violent resolution of conflict], access to help, treatment adherence) are more comfortable for a patient to discuss with a mental health professional than are risk factors and thus may be given excess weight by the evaluating clinician. (Simon, 2008, p. 1642) Most studies of CS come from *Europe* (UK and Scandinavia in particular) and *North America*, many studies use *chart diagnoses* of admitted patients, and use of *different diagnostic manuals* renders comparisons problematic. (Bertolote ea, 2003)

Increasing

Abortion

Absence/retirement of significant mental health professional

Access¹⁴⁸³ e.g. farmer and firearms¹⁴⁸⁴, pharmacist/doctors/nurses and tablets/expertise (Agerbo ea, 2007), suitable sites (e.g. The Golden Gate Bridge in San Francisco¹⁴⁸⁵ and, in Seattle, the 'Aurora' [George Washington Memorial] Bridge: Zarkowski, 2008; Blaustein & Fleming, 2009, 2010)

Acceptability of suicide by society/culture¹⁴⁸⁶

Adjustment disorder – interval to CS may be brief (Runeson ea, 1996)

Age¹⁴⁸⁷ – 60% of CSs in 1950 were > 45 years old, falling to 45% in 1998 (McKenzie ea, 2003) Children do not grasp the finality of death.

Agitation/anxiety/akathisia

AIDS - the suicide rate has been put at 60 times the expected rate; risk factors include depression, social isolation, poor social support, stigma, abandonment, substance abuse, co-morbid psychiatric disorders, employment or financial difficulties, unrelieved pain, and delirium. The situation may have improved since the introduction of HAART. (Keiser ea, 2010)

¹⁴⁸² Silverman (2003) reported that the US CS rate fell by only 1.2/100,000 between 1901 (11.8/100,000) and 2000 (10.6/100,000). One cannot confidently therefore conclude that treatments for depression do not work or at least prevent CS because we can't be sure of the statistics, antidepressants relieve depression but the patient may not be taking them (or may take them in excess) at the time of death, and whilst similar findings were reported for TB (no effect of streptomycin or BCG on declining rates) no one would seriously accept such arguments as favouring non-intervention.

¹⁴⁸³ Carrying firearms also increases the risk of being murdered. (Tanne, 2005)

¹⁴⁸⁴ Within the US laws governing access to firearms by people with mental illness/substance abuse are not uniform. (Norris ea, 2006) Legally restricted firearm availability in Austria reduced gun-related suicide and homicide. (Kapusta ea, 2007)

¹⁴⁸⁵ Golden Gate Bridge counselling offer. Putting up barriers (e.g. at Bloor Street Viaduct in Toronto) may merely lead to a shift to a different jumping point. (Sinyor & Levitt, 2010)

¹⁴⁸⁶ Seneca viewed CS as 'the only permitted expression of freedom and autonomy'. (Porter, 2003, p. 4)

¹⁴⁸⁷ The elderly are, in general, relatively physically frail/non-resilient, more often have a number of somatic disorders, have greater access to prescribed medications, are more socially isolated (less likely to be found) and are poorer, and are more likely to be decisive (planned, resolved, lethal) and give less warning, compared to younger people.

Alcohol abuse/dependence¹⁴⁸⁸ - 3-4% in hospital-treated cases commit CS, especially if there is recent loss of a close emotional relationship, or if the patient is male, highly dependent on alcohol, has a long history of drinking, low mood, poor physical health, or recent poor work record. However, Harriss ea (2005) found high suicide intent scores to correlate with 'an absence of alcohol misuse' in males! Alcohol-dependence in sub-Saharan Africa is a major contributor to CS.(Ndosi, 2006) Walsh (2008) estimated that 1 in 6 CS is alcohol-related. An Irish study found 56% of CS tested positive for alcohol, rising to 92% in the under 30s. (IMO Position Paper, 2008, p. 5)

Antidepressants¹⁴⁸⁹ Jick ea (1995) found that only 1 in 7 people who killed themselves while on antidepressant treatment used the drug to kill themselves. Jick ea (2004) found no difference in suicidal behaviour between fluoxetine, paroxetine, amitriptyline, and dothiepin and BZDs and Tauscher-Wisniewski ea (2007) found no association between fluoxetine treatment for adults with various non-major depressive disorder diagnoses. Between 1971-88 TCAs accounted for <4% of all CS in Ireland. A 1995 UK GP study found that antidepressants caused 14% of CS but the risk was similar for a wide variety of agents, including mianserin and trazodone. Most lethal TCAs in overdose are dothiepin¹⁴⁹⁰, amitriptyline, imipramine and trimipramine. Of 4162 drug-related suicides in England & Wales during 1997-9, 22% involved TCAs alone, 18% co-proxamol alone, and 9% paracetamol alone.(Hawton ea, 2003a) During 1998-2000 in England and Wales, 80% of deaths from antidepressants were suicides¹⁴⁹¹.(Cheeta ea, 2004) Gibbons ea (2005) found that whilst new antidepressants and TCAs were associated with lower and higher CS rates the aggregate nature of these US data precluded a direct attribution of cause. Tihihonen ea (2006a) found that being on an antidepressant was associated with a marked risk of AS but also a greatly reduced risk of CS, the authors attributing the latter to the use of SSRIs. However, according to Reseland ea (2006) some countries may have experienced a fall in CS before the rise in antidepressant sales. Dumais ea (2005a) found that impulsive-aggressive personality disorders and alcohol abuse/dependence were independent predictors of CS in men with major depression. Hawton ea (2003c) looked at 300 cases of CS/probable CS in people who presented to hospital after deliberate self-harm (DSH) and found that the risk in the first follow-up year was 0.7%¹⁴⁹², 1.7% after 5 years, 2.4% at 10 years, and 3% at 15 years; males were at greater risk than females and risk for both sexes increased markedly with age at first presentation. Zahl and Hawton (2004) followed up deliberate self-harm (DSH) cases and found that 39% repeated DSH; repeaters were at greater relative risk of CS than single episode cases, especially for females. Cooper ea (2005) conducted a prospective study (1.9.97-31.8.01) of A&E DSH attenders and found a 30-fold increase in suicide risk, the standard mortality ratio (SMR) being much higher for females, and CS was particularly likely in first 6 months after index episode.¹⁴⁹³ Escalating severity of self-poisoning episodes puts people at high risk of CS.(Carter ea, 2005) Juurlink ea (2006) found that the elderly had an increased rate of CS during the first month of therapy if started on SSRIs, but the absolute risk is low¹⁴⁹⁴. Hall (2006) examined the relationship between SSRIs and suicide risk and concluded that any increased risk in adults may not be specific to SSRIs and is very small and outweighed by benefits; the risk-benefit ratio is less certain in children/adolescents (except for fluoxetine), although any risk is small and short-term (Dubicka ea, 2006; Bridge ea, 2007); and one should monitor suicidal ideation¹⁴⁹⁵ during the first few weeks of treatment. Gibbons ea (2006) found that higher prescription rates for SSRIs were associated with lower CS rates in children and adolescents. Gibbons ea (2007b) showed that restricting SSRI use in young people increases suicide rates. The finding of an excess of AS and CS in patients on venlafaxine (Rubino ea, 2007) was distorted by non-adjustment for confounders (Cipriani ea,

¹⁴⁸⁸ See Kølves ea.(2006)

¹⁴⁸⁹ See Edwards (2005) and Simon ea.(2006) The person may use another person's tablets. Possible disinhibition, possibly early return of volition. No evidence that TCAs lead to murder although there are published suggestions of released aggression.

¹⁴⁹⁰ A drug of abuse in Dublin during the 1990s.

¹⁴⁹¹ TCAs accounted for more drug mentions than other antidepressants and SSRIs were safer; SSRI-related deaths were most often (93%) associated with taking other drugs as well, esp. TCAs (24.5%); combination deaths also often associated with a history of drug misuse.

¹⁴⁹² 66 times the general population annual risk of CS.

¹⁴⁹³ Discovery avoidance, not living with close relative, past psychiatric treatment, self-mutilation, alcohol misuse, and physical disorders were independent predictors of future suicide.

¹⁴⁹⁴ Is this idiosyncratic or an artefact of matching a higher risk patient with an SSRI?

¹⁴⁹⁵ Borges ea (2006) conducted a household survey of adults and found 12-month prevalence estimates of suicidal ideation, plans and attempts to be 2.6, 0.7, and 0.4% respectively.

2007) such as diagnosis, comorbidity, dosages, adherence, and depression or suicidal ideation before going on the drug.

Anti-epileptic drugs – European and US reviews suggest that such agents may be associated with a small risk of suicidal thoughts and behaviour (Irish Medicines Board, 2009)

Anti-viral drugs – reports from Japan of delirium, convulsions, encephalitis, and suicide in patients receiving oseltamivir (Tamiflu) may be due to the drug or to a high rate of flu related encephalitis in that country (Maxwell, 2007)

Availability, e.g. household or industrial products; paracetamol caused >150 deaths annually in UK in early 1990s

Birth (of self) during April to June, especially for females (Salib & Cortina-Borja, 2006); low birth weight (Riordan ea, 2006)

Calcium channel blockers (not confirmed in a small sample study)

Cancer – especially of head and neck; prostate cancer in older males (Llorente ea, 2005¹⁴⁹⁶)

Certain days/dates, e.g. Mondays, start of a month, New Year's Day

Cholesterol lowering drugs (controversial - possible reduced central 5-HT density or missed alcohol abuse)

Coal gas

Command hallucinations

Cosmetic breast augmentation (Sarwer ea, 2007)

Cerebrovascular accident (especially younger people and women in a Danish study)

Divorce (may have different effects in different countries)

Early stages of bipolar disorder (BP) – or alcohol abuse and deteriorating function in BP (Dutta ea, 2007¹⁴⁹⁷)

Economic depression/excess borrowing (e.g. Wall Street Crash in USA or South Korea and Japan in the late 1990s or charcoal burning¹⁴⁹⁸ in post-transition Hong Kong)(e.g. Chan ea, 2005); social fragmentation may be more important than poverty (Whitely ea, 1999); Japanese middle-aged male CS may be a show of personal responsibility and remorse (*inseki-jisatsu*- responsibility-driven suicide) for economic problems (Takei & Nakamura, 2004); in Australia, male CS rates increased with markers of economic adversity (opposite effect in females) and younger person CS rates increased with higher housing loan interest rates (opposite in older people)(Berk ea, 2006)

Epilepsy

Family (Qin ea, 2002) or spousal (Agerbo, 2003) history of mental illness

Females – very high CS rate in rural southern India (Aaron ea, 2004); female medical students/doctors (Schernhammer, 2005); older women of South Asian origin in England and Wales (McKenzie ea, 2008); younger female prisoners in England and Wales (Fazel & Benning, 2009)

Fundamentalism/suicide terrorism: (Salib, 2003a) a receptive mind plus the right circumstances, e.g. poverty, sense of injustice or a callous and charismatic leader

Genes. CS 6 times more concordant in MZ twins than in DZ twins – what is inherited? depression? SSAT, the rate-limiting enzyme in polyamine metabolism, might be important in suicide and depression, with higher frequency of SSAT342C allele among suicide cases in a study of French Canadians.(Sequeira ea, 2006) Rap-1¹⁴⁹⁹ was found to be reduced in prefrontal cortex and hippocampus of depressed CS cases.(Dwivedi ea, 2006) BDNF G196A and 5-HTT-LPR polymorphisms were found independently to

¹⁴⁹⁶ Retrospective study of men aged at least 65 years who resided in South Florida during 1983-93. Of 667 CSs 20 cases had prostate cancer (3% of total male CS sample). Risk of CS in males with prostate cancer was 4.24 times that of an age- and gender-specific cohort. Clinical correlates were depression in 70%, diagnosis of cancer within 6 months of death (80%), physician visit within 1 month of death (60%), and being foreign-born (70%).

¹⁴⁹⁷ These authors found a standardized mortality ratio (SMR) for CS of 9.77 in BP. They traced 98.3% of their sample.

¹⁴⁹⁸ Barbecue charcoal burning as a method of suicide rose from 2% to over 26% of all CS between 1998 and 2003 in Hong Kong.(Yip ea, 2010)

¹⁴⁹⁹ Rap-1 is a substrate of PKA.

increase risk of suicidal behaviour in BP (Vincze ea, 2008); reduced BDNF expression in CS cases may be epigenetic (Keller ea, 2010)

Grief/bereavement: *widowed at highest risk in days following loss, risk falling over the first year (Ajdacic-Gross ea, 2008)*

Gun availability¹⁵⁰⁰ (especially USA; having a gun at home or for work/sport; removal of guns may only reduce CS among those who would have used a gun)

Haemodialysis – *the CS rate is increased times among end-stage renal disease patients and those on haemodialysis (e.g. Brendel ea, 2008, p. 735) but not all patients to withdraw from treatment are suicidal (Levenson, 2008)*

High homicide rate – *also, offspring of psychiatric inpatients are more likely to die of homicide, CS, and open verdicts by poisoning (Webb ea, 2007)*

High risk/low rescue situations: lethality of past self-poisoning (Owens ea, 2005)

Hopelessness - more predictive of eventual [not immediate] CS (Chiles & Strosahl, 2005, p. 11); Beck Hopelessness Scale identifies those at high risk of CS but the magnitude of the risk is not as high as previously reported, and low specificity reduces its usefulness in therapeutic targeting of self-harm repeaters (McMillan ea, 2007)

Hot weather (Page ea, 2007)

Immigrants, e.g. women born in Indian subcontinent living in Britain; loss of privileges among Russian minority in Estonia (Värnik ea, 2005)

Impulsive-aggressive traits – may be more relevant in younger people (McGirr ea, 2008)
